Every attempt has been made to ensure the correct source of images and other potentially copyrighted material was ascertained, and that all materials included in this book have been attributed and used according to their license. If you believe that a portion of the material infringes someone else's copyright, please contact [a.a.kana@tudelft.nl](mailto:a.a.kana@tudelft.nl).

### Peer Review Statement:

The editor of the proceedings warrants that 1) they adhere to TU Delft OPEN Policy on publishing integrity and good scientific publishing practices; 2) all papers have been subject to blind review by at least 2 reviewers, of which one from the International Committee, and the other from either the National Organizing Committee or the list of additional reviewers, administered by the editor; 3)

Reviews were conducted by expert referees who were requested to provide unbiased comments aimed at improving the work.

## Preface

The **15<sup>th</sup> International Marine Design Conference (IMDC-2024)** was organized by the Department of Maritime and Transport Technology, Delft University of Technology, and was hosted by the Netherlands Defence Materiel Organisation at the Marine Etablissement Amsterdam (MEA). The aim of the IMDC is to promote all aspects of marine design as an engineering discipline. The focus of IMDC-2024 is on the key design challenges and opportunities in the maritime field with special emphasis on the following themes.

- **Ship design methodology** issues such as: design spiral, systems engineering, set-based design, design optimisation, concurrent design, modular design, configuration based design, or “fuzzy” design aspects.
- **Novel marine design concepts**, such as: hull form design, transport ships, service vessels, naval vessels, yachts and cruise ships, or specialized and complex vessels.
- **Offshore design methodology**, such as applications to: offshore wind turbines, semi-submersibles, floating fish farms, or floating cities.
- Influence of **energy transition** on maritime design, including both zero emission and high power and energy systems.
- Influence of **unmanned and autonomous transition** on maritime design.
- Influence of **digital transition** on maritime design, such as: digital shadows and twins, model-based systems engineering, AI, ML and big data.
- Influence of **regulations** on maritime design.
- **Maritime design education**

### **Professor Stein Ove Erikstad**

Chair, International Committee  
Department of Marine Technology  
Norwegian University of Science and Technology  
Norway

### **Associate Professor Austin A. Kana**

Chair, National Organizing Committee  
Department of Maritime and Transport Technology  
Delft University of Technology  
The Netherlands

# Acknowledgements

IMDC-2024 would like to acknowledge the following individuals and organizations for their support.

## INTERNATIONAL COMMITTEE

- **Chair: Professor Stein Ove Erikstad**, Norwegian University of Science and Technology, Norway
- **Prof. David Andrews**, University College London, UK
- **Prof. Richard Birmingham**, Newcastle University, UK
- **Adj. Prof. Per Olaf Brett**, Norwegian University of Science and Technology, Norway
- **Julie Chalfant, PhD**, Massachusetts Institute of Technology, USA
- **Kelly Cooper**, US Navy Office of Naval Research, USA
- **Prof. Hans Hopman**, Delft University of Technology, the Netherlands
- **Prof. Stefan Krüger**, Hamburg University of Technology, Germany
- **Associate Prof. Taiga Mitsuyuki**, Yokohama National University, Japan
- **Prof. Apostolos Papanikolaou**, National Technical University of Athens, Greece
- **Patrik Rautaheimo, PhD**, Elomatic, Finland
- **Prof. Myung-il Roh**, Seoul National University, Korea
- **Associate Prof. David Singer**, University of Michigan, USA
- **Prof. Dracos Vassalos**, University of Strathclyde, UK

## NATIONAL ORGANIZING COMMITTEE

- **Chair: Associate Prof. Austin A. Kana**, Delft University of Technology
- **Venue chair: Bart van Oers, PhD**, Dutch Command Materiel and IT (COMMIT)
- **Nikoleta Dimitra Charisi**, Delft University of Technology
- **Koen Droste**, Damen Naval
- **Etienne Duchateau, PhD**, Dutch Command Materiel and IT (COMMIT)
- **Sietske de Geus**, Delft University of Technology
- **Agnieta Habben Jansen, PhD**, Dutch Command Materiel and IT (COMMIT)
- **Prof. Hans Hopman**, Delft University of Technology
- **Carmen Kooij, PhD**, NHL Stenden Hogeschool
- **Ben Noble**, Delft University of Technology
- **Zacharias-Panagiotis Oikonomou**, Delft University of Technology
- **Joan le Poole, PhD**, Delft University of Technology, Dutch Command Materiel and IT (COMMIT)
- **Associate Prof. Jeroen Pruyn**, Delft University of Technology
- **Evelien Scheffers**, Delft University of Technology
- **Apostolos Souflis-Rigas**, Delft University of Technology
- **Jesper Zwaginga**, Delft University of Technology
- **Secretarial and management support staff**, Department of Maritime and Transport Technology, Delft University of Technology
- **Conference organizing staff**, Marine Etablissement Amsterdam (MEA)

## ADDITIONAL SCIENTIFIC REVIEWERS

- **Richmond Anku**, Delft University of Technology
- **Assistant Prof. Lindert van Biert**, Delft University of Technology
- **Anna Boon**, Delft University of Technology
- **Miguel Calvache**, Delft University of Technology
- **Associate Prof. Andrea Coraddu**, Delft University of Technology
- **Sanne van Essen**, Delft University of Technology
- **Assistant Prof. Daniele Fiscaletti**, Delft University of Technology
- **Jaap Gelling**, Delft University of Technology
- **Robert Hekkenberg**, Netherlands Ministry of Infrastructure and Water Management
- **Joseph van Houten**, University of Michigan
- **Herbert Koelman, PhD**, NHL Stenden Hogeschool
- **Benjamin Lagemann**, Norwegian University of Science and Technology, Norway
- **Anna-Louise Nijdam**, Delft University of Technology
- **Erin van Rheenen**, Delft University of Technology
- **Assistant Prof. Harleigh Seyffert**, Delft University of Technology
- **Assistant Prof. Cornel Thill**, Delft University of Technology
- **Assistant Prof. Peter de Vos**, Delft University of Technology
- **Niels de Vries**, Delft University of Technology
- **Associate Prof. Peter Wellens**, Delft University of Technology

# Ship Design in the Era of Digital Transition - A State-of-the-Art Report

Apostolos Papanikolaou<sup>1,\*</sup>, Evangelos Boulougouris<sup>2</sup>, Stein-Ove Erikstad<sup>3</sup>, Stefan Harries<sup>4</sup> and Austin A. Kana<sup>5</sup>

## ABSTRACT

The evolution of ship design from a manual toward a computer-aided, digital approach has been drastic after the 1970s, with the explosive development of computer hardware and software systems. In today's era of smart digitalization in the frame of Industry 4.0, recently introduced digital/software tools and systems increase the efficiency and quality of the life-cycle ship design process, but also the operational complexity and the demand for proper training of users of software platforms. Parametric optimisation and simulation-driven design, product lifecycle management, digital twins and artificial intelligence are nowadays frequently used by the maritime industry during the commissioning/quality control activities and in the various phases of ship design, ship operation and ship production. This paper presents an overview of notable developments in the above areas and the way ahead to respond to present and future challenges of the maritime industry.

## KEY WORDS

State-of-the-Art report; Ship Design Methodologies and Tools; Holistic Ship Design; Multi-objective & Parametric Optimisation; Simulation-Driven Ship Design; Product Lifecycle Management; Digital Twins; Artificial Intelligence.

## PREAMBLE

The design methodology (DM) state-of-the-art reports (DM-SoA) are inherent constituents of the International Marine Design Conference (IMDC) and its long history. A synopsis of the DM-SoA timeline from the start of the IM(S)DC until 2018 was given by Andrews et al (2018) at the 13<sup>th</sup> IMDC, held in Helsinki. This timeline shows a large variety of interpretations of what the SoA report at the IMDC should or rather could comprise, ranging from reviews of the ship design history, different variants of "Design-for-X" (Papanikolaou et al, 2009, Andrews et al., 2012), as well as challenges related to the design of particular ship types.

Recognizing the importance of the DM-SoA as a binding thread between the tri-annual IMDC conferences, and the so far lack of a clear consensus on style, form and structure, the last SoA report (Erikstad & Lagemann, 2022) has more clearly formulated the goals and purpose of the DM-SoA reports, namely to "*analyze and summarize, on behalf of the marine systems design community, the current state and key developments within our field, based on a review of current research and technology achievements, as well as feedback from academia and industry*". Regarding form, style and structure, a set of characteristics was proposed. It should be focused on marine systems design, with a clear emphasis on design methodology within the larger

*framework of engineering design/systems design. It should be contemporary, giving priority to what have been key topic areas and achievements since the last conference, as well as ongoing research developments towards the next venue. It should be opinionated, to the extent that the authors of the report need to make an educated prioritization of what are the most important developments, as well as provide a basis for discussions and comments at the conference. Finally, it should also balance the focus between academia and industry and look into how research and technology developments are adopted in industry and actual design practice.*

In this year's DM-SoA paper, we have aimed at following up on these principles. The focus will be on recent and emerging developments as well as on state-of-the-art, mature and *smart* ship design methodologies in the frame of *smart digitalization of the maritime industry (Industry 4.0)*. Parametric optimisation and simulation-driven ship design, ship product lifecycle management, digital twins and artificial intelligence are nowadays frequently used by the maritime industry during the commissioning/quality control of marine products and in the various phases of life-cycle ship design, ship operation, ship production and decommissioning/scraping. This paper presents an overview of notable developments in the above areas and the way ahead to respond to the present and future challenges of the maritime industry.

## INTRODUCTION

The evolution of ship design from a manual toward a computer-aided, digital approach has been drastic after the 70s, with the explosive development of computer hardware and software systems. In today's era of smart digitalization in the frame of Industry 4.0, recently introduced digital/software tools and systems increase the efficiency and quality of the life-cycle ship design process, but also the operational complexity and the demand for proper training of users of software platforms. It is evident that the international maritime industry and its representatives (shipping and shipbuilding industry, class societies, design companies, research institutes and academia) have widely adopted the smart digitalization concept in ship design, shipbuilding, and ship operation, long before Industry 4.0 was formally introduced, mainly in production processes. This is due to the very strong competition in the worldwide shipping and shipbuilding market. However, the degree of adoption the smart digitalization concept of Industry 4.0 strongly varies, depending on the size and competitiveness of the specific maritime industry and its representatives.

Typical forerunners in the introduction of smart technologies and associated digital services to the maritime industry are all major classification societies (e.g., Det Norske Veritas/DNV, 2023, Class NK, 2023, American Bureau of Shipping/ABS, 2023, Lloyds Register/LR, 2023, Bureau Veritas, 2023). The same applies to all major software vendors (e.g., NAPA, 2023, Dassault, 2023, Siemens, 2023) offering software tools for all phases (or part of) of the ship's life cycle (ship design, construction, operation). In between the end users/customers (shipyards and shipping companies) are in general the design offices/consultants, fitting the offered software tools to the needs of the end users or running specific software tools on their behalf. Of course, large shipyards and shipping companies may have their own specialists/software engineers to work directly with advanced software tools and adjust them to the needs of their companies. Finally, research institutes and academia may be in the forefront of initial developments of software tools, the marketing of which is however left to software vendors and partly class societies.

When looking at the level of digitalization, the maritime industry and particularly shipbuilding is often considered as one of the least digitally advanced industries. It is, however, important to understand the differences between digitization, digitalization and digital transformation:

- *Digitization*: is the conversion of information into a computer-readable format. A prime example of digitization in shipbuilding is moving from a drawing board to a CAD procedure or more generally, transforming a document or piece of information that was originally not in digital form into a computerized representation. With respect to ship lines, their digital form does not only serve as a digital drawing board that speeds up drafting and reduces the required time to create and modify technical drawings. This digital representation is the nucleus of all software tools dealing with ship design, production, and operation and the first step in creating a digital twin (DT). This stage of development is nowadays common in both the shipping and shipbuilding industry.
- *Digitalization*: is the use of digital technologies to optimize ship design, ship operation and business processes. It particularly refers to changes in the design work and in the way stakeholders of a maritime product engage and interact. It goes well beyond the implementation of technology for certain tasks and optimizes the global-scale performance of organizations, yielding a significant competitive advantage for them. This stage of development is nowadays quite advanced in all major shipping companies and class societies and to a lesser degree in some major shipbuilders.
- *Digital Transformation*: in the sense of Industry 4.0, it is the holistic, overall societal effect and wide-spread digitalization of the industry. It refers to the transformation of business models, socio-economic structures, legal and policy measures, organizational patterns, and so forth. The present stage of development of the maritime industry has

only a few “shining” examples of digital transformation, e.g., major class societies and shipping companies, software vendors.

There are only very few published studies on the digital transformation of the maritime industry, with emphasis on virtual prototyping and cyber security. According to Diaz (Diaz et al, 2023), “*the evolution of maritime and shipbuilding supply chains toward digital ecosystems increases operational complexity and needs reliable communication and coordination. As labor and suppliers shift to digital platforms, interconnection, information transparency, and decentralized choices become ubiquitous. In this sense, Industry 4.0 enables “smart digitalization” in these environments. Many applications exist in two distinct but interrelated areas related to shipbuilding design and shipyard operational performance. New digital tools, such as virtual prototypes and augmented reality, begin to be used in the design phases, during the commissioning/quality control activities, and for training workers and crews*”. Ichimura et al (2022) rather focus on Artificial Intelligence (AI), Big Data Analytics (BDA), Cloud Computing and the Internet of Things (IoT), which are already used by the maritime industry, particularly in a variety of applications of the shipping industry. The maritime transport industry is already transitioning into a new operations paradigm, often termed as “*shipping in the era of digitalization*”. Shipping companies promote digitalization as the future of the maritime industry and their efforts to set up strategies are already in progress. Examining those visions and strategies in relation to digitalization would be beneficial to better understand the way towards which the maritime industry is heading.

Turning to *smart* ship design methodologies and independently of a variety of professional software tools addressing main parts and specific aspects of ship design, the recently completed Horizon 2020 European Research project – HOLISHIP – Holistic Optimisation of Ship Design and Operation for Life Cycle (2016-2020) (Papanikolaou et al, 2022), in which 40 major representatives of the European Maritime industry participated (<http://www.holiship.eu/>), introduced an innovative, holistic approach to ship design and the development of integrated design software platforms and tools, which were used by the European maritime industry in a series of practical applications (demonstration studies). In the era of the 4<sup>th</sup> industrial revolution, the project set out to substantially advance ship design by the introduction of a fully computerized, multi-disciplinary optimisation approach to ship design and life-cycle operation. The approach enables the exploration of the huge design space in relatively short time, the distributed/multi-site working and the virtual reality testing, thus it is a strong asset for the development of innovative maritime concepts in response to the needs of the 21<sup>st</sup> century. The HOLISHIP approach is based on an open architecture scheme and the buildup of flexible s/w platforms (like CAESSES<sup>®</sup>) with simple communication protocols and a long list of integrated external s/w tools. This includes, also, communication with professional naval architectural s/w platforms (like NAPA<sup>®</sup>) and interchange of data through macros. A comparison of the conventional ship design approach with a contemporary, fully computerized design procedure, as implemented in the HOLISHIP project, is shown in Figure 1, reproduced from (Papanikolaou, 2022).

Criterion	Conventional	HOLISHIP
Concept design	Empirical approach; supported by available computer-added calculation and graphics processing procedures, manual generation of 1...3 variants of baseline design and intuitive selection of the most promising variant	Automated parametric generation of hundreds of variants ( <i>digital siblings</i> ; cloning) and comparison to baseline design, including their documentation; <i>global optimisation</i> of main ship dimensions and main characteristics; rational (mathematical) identification of most promising variants on the basis of set criteria
Preliminary/ Contract design	Sequential processing of design steps (design spiral); individual optimisation of design properties (hydrodynamics, structures, machinery, economics) of just a few design variants	Parallel processing of design steps and design synthesis; multi-objective and multi-disciplinary optimisation of several/hundreds of design variants; local hull form optimisation
Accuracy of calculation methods	Low at concept design level (mostly empirical modelling); high at contract design level	High at any design level depending on the capability of the employed s/w tools; use of surrogate models for intensive calculation tasks
Design lead time and person months effort	<i>Assuming the availability of a baseline design:</i> <u>Concept design</u> : some person days, depending on the experience of the design team <u>Contract design</u> : several person months, depending on the experience of the design team <i>If no baseline is available:</i> <u>Concept design</u> : many person days of collecting information, identifying and analyzing similar ships already built from public data	<i>Assuming the availability of suitable parametric models, e.g. from a previous design campaign:</i> <u>Concept and contract design</u> : lead times are significantly reduced by a factor > 5 (est.); smaller design team with less need for experience of all team members <i>If no parametric models are at hand:</i>

		Several days to weeks for building up robust and meaningful parametric models, depends on modeler's experience
Costs	The effect of design variants on cost is done at early design stage intuitively by designer's experience or at best by checking the costs of only a few design variants	Early assessment of the effect of hundreds of design variants on cost leads to significant cost reductions in the production cost (CAPEX) and operational cost (OPEX) or maximization of the Net Present Value (NPV)
Quality of design (concept and contract)	Highly depend on the designer's and yards' experience	Superior quality thanks to systematic optimisation and selection of the best out of hundreds of variants; consolidated standard design documentation; Quality assurance via consistency in the assessment of variants
Safety of ship & the marine environment	Rules-based design with undefined safety level	Risk-based design with quantifiable risk consequences and safety level
Energy efficiency	Studies on energy efficiency are commonly done at contract design stage and mostly refer to the hull-propeller interaction; individual studies on overall energy consumption are nowadays common for high energy consumers (passenger ships, high-powered, special type of ships)	Improved energy efficiency in view of the integration of s/w tools for the simulation of energy consumption, including the machinery-propeller-hull interaction at early design stage
Life-cycle Performance and Assessment	Mostly restricted to the economics of an investment (shipowner's side); environmental impact is only considered by enforced regulations (considering the set IMO targets as constraints)	Life-cycle assessment and optimisation of economics and environmental impact at early design stage
Innovations in ship design	Limited, due to the lack of baseline designs to build upon	Enabled in view of the simulation-based (first principles) ship design approach; main design problem issue: definition of parametric model (transfer of innovation idea to a mathematical model)
Software platforms	Professional naval architectural software platforms with limited or no collaboration with external software tools; strict communication protocols	Flexible s/w platforms with simple communication protocols; long list of integrated external s/w tools, including communication with professional naval architectural platforms (CAESES); interchange of data with NAPA® through macros
Design workflow procedures	In general, manual planning of design workflow, which depends on designer's experience; limited coded design workflow procedures	Enables coding of design workflow procedures by macros; HOLISHIP demonstrated more than ten (9+3) coded design procedures for several ship types and marine assets
Distributed working/cloud communication	Not known in ship design	Enabled through cloud communication (IoT) and demonstrated through the RCE/CAESES HOLISHIP platforms
Virtual prototyping	Not known/limited in ship design	Demonstrated by simulation of the maneuverability of a ship with alternative rudders on MARIN's bridge simulator and feedback by the captain (man-machine interaction)
Acceptance by industry	Trivial, as conventional	At present the acceptance is limited to the HOLISHIP partners and knowledgeable academia; growing acceptance; education of future naval architects is essential; HOLISHIP book and dissemination through partnership

**Figure 1: Conventional vs. an Advanced, Holistic Approach to Ship Design (Papanikolaou, 2022)**

The present paper aims at an overview of notable, recent developments in methodologies of *smart ship design and operation* and a description of the way ahead to respond to present and future challenges of the maritime industry. It has a particular focus on the impact of the digital transformation on ship design methodologies, as of the remit of IMDC, but extending on ship production and ship operation with applications nowadays common to the maritime industry. After a brief introduction, Apostolos Papanikolaou presents an advanced parametric ship design optimisation, as implemented in project HOLISHIP, its historical development, and applications. Stefan Harries deals next with simulation-driven ship design (SDSD), what is closely related to ship design optimisation and the HOLISHIP project. Stein Ove Erikstad elaborates on the impact of digitalization on ship production and life cycle management. Austin Kana presents an overview of recent developments in the field of digital twins (DT) in the design and retrofit of ships and last, but not least, Evangelos Boulougouris presents methods and tools of Artificial Intelligence (AI) with applications in ship design and operation.

## PARAMETRIC SHIP DESIGN OPTIMISATION

### Ship Design Optimisation

Inherent to design is design optimisation, namely the identification of the best out of all feasible solutions for a set design problem. The progress in ship design optimisation in the last five decades has been revolutionary and in line with developments in hardware and software, moving from a single-objective optimisation for the minimum required freight rate (RFR) of a tanker (Nowacki et al, 1970), to multi-objective ship design optimisation of various types of ships for a variety of criteria and constraints (Figures 2 and 3).

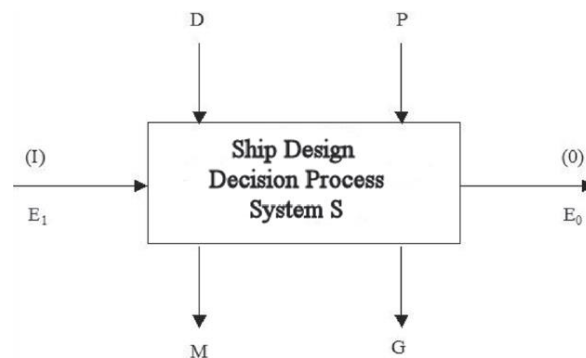

Figure 2: Single Objective Ship Design Optimisation for RFR (M: merit function, D: design variables, P: parameters, G: constraints) (Nowacki et al., 1970)

Figure 3: Multi-objective Ship Design Optimisation for multiple criteria (Papanikolaou, 2010)

The holistic approach to ship design and multi-objective ship design optimisation was introduced by A. Papanikolaou in a Special Issue of Journal CAD, which was dedicated to the 75<sup>th</sup> birthday of Professor Horst Nowacki (Papanikolaou, 2010). The outlined approach was later implemented in the EU funded project HOLISHIP (2016-2020).

## Parametric Modelling - Digital Siblings

An important feature of the multi-objective optimisation procedure presented in Figure 3 is the *Parametric Ship Modelling*, namely the systematic variation of design parameters for the generation of digital “siblings”. This generally refers to the variation of ship’s geometry (e.g., of the wetted hull form, Figure 4), of main internal spaces (e.g., for a RoPax, Figure 5), of main structural elements (e.g., for a RoPax design, Figure 6), of ship’s machinery/propulsion and main outfitting arrangements, as necessary for the processing of selected design parameters that are optimised in the frame of a defined optimisation procedure.

**Figure 4: Three hull forms with lengthened and shortened *parallel mid-body* (shown in blue) but *identical displacement and longitudinal centers of buoyancy* by CAESSES® (Courtesy Claus Abt, Friendship Systems, 2023)**

**Figure 5: Internal subdivision for two RoPax hulls of different length, but identical arrangement of spaces concept, for damage stability calculation and assessment by NAPA® (Zaraphonitis et al., 2012, project HOLISHIP)  
Top layout for LBP=170m, bottom layout for LBP=210m.**

**Figure 6: Parametric structural design of RoPax by NAPA Steel® (Basic model, Tuzcu et al., 2021, project HOLISHIP)**

Historically and conceptually, the *parametric* optimisation of ship design was introduced by Murphy et al. (1965), when varying ship's main dimensions by systematic permutation within a certain range and identifying manually (graphically at that time) the best variant corresponding to the ship of *lowest cost*. A few years later, Nowacki et al. (1970) applied also parametric modelling by the variation of ship's main dimensions and form parameters to the optimisation of a tanker design to find the variant with the minimum required freight rate (RFR), while solving the ensuing optimisation problem by a Tangent Search Algorithm (TSA). It took about 10 years for the parametric modelling to be formally introduced into the hydrodynamic optimisation of ships by *variation of ship's hull form*, next to ship's main dimensions, in the frame of a *continuous function optimisation*. This was first applied to slender ship hull forms (mathematical hull forms, e.g., SWATH-like forms) by Kusaka et al. (1980), Salvesen et al. (1985), Papanikolaou & Nowacki et al. (1989), Papanikolaou & Androulakis (1991) and it was later extended to a wider range of slender, high-speed vessels (Papanikolaou et al. 1996, Zaraphonitis et al., 2003). Applications to a wider class of conventional ship hull forms were first shown by Harries (1998).

The parametric modelling refers in general not only to the variation of a ship's wetted surface geometry, when dealing with hydrodynamic optimisation, but also to the internal subdivision and space arrangements of ships, when dealing with ship's damage stability of RoPax ships (Boulougouris-Papanikolaou-Zaraphonitis, 2004), while also including the parametrization of main structural elements (Tuzcu et al., 2021), or when dealing with the probability of oil-outflow of damaged tankers (Figure 7), etc. Thus, it covers both continuous, integer and discrete optimisation problems and associated techniques. It depends on the completeness of the ensuing parametric model with respect to the specific design parameters that are to be optimised in the frame of a defined optimisation problem and its processing in the frame of a simulation-driven design procedure.

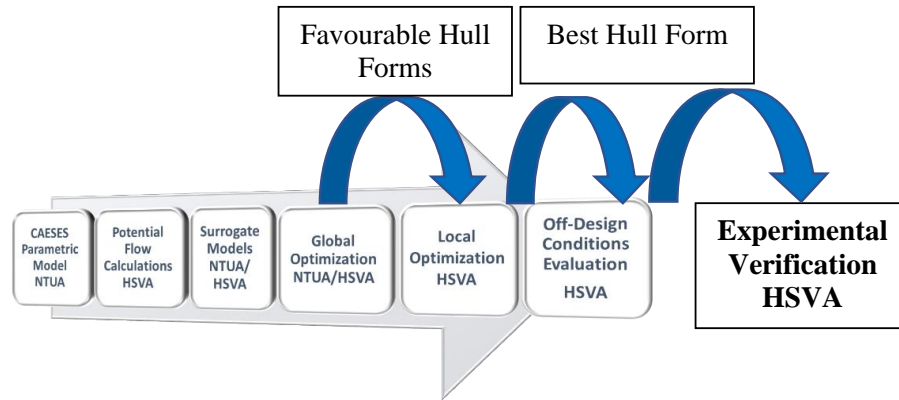

**Figure 7: Parametric structural design of AFRAMAX tanker by use of POSEIDON® s/w for minimization of structural weight and of oil outflow (Papanikolaou et al, 2010, project BEST)**

Parametric modelling is inherently related to *Digital Siblings*. Digital “siblings” may be seen related to digital “twins”. However, they are of different origins and are differently used. The concept of *Digital Twin*, namely of a virtual, digital equivalent to a physical product, was introduced in 2003 by Grieves (2015). It is a virtual replica (model) of a real-world asset and it is based, besides on a digitised description of a real-world asset (here a ship), on a continuously enriched database of performance data transmitted to the virtual model from the real-world asset. This allows the virtual object to exist simultaneously with the physical one and it can be readily used in the virtual prototyping and testing of new products, e.g., in the optimisation of ship's operation after refitting a bulbous bow or of a new propulsive device; thus, it is a powerful tool of the contemporary manufacturing industry (Sharma et al., 2022, Mauro & Kana, 2022).

*Digital Siblings*, on the other side, are not based on the feeding with a continuous transmission of performance data of the physical asset, but are generated by the use of the design data of a *basic* digital model that is modified by systematic variation of its design parameters, *resembling the biological process of mutation, crossover and selection*. The extent of the design parameters is associated to the complexity and completeness of the ensuing parametric model that is set up by the use of a CAD software system (e.g., CAESSES®, NAPA®, etc.). They should have enough modelling accuracy to allow the exploration of the huge design space in the frame of a *global* optimisation procedure, aiming at determining the object's main characteristics (Papanikolaou, 2024).

Following an advanced, conceptual/preliminary ship design approach, a ship's optimal main dimensions and main characteristics may be determined by the conduct of a properly set-up multi-stage optimisation procedure (Figure 8), as also outlined in Figure 3.

**Figure 8: Multi-stage optimisation procedure applied to the hydrodynamic optimisation of a fast catamaran (project TrAM, Papanikolaou et al., 2020)**

Following the *global optimisation*, in which the optimal main dimensions (length, beam, draft, and separation distance of the catamaran's demi-hulls) were identified, a *local* optimisation procedure generally follows. This can be the ship's bow (fitting or optimisation of a bulbous bow) or ship's stern or both. In the case of the optimisation of a fast catamaran, it was the transom stern region, while considering various transom stern geometries and the interaction between the ship's hull, propeller, propeller shaft, shaft-brackets and rudder (Figure 9).

**Figure 9: Local optimisation of the stern tunnel area of the Stavanger Demonstrator (catamaran *Medstraum*) by use of FreSCo+ (5.7M) - Project TrAM (Xing-Kaeding & Papanikolaou, 2021)**

Because large sets of design variants need to be generated and independently assessed by partly computer-intensive procedures (e.g., CFD calculations) to determine their performance, Designs-of-Experiments (DoE), such as a SOBOL or a Latin hypercube sampling technique, are being utilized to generate variants for pre-selected free variables; the superset of all free variables representing the design space for the design task is used to generate *surrogates* of the directly calculated models. For

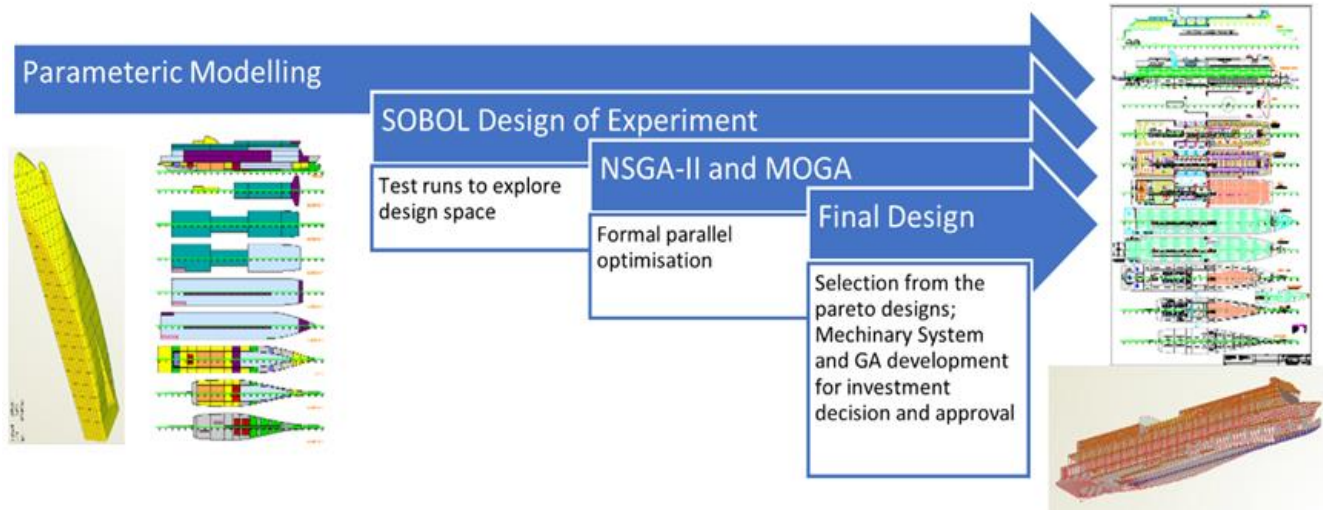

surrogate modelling, different techniques are available such as kriging, artificial neural network analysis and polynomial regression (Harries & Abt, 2019).

## Application / Demonstration Study

A variety of application case studies, which were developed in the frame of the HOLISHIP and earlier projects, are presented in details in the co-authored book Papanikolaou (ed.) (2021). A typical representative of these studies is briefly elaborated in the following. It refers to the multi-objective optimization of the design of a RoPax ship, assumed to operate between the ports of Patras (Greece) and Ancona (Italy), with a route length of 520 nm. The vessel's capacity has been specified by the end user, Tritec Marine. The service speed should be 24 knots at design draught, even keel and in deep water, with a 15% sea margin and with the main engines operating in the region of 85% MCR. The ship will be operated for 30 years, and at the end of this period, it is assumed to be sold at a value of 15% of its CAPEX.

For this optimization study of the RoPax vessel, the parametric models developed in HOLISHIP have been applied. The parametric model for the elaboration of the hullform was created in CAESES®, while the parametric models for the internal layout (the watertight subdivision and the internal arrangement of the upper decks) and for the structural arrangement were developed in NAPA® (Figures 6 and 7).

The adopted optimisation process is outlined in Figure 10.

**Figure 10: RoPax Optimisation Process (project TrAM)**

The minimization of the payback period was selected as the objective of the optimisation, as it is a comprehensive Key-Performance Indicator (KPI), which takes into account the CAPEX as well as the yearly earnings and expenses. The implemented, most important constraints were related to intact and damage stability regulations and the EEDI requirements. With respect to the probabilistic damage stability, the Attained Subdivision Index should be greater than the Required Index by a margin of 0.01. In addition, each Partial Attained Index should be larger than 90% of the Required Index by the same margin. The attained EEDI should be less than the required Phase 2 EEDI by at least 0.2 g/tm. This is a modest requirement from the operator's point of view, presently not addressing yet Phase 3 requirements until the preferred green fuel option has been clarified.

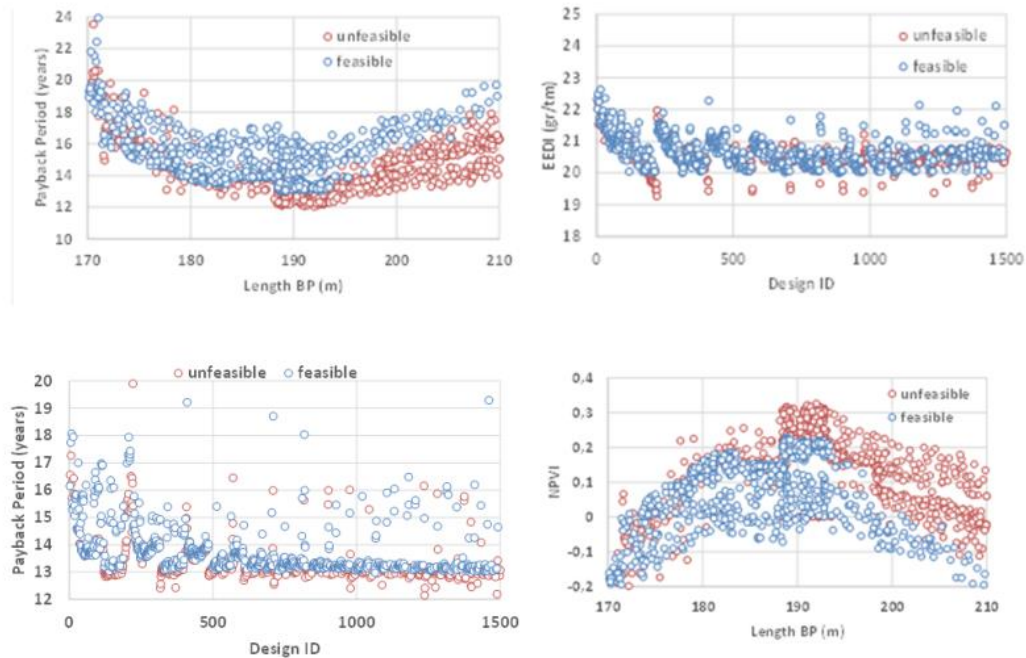

As a first step, before the formal optimization, a Design-of-Experiment was carried out to identify significant correlations (or lack thereof) between the variables of interest within the design space, in addition to verifying the robustness of the parametric models. To this end, the well-known SOBOL algorithm was used for a total of 450 designs. Main design variables were varied within the limits, specified in Table 1.

**Table 1: Design variables of RoPax Case Study (project HOLISHIP)**

Design variable	Lower limit	Upper limit
Length PP	170 m	210 m
Beam	26.0 m	28.5 m
Depth to deck 3	9.0 m	9.4 m
Block coefficient	0.58	0.62

Next, a formal, global optimization for the ship's main dimensions was carried out. Two runs were conducted in parallel, one with the Non-Dominated Sorting Genetic Algorithm (NSGA-II, Deb et al., 2002) and another using the Dakota toolkit (<https://dakota.sandia.gov/>), which is embedded within CAESSES® and uses the Multi-Objective Genetic Algorithm (MOGA) algorithm. A total of 3,000 designs were generated and assessed on top of the 450 generated during the DoE.

Typical results of the conducted multi-objective optimisation while considering 3,000 design siblings are shown in Figure 11 and the best ones with respect to specific predefined objectives and criteria were identified. The payback period of investment is about 13 years for a ship with a length of about 190m.

**Figure 11: Sample of results of RoPax Optimisation (Project HOLISHIP)**  
**Economic (payback period and NPVI) and Environmental Impact Indicators (EEDI)**

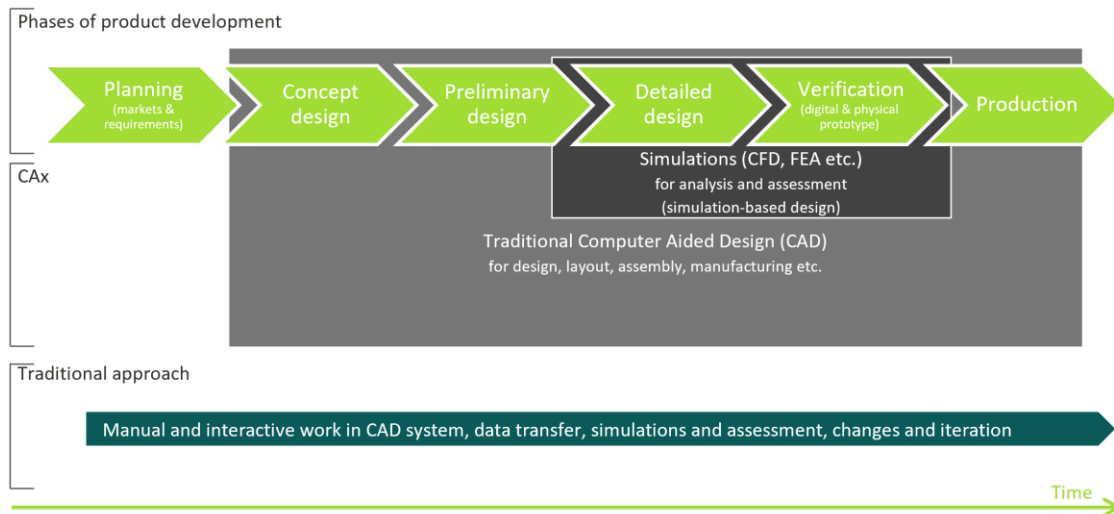

The Net Present Value Index (NPV/investment) is about 22%. The Energy Efficiency Design Index (EEDI) converges to about 20 gr/ton-miles. Optimisation studies with respect to more objective functions and other ship types can be found in the co-authored book of Papanikolaou (ed.) (2021), further illustrating the potential of holistic and formal design optimisation.

## SIMULATION-DRIVEN SHIP DESIGN (SDD)

### Introduction to SDD

Over the last two decades, simulation-driven ship design has gained considerable momentum and is now used at different levels as well as at various phases, from globally scanning promising candidates early on to fine-tuning specific components just before a design freeze. While the previous section gave an introduction and an overview along with an elaboration of holistic simulation-driven ship design, taking into account different disciplines, this section will give further details, focusing on hydrodynamics as a decisive element. Let us start with a definition and a clarification:

According to Funke and Jonsson (2019) “*simulation-driven design (SDD) is an approach where simulations are performed throughout the entire design process with the intention to explore options and guide the user, as opposed to just verify or falsify a design in the later stages of the process.*” This means that simulations are utilized to actively bring about design variants, shifting the usage of simulations from late cycles towards the front, see Figure 12, while enriching the set of proposals that design teams would typically come up with by traditionally combining their specific knowledge, experience and creativity (see also Figure 1).

(A) Traditional design approach, using simulation-based design

(B) Simulation-driven design, complementing the traditional approach

**Figure 12: Phases of product development and utilization of simulations**

While manual design work rarely surpasses the creation and analysis of more than a handful of options, SDD typically results in many variants, often several dozens and sometimes hundreds or even thousands, see section above. Clearly, this differs from simulation-based design (SBD) in which just one or several rather mature designs undergo some selected simulations to ensure sufficient performance or to identify problems to be mitigated manually within another design iteration. Figure 12 (A) and (B) illustrate differences between the traditional approach and the various SDD approaches available so far. It should be noted that SDD does not replace traditional design as such but rather complements it. (In this sense Figure 12 (B) can be seen as an overlay to Figure 12 (A).)

Traditional design is typically built on using one or combining several CAx systems. Geometry is created interactively by means of Computer Aided Design (CAD), introducing parameters while doing so. Components and systems are added and assemblies are established step by step, making changes increasingly tedious and expensive to realize. The CAD systems employed mostly originate from a time in which computer resources and simulation tools were not yet advanced enough to incorporate sophisticated simulations – e.g., Finite Element Analysis (FEA), Computational Fluid Dynamics (CFD) and, in ship design, damage stability analyses – tightly and at an early stage.

Many of today's CAD systems were production-oriented when started, see Harries et al. (2015), and most follow a history-based modelling approach in which the interactive modelling steps taken by the user are "recorded." The systems are very powerful and many of them now cover several if not all phases of product development. However, they frequently fail to

regenerate shapes readily when several input parameters are changed at a time and the history-based model is replayed for an update. Failures can be fixed interactively by the CAD user but any need of manual interference hinders the creation of large sets of variants as is representative of SDD.

The previous section of this paper describes how preliminary design can benefit from SDD by building synthesis models, and partially replacing expensive simulations with surrogates. In preliminary design, the focus is to identify the main dimensions and to find the best topology for the expected operational profile. The purpose is to make the right decision globally. Once the concept and the preliminary design are established SDD comes into play again with the aim of improving the product even further. Within this section, this local application of SDD shall be explained in more detail. Special attention is given to hydrodynamics as a key for energy-efficient operations. On most commercial ships resistance and propulsion account for more than two thirds of energy consumption, see for instance Harries et al. (2023).

As done in preliminary design and at a global level, the overwhelming majority of SDD applications at local level are built on parameters. Parameters are meaningful descriptors of a product that can be addressed and, interpreted as free variables, modified during the development process, see Harries et al. (2015) and Harries (2020). As shown in Figure 12 (B) there are parameter-free approaches like topology optimization and adjoint simulations, too.<sup>1</sup> However, they are not easily applied in multi-objective or even multi-disciplinary optimization campaigns while parametric modelling readily allows mixing objectives and disciplines by creating supersets of free variables from the various parametric models.

Since simulation results form an essential part of the SDD process there is one decisive prerequisite: The simulation(s) employed need to be good enough to ensure the correct ranking of variants. While high absolute accuracy is desirable it is often sufficient that the simulations yield correct relative accuracy. If that was not the case SDD would very likely mislead the design team. Therefore, before engaging SDD it is critical to ensure that an improvement found in a simulation would also materialize in real life.

In ship hydrodynamics, this has been regularly done by comparing simulation results with measurements from model tests. However, an additional challenge is that results at model scale, particularly for energy-saving devices attached to the aftbody, are not easily transferable to full-scale. Moreover, not many full-scale measurements are available but for a recent industry initiative, see Ponkratov (2023) and <https://jores.net>, to provide suitable benchmarks. For direct comparisons between two ships that are identical except for only one design element there is even less data to be found. Çelik et al. (2022) reported sea trials in which a conventional rudder was compared to a Gate rudder system that had been optimized using SDD, see Gürkan et al. (2023).

Let us assume for the sake of discussing SDD further that the chosen simulations are good enough. This has been the situation in several industries for quite some time, e.g., for selected applications in naval architecture like optimization of calm-water resistance and propulsion, in turbo-machinery for increasing efficiency and operating range as well as in automotive and engine design for better aerodynamics and cleaner combustion, respectively.<sup>2</sup>

---

<sup>1</sup> In topology optimization – sometimes also referred to as generative design – a volume is provided that is sequentially filled with material, for example, to find a light-weight structure for clearly known load cases. While this is applied for the design of components it has not become popular (yet) for the large structures that ships and even boats are made of. In fluid dynamics topology optimization is used to identify meaningful flow paths within enclosed spaces for which inlets and outlets are prescribed. The available space is iteratively filled up, constricting the fluid domain, until an objective is minimized, e.g., pressure drop. Again, this is rather done for internal flows at component level.

In adjoint simulations some of the boundaries of a geometry to be optimized are considered to be free to change, primarily in normal direction to the original shape. From the adjoints so-called shape sensitivities are derived that suggest which parts of the boundary have to be pulled out and which have to be pushed in so as to improve a chosen objective. This is mostly undertaken at the stage of fine-tuning an already good design as adjoint simulations inherently identifies a local optimum close to the original shape. See Harries and Abt (2019) for more details and references.

<sup>2</sup> Success stories have been reported by users of high-fidelity CFD codes such as ANSYS CFX, Cadence® Fidelity™ CFD (formerly known as FINE/Marine), SHIPFLOW, Siemens Simcenter STAR-CMM+ and certain OpenFOAM set-ups as well as Process Integration and Design Optimization (PIDO) systems such as CAESSES®, modeFRONTIER, Optimus®, and optiSLang to mention a few.

## Standard Ingredients of SDD

The standard ingredients of SDD are versatile parametric models, accurate simulations, formal strategies of exploration and exploitation and, since a few years, surrogates:

- A parametric model is any model that captures the information of interest about a system within a finite set of descriptors, i.e., the parameters. This may be a product's geometric representation as needed for engineering.<sup>3</sup> It may also be just an empirical relationship between certain inputs and required outputs.
- Simulations are predictions of aspects of system behaviour via an approximate (mathematical) model, omitting less important characteristics. Potential flow analysis of seakeeping behaviour may serve as an example in which viscosity is neglected yet the numerical results are of sufficient practical value. RANS simulations capture viscous flows by averaging the influence of turbulence, giving a close enough account of the flow field for many design purposes.
- Exploration is the automated scanning of a design space within the bounds chosen for the free variables, i.e., a sub-set of parameters that can be controlled by the design team. The purpose is to understand correlations between inputs and outputs, to identify promising regions (for further exploitation) and to provide data for building surrogates and/or to feed machine learning. The algorithms are those of Design-of-Experiments (DoE), for instance, the quasi-random Sobol sequence, allowing repetition and extension, and Latin Hypercube sampling. An illustration from a Sobol sequence is shown in Figure 13. The idea of a DoE is to spend as few resources as possible while getting a good overview. In recent years adaptive sampling algorithms have been introduced that place additional variants where the expected error and/or lack of information is still (the) high(est).
- Surrogates are the replacement of simulations by means of approximating models, also known as meta-models and response surfaces. Polynomial regression, Kriging and Artificial Neural Networks are popular surrogates. Upon computing a surrogate, for instance, by training on data produced during exploration, the execution of a rather expensive simulation can be sidestepped. Surrogates take just split-seconds to execute but do not necessarily yield the result that the actual simulation would give, introducing additional errors. Occasionally, a supplementary simulation is run once a promising design candidate was found, checking and, if need be, improving the surrogate afterwards.
- Exploitation is the automated improvement within the chosen design space with respect to one or several objectives, observing inequality (and sometimes equality) constraints. Exploitations can be run on the basis of simulations, surrogates or a mixture of both. Depending on which algorithm is utilized, deterministic and stochastic strategies are distinguished. Popular are local optimization based on pattern search, like the Nelder-Mead Simplex due to its simplicity, and global searches via genetic algorithms, like the NSGA-II. Global strategies cover the design space widely and advance towards non-dominated variants, yielding a Pareto frontier.<sup>4</sup>
- Exploration, surrogates and exploitation are combined in advanced and encapsulated strategies. Here, an initial set of variants is produced and analysed via simulations from which then a first surrogate can be derived. Additional variants are produced by further populating the design space while reducing the deviation between the surrogate(s) and the underlying simulation(s).

Ingredients and benefits of SDD are also summarized by Massobrio (2023) and are elaborated in Harries (2020).

Importantly, when commencing with an SDD campaign the people involved need to get together and agree on the following: Which key performance indicator(s) should be improved (objectives) and which should be observed and complied with (constraints), what parameters are really under the control of the design team and shall be deliberately modified (free variables) and what can actually be simulated within the given time, the available resources and with acceptable accuracy. While this seems trivial at first glance it more often than not turns out to be complex and is, frequently, no subject of spontaneous agreement.

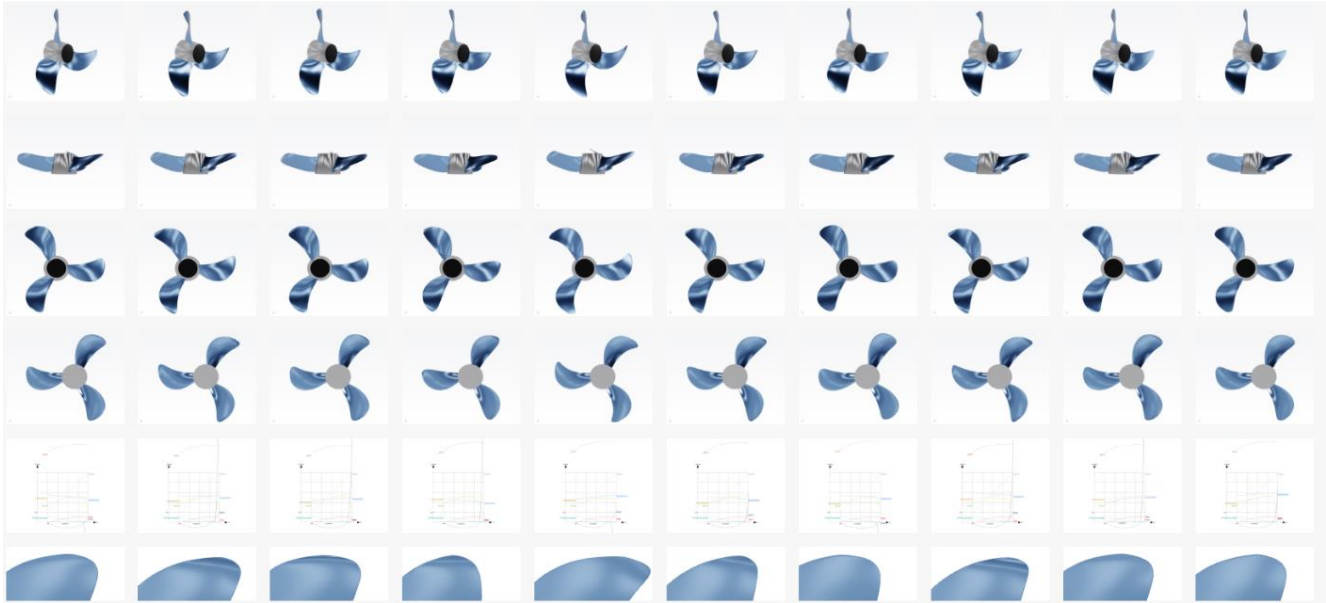

Furthermore, SDD should not be understood solely as another term for optimization. A Design-of-Experiment, for instance, helps to understand cause-and-effect, getting an appreciation of the potential for improvement and yields insight into which of the free variables are important and which could possibly be fixed subsequently to reduce the design task's dimensionality. A surrogate built from a DoE allows capturing, providing and storing expert knowledge for a certain type of simulation by summarizing results in terms of a simple mapping between inputs and outputs, e.g., saved in csv-files. A complex simulation is taken care of by the specialist with software whose license may be expensive and whose usage may require a lot of experience. This unloads the burden from the design team and may even help improve the quality of the outcome, see Harries and Abt

---

<sup>3</sup> This may well differ from a parametric model suitable for production.

<sup>4</sup> A Pareto frontier is formed by the set of non-dominated variants, i.e., variants which cannot be further improved with regard to one objective without deteriorating the performance of one or several other objectives at the same time.

(2019). It also paves the ground to combine various design solutions that could not be simulated concurrently, see for instance RETROFIT55 (2024) and Marzi et al (2024), albeit at the cost of neglecting mutual influences of higher order.

**Figure 13: Excerpt from a DoE for the SDD of a propeller**  
(Differences can be best seen at the tip in the bottom row where various tip rakes occur)

Moreover, in situations in which many components need to play together in a concerted way like in retrofitting a ship in operation – such as changing a bulbous bow, placing a wind-assistance device on deck and modifying the propeller – the behaviour of each system can be captured without the need to already know the influence of all other systems beforehand. Thus, the interdependence can be left to finding the most favourable balance at a later stage when employing the surrogates. This is not only faster but also allows replacing quickly certain components with alternatives and/or adjusting the design task to changing requirements. Additionally, it helps reduce the complexity of the design task.

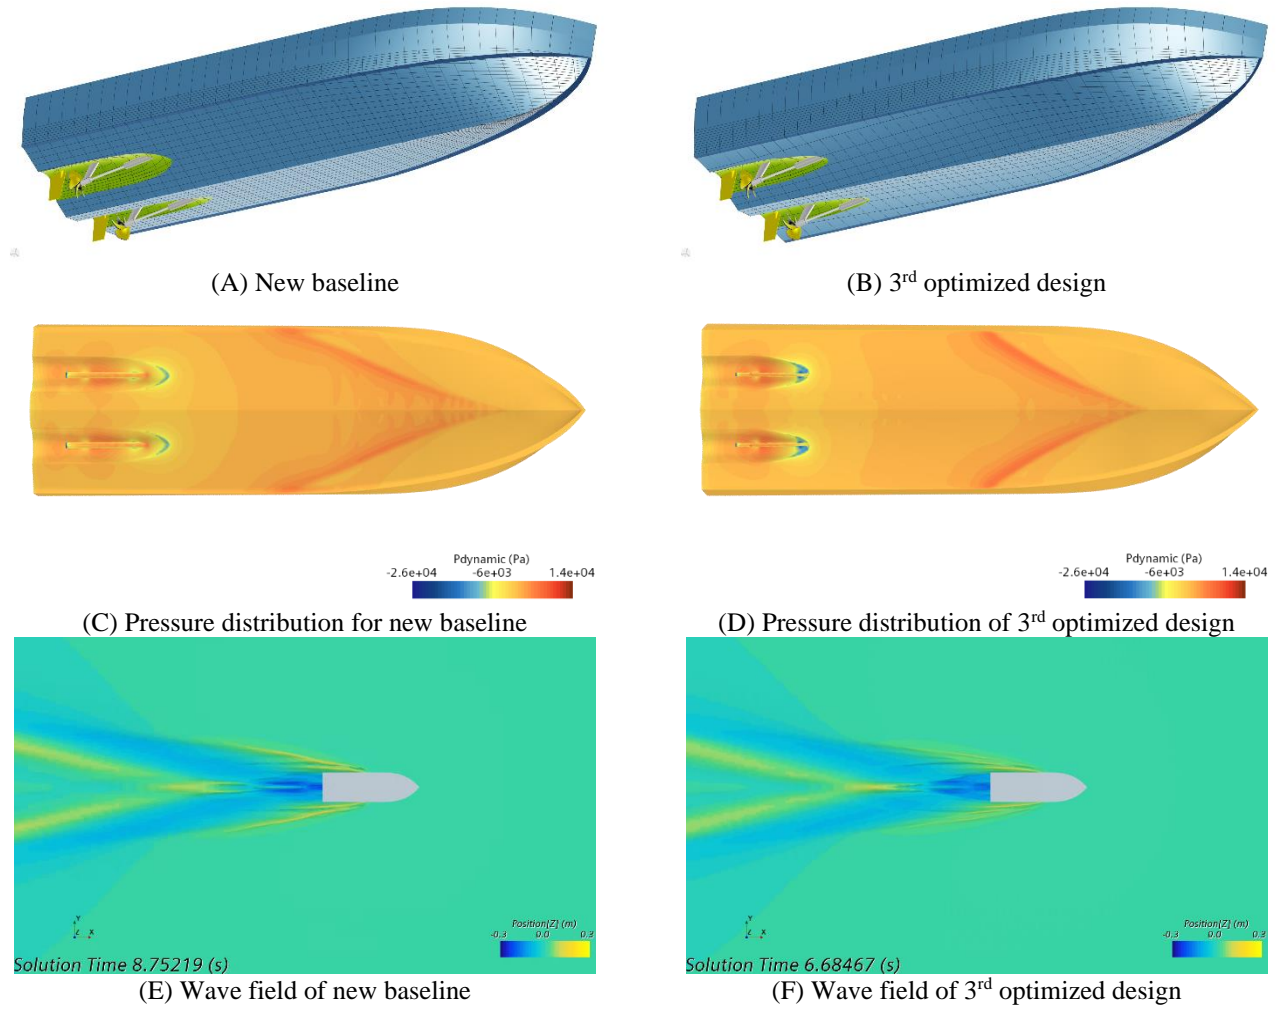

## Illustrating Example of SDD

For the sake of a better appreciation let us take a closer look at a selected example: The hull form of a fast pilot boat was to be optimized for its design speed of 27.5kn at 9.5 tons of displacement. Details of the project are presented in Ahmed et al. (2023) and a thorough elaboration is given in Harries et al. (2024). Here, just the general SDD process shall be explained, see Table 2. Additional SDD examples can be found in Harries (2020), covering naval architecture, turbo-machinery and related fields of application.

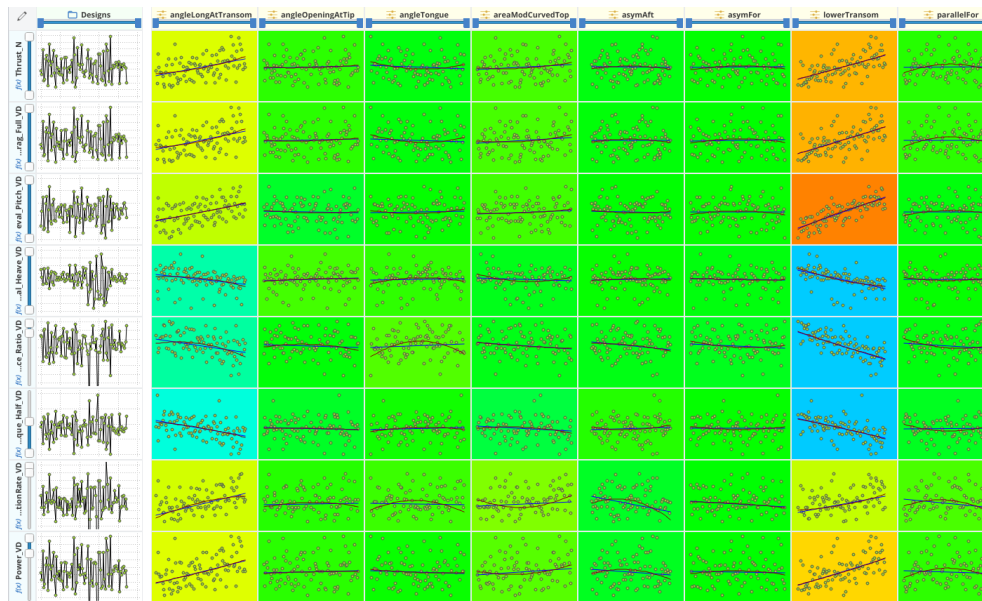

**Table 2: Typical SDD process**

Step	General	Illustrating example
1	Discuss and define the objective(s), constraints, free variables and their bounds; decide which less important characteristics are to be omitted	The shipyard wants to build a fast monohull with conventional propulsion – diesel engine, shaft, bracket, propeller and rudder – with high energy-efficiency at 27.5kn, estimating weight to be 9.5 tons. The pilot boat is to operate in protected waters by professionals, allowing to focus on calm-water performance.
2	Build parametric model(s); balance freedom to change the design (i.e., degrees-of-freedom) with resources available (time and budget)	The hull features two propellers and tunnels for their accommodation. A parametric model, ready for simulation, is created (here in CAESES®) with eight parameters for the bare hull and ten parameters of the tunnel as free variables, see Figure 14 (A) and (B).
3	Set-up simulation(s); check the accuracy of simulation (unless already proven) and possibly reduce simulation effort per variant	Calm-water RANS simulations are set-up (here in Simcenter STAR-CCM+), see Figure 14 (C) to (F). A systematic comparison to model tests shows very good agreement for free trim and sinkage. Grid variation studies are performed to identify a compromise between accuracy and effort per variant. Appendages are found to be negligible for the optimization runs since they do not disturb the correct ranking of variants.
4	Undertake exploration; identify promising designs (and favourable regions in the design space)	Many dozens of variants are automatically generated and analysed without manual interference (hereby coupling STAR-CCM+ to CAESES® as a PIDO environment).
5	Study correlations; possibly adjust bounds and/or eliminate less important free variables	As depicted in Figure 15 thrust (see first row) as objective along with other key performance indices depends on all free variables. Some free variables have a very strong influence, e.g., lowerTransom which controls the bare hull's stern geometry (see second-to-last column in Figure 15).
6	Discuss potential for improvements; possibly redefine, swap and/or drop objectives and constraints	First improvements are found during the DoE, see Figure 16, giving an appreciation of optimization potential.
7	Build surrogate(s) and train machine-learning models	Kriging is used for a surrogate of thrust as a function of all free variables. For further machine learning (ML) see Ahmed et al. (2023). As illustrated in Figure 17 a ML model allows estimating the flow field, too.
8	Undertake exploitation directly on simulation(s) and/or on surrogate(s)	Starting from a particularly good design, i.e., variant number 15 as shown in Figure 16, two local searches, one using simulations and another using the surrogate are performed.
9	Pick promising designs; possibly repeat some of the previous steps	Various other exploitations are run (not shown here). Details can be found in Harries et al. (2024).
10	Determine performance of promising designs; refine simulation(s), study other design aspects not taken into account during the SDD campaign; possibly repeat some of the previous steps	Additional simulations with higher grid resolution, also with appendages, are run to confirm the improvements found during the optimization, see Figure 14 (C) to (F). For thrust as an objective, using an actuator model for the propeller, a reduction of about 10% could be found for the so-called 3 <sup>rd</sup> optimized design when compared to the new baseline.

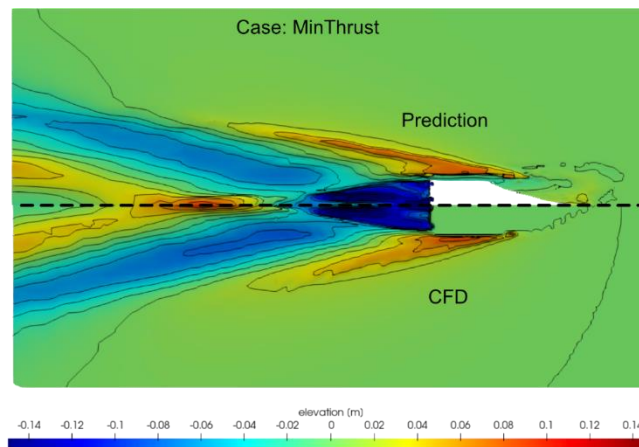

**Figure 14: Parametric model built from assembly of bare hull, tunnel and propulsion train and associated flow fields**

**Figure 15: Excerpt of results from DoE (thrust, drag, pitch, heave etc. as functions of several free variables)**

**Figure 16: History of DoE and deterministic local searches run on simulation (orange) and on surrogate (grey)**

## SHIP PRODUCTION AND LIFECYCLE MANAGEMENT

### Lifecycle aspects of marine systems design methodology

In the previous IMDC state-of-the-art report (2022), specific lifecycle aspects were discussed under the headings of “design for sustainability” and “design for uncertainty and flexibility”. The former of these now permeates every aspect of the ship and fleet development process as the industry aims towards net zero by 2050. The latter is simply a consequence of the road ahead being neither constant nor known. Since 2022 the importance of lifecycle aspects has continued and even strengthened, as well as increased in scope and complexity by the introduction of market-based mechanisms in the EU.

In this section, we will define the concept of “Design for Lifecycle” (DfLC) from the point of specific design methodology developments in various phases of the ship design process.

A pertinent question to begin with is, what is “design for lifecycle”? The 30-year-old definition by Ishii (1995) is still valid: *“Life-cycle engineering seeks to incorporate various product life-cycle values into the early stages of design. These values include functional performance, manufacturability, serviceability, and environmental impact”*.

Often, this concept is tied to “Product Lifecycle Management”, or PLM for short. PLM, and its sibling Product Data Management (PDM) is basically about managing all data about a product from cradle to grave. PLM is an important pre-requisite for digital twins and is a key part of what is often termed “Industry 4.0” or “Shipbuilding 4.0”. However, PLM as such is not particularly about *design*, but rather how to manage the *outcome* from the design process throughout the lifecycle.

Thus, DfLC is here understood as “all activities within the overall design process that explicitly takes into account the lifecycle aspects of the ship”. But do we not always design for the lifecycle? As stated in (Papanikolaou, 2019): “*One of the most important design objectives is to minimize total cost over the life cycle of the product, taking into account maintenance, refitting, renewal, manning, recycling, environmental footprint, etc.*”. We typically assume a certain longevity of the vessel, say, 25 years, and this indeed drives many design parameters. Still, in the design process we need to make simplified assumptions about the operational life of the vessel. For instance, it is common to assume a fixed deployment or contract, even when there is a positive probability that the vessel will change missions. We may define a static external operating context, such as prices, fuels, technologies, regulations, etc., while in reality these are highly uncertain and vary substantially. More basically, we implicitly act as if we know and understand the future, by capturing this in a model or a set of parameters. However, while we are *always* designing for the future, the future is intrinsically uncertain, and this should be explicitly captured in a DfLC process.

Thus, a more fitting interpretation of DfLC would be “design aspects related to explicitly taking into account an extended set of design parameters that are dynamic, multi-faceted and uncertain”. To cater for this, there are four distinct aspects of the design process we need to address:

1. The capturing of needs and requirements that have an impact on lifecycle value creation and compliance.
2. The appropriate modelling of the anticipated future technical, commercial, and regulatory context in which the ship or fleet is going to operate, considering that this future is both uncertain and changing.
3. The development of design solutions that are capable of delivering value and meeting stakeholder expectations throughout this changing and uncertain lifecycle.
4. Prepare for the continued management of all aspects of the ship’s future operation, bridging the gap between the ship “as-designed” and “as-operated”.

## Needs and requirements in a lifecycle perspective

The ship design process starts with understanding the needs and requirements of key stakeholders, (Brett and Ulstein, 2015). We have seen a gradual development towards an increased emphasis on lifecycle aspects of this step in the design process.

*First, needs and requirements have become more dynamic and long term.* This is a shift from a more static set of needs and requirements towards a situation with partly known and partly anticipated requirement changes along the vessel’s lifecycle, with a “license-to-operate” level of criticality. Largely, this is a consequence of the planned stepwise reduction in greenhouse gas emissions from shipping and the net zero ambitions by 2050.

With global warming at the top of the political agenda, and the IMO goal of near zero emission shipping by 2050, design-for-sustainability becomes the most important lifecycle element of the design process. For ships to be designed and delivered during the next couple of years the powering technology and fuels required for meeting the 2050 targets is simply not commercially available in the market. This implies that needs and requirements will change throughout the lifetime of the vessel (Erikstad, 2022).

The revised IMO strategy that was adopted in July 2023 calls for international shipping to achieve net zero by 2050, which is a significantly more ambitious goal than the 50% reduction that was the previous target. Along this way, there is a goal of 20% reduction by 2030, and 70% reduction by 2040. Thus, from a design perspective, we are in a somewhat new situation with explicit and changing requirements with a 25 year perspective, i.e., still within the lifespan of ships designed and built within the next few years.

In the shorter term, IMO has also adopted non-static requirements such as EEDI, EEXI, and, most recently, CII. These are all measurable index requirements that are tightened stepwise. The Energy Efficiency Design Index (EEDI) defines minimum energy efficiency level requirements for new ships, motivating for energy-efficient equipment and engines. A similar measure is the Energy Efficiency Existing Ship Index (EEXI) covering the energy efficiency of existing vessels. The more recent Carbon Intensity Indicator (CII) rates ships on a scale from A to E based on their CO<sub>2</sub> emissions during operations. Even if a new vessel has an adequate rating at delivery time, the gradual tightening of the CII indicator is likely to require that the vessel is retrofitted at regular times during its lifecycle. To ensure this a Ship Energy Efficiency Management Plan (SEEMP) is required for the monitoring of the ship’s energy efficiency over time in order to comply with CII targets.

This focus on carbon efficiency in the short term, and zero emission for the longer perspective can also be traced to the shipowner’s fleet renewal processes. Some examples from the stated strategies of major shipowners illustrate this, e.g., “*Our ambition is to continue as a frontrunner, providing carbon-efficient freight ‘right here, right now’, and to enable zero-emission shipping in the medium-to long term*” (Klaveness, 2024), and “*Net zero across the business in 2040*” (Maersk, 2024).

## Capturing the lifecycle operating scenario of the vessel

A prerequisite for finding preferable design solutions from a lifecycle perspective is that we are able to model the future external operating context at a level of detail sufficient for deriving relevant performance indicators for the system of interest, whether this being monetary, environmental or technical. Key players in the maritime industry have put substantial efforts into this, using a wide array of methods and strategies. One example is DNV's annual "Energy Transition Outlook" which presents forecasts to 2050 covering renewable energy technology cost and implementation schedules, prognosis on regulatory framework and policies, fuel availability and prices, to name a few (DNV, 2023). Interestingly, DNV's approach in this report is to present a "single best estimate" forecast of the future energy situation, based on what they call a "comprehensive system-dynamics model". Thus, this is a deterministic rather than a stochastic model, using expected value input parameters towards one particular output, corresponding to what is called a "maximum likelihood model" in risk analysis. The benefit of this is simplicity and improved transparency. One drawback is that even if this is the most likely forecast, it is still rather unlikely given the model's complexity and the stochastic input parameters. Further, if used as part of a systems design process, the value of incorporating flexibility towards alternative, uncertain futures becomes zero for a single scenario model (de Neufville & Scholtes, 2011).

The alternative to this modelling approach is to explicitly model multiple futures as scenarios, and then evaluate a prospective design towards a (probability-weighted) distribution of the outcomes from each. There have been multiple examples of this in the maritime design literature (see Gaspar, 2012). One interesting recent example is based on the exploration of market uncertainty towards the design of offshore wind foundation installation vessels. To reduce the levelized cost of energy (LCOE), the offshore wind energy market has seen an increase in market demand, turbine size and distance from shore. According to Zwaginga (2021), *"this makes it difficult for ship designers to design a construction vessel that has the right size and capabilities for use over multiple decades."* Designing for the first contract is likely to make a vessel increasingly less competitive over time, though how far and how fast this will go is highly uncertain. As a consequence, a large number of scenarios were generated with variations of characteristics such as range, sizes, contract types and market parameters, to be used for evaluating alternative concept designs, see Figure 18.

Figure 18: Scenario development for HLCV (Zwaginga et al, 2021)

Again related to lifecycle sustainability considerations, it is perhaps the uncertainty related to the availability and cost of fuel alternatives along the lifetime of the vessel that has become the most serious challenge in the conceptual design phase (Lagouvardou et al, 2023). According to DNV (2023), in order to meet the IMO GHG goals of 2030 shipping will require 30%-40% of the estimated annual global supply of carbon-neutral fuels, in competition with other sectors. Adding to complexity is the inclusion of shipping into the European Emission Trading System (ETS). In ETS, the price for carbon emissions is not set directly, but by the market in a cap-and-trade system. The FuelEU directive is likely to take this some steps further, possibly allowing across- and between-fleet emission caps, thus opening up for strategic collaboration and alliances to be considered as part of the fleet renewal and retrofit process. As a consequence, making informed decisions today that are dependent on, say, the cost and availability of a certain fuel in 2030 or 2040, becomes difficult.

Criteria relevant for fuels that can be used in existing ships				Criteria relevant for fuels that can be used in new types of propulsion systems not typically used in shipping			
Environmental criteria	Technical criteria	Economic criteria	Other criteria	Environmental criteria	Technical criteria	Economic criteria	Other criteria

## Developing design solutions for lifecycle value delivery

In the two previous sections, we have pointed to the changing needs and requirements along the lifecycle timeline of the vessel, as well as the uncertainty and variability of the external operating context. This leads to the question: How can we, as ship designers, find system solutions that are capable of providing sustained value along this timeline?

First, lifecycle-oriented system performance indicators, such as changeability, flexibility, adaptability and robustness, should be integrated into the design process. However, it is often difficult to make the connection between these high-level concepts and the main design decision variables. One interesting contribution is the efforts by Maggiancalda (2019) towards developing a Life Cycle Performance Assessment (LCPA) tool for the assessment of both the economic and environmental performance of a vessel over its life cycle. More specifically, an effort to quantify the changeability performance of a vessel is developed by Rehn et al. (2018), by making it possible to compare alternative design solutions towards their ability to deliver the required performance over a range of possible future operating scenarios. The changeability concept is closely tied to flexibility and retrofitability, which are both lifecycle-oriented performance concepts that takes into account the value for the shipowner of being able to have cost-efficient options that can be exercised after the outcome of a particular uncertain operating aspect has been revealed, (Lagemann 2023), as illustrated in Figure 20. The basis for the quantification of this value is based on real options models.

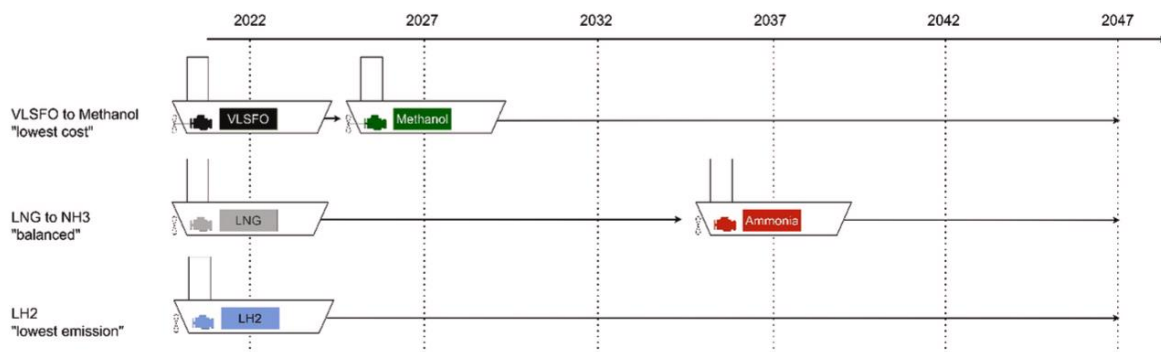

Figure 20: Pareto-optimal lifecycle machinery-fuel configuration with carbon pricing uncertainty (Lagemann et al., 2023)

## Lifecycle stewardship consideration at the design stage

Lifecycle aspects of ship design also include those measures taken at the design stage for the continued management of the ship beyond delivery. For ship designers and shipbuilders this also represents a business opportunity. Traditionally, their responsibility for the delivered vessel was capped by the guarantee period. So was also the income stream. Recent developments in digitalization and the Internet of Things (IoT), having fostered a wide array of different digital twin solutions, have provided a platform for ship designers, equipment manufacturers and shipbuilders to maintain a tighter relationship with the customer throughout the lifecycle. Basically, the idea is to provide value-adding services based on both an intimate knowledge of the

ship itself combined with real-time data streams from onboard sensors. One example of such services might be the tracking vessel “inventory” all the way to scrapping, proactively offering docking services for repairs, upgrades and retrofits. Another example is online shore-based operations centers which can offer both deep expertise and economy-of-scale by the concurrent management of multiple vessels. Both these examples would benefit from action taken already at the design stage, in which both the digital twin of the vessel is born, and the control and sensor architecture of the vessel is determined. In addition, these operation stage, value-adding services should themselves be designed, preferably according to the same design methodology as the ship itself, (Erikstad 2019).

To summarize, this section has focused on the lifecycle perspectives on ship design. With our common goal of zero emission shipping by 2050, this “cradle to grave” holistic approach, where we explicitly face the uncertainty inherent in the 25-30 years lifetime of the vessel has become even more important.

## DIGITAL TWINS IN THE DESIGN AND RETROFIT OF SHIPS

This section provides a review of digital twins (DTs) in the *design* and *retrofit* of ships. It also covers lessons learned from other industries, a proposal for digital twin modelling, and concludes with areas for future research and application of DTs.

### Background on Digital Twins for Ship Design and Retrofit

The concept of the digital twin has existed since the beginning of space explorations when NASA implemented similar concepts to a digital twin in the 1960’s (Ibrion et al, 2019). However, DTs really became a widespread concept after Grieves (2014) developed a framework of the DT where the information of the physical entity and the virtual entity are synchronized. The DT is envisioned to assist in all phases of the lifecycle but up until now research has primarily focused on the *manufacturing* and *operation* phase and has been specifically lacking in the *design* and *retire* phase. When analysing a ship’s life-cycle, Mauro and Kana (2023) suggest incorporating retrofitting into the decommissioning phase of a ship. Therefore this section aims to explore this research gap and determine the state-of-the-art and current limitations related to DT-enabled ship *design* and *retrofit*.

Before proceeding, an overview of DTs is presented. Grieves (2014) provides a clear definition of a DT that is composed of three main parts:

1. a physical product in the real environment composed of information about itself
2. a virtual product in a virtual environment representing the physical product
3. a data connection between these two product actively flowing in both ways as so-called mirroring or twinning

The function of this bi-directional data connection is to process the information from the physical product, update the virtual product, assess the current state, predict the future state, and provide further instructions for the physical product, all in an automated way.

Based on this definition, unfortunately, the term “digital twin” has traditionally been used inconsistently throughout literature, with many virtual and computer models often falsely labelled as a DT. Kritzinger et al. (2018) have provided three distinct types of models to support the nomenclature (see Figure 21), which this state-of-the-art report argues should also be adopted throughout ship design DT-related literature:

- A *digital model* (DM) is a virtual representation of the physical product, but with no formal automated exchange of data between the physical and virtual entity. Data exchange could occur but only performed manually. The DM is mostly used for simulation and planning-based operations which does not require automatic data integration.
- A *digital shadow* (DS) is an extended version of a DM including only an automated data flow from the physical product towards the virtual product by which it is actively updated.
- A *digital twin* (DT) is composed of a physical and virtual product including an automated bi-directional data flow between both entities.

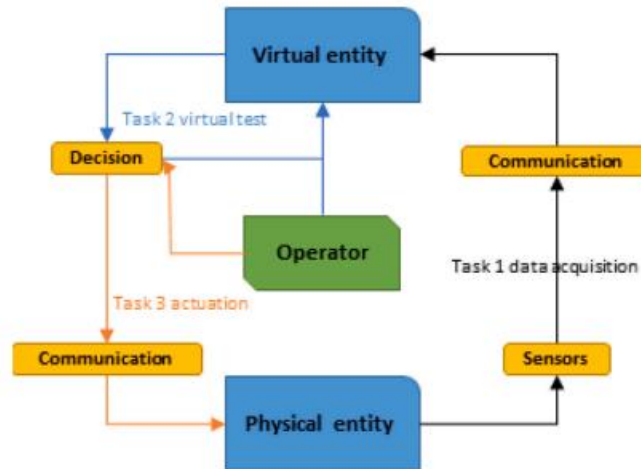

**Figure 21: Integration levels between virtual and physical environment for (a) digital models, (b) digital shadows, and (c) digital twins (Kritzinger et al., 2018; Mauro and Kana, 2023)**

The bi-directional communication is a crucial element because this enables a mirroring between the virtual and physical entity (Grieves, 2014). This creates opportunities to improve each stage of the ship life cycle through direct monitoring, decision making, and advanced predictive algorithms. Importantly the direct response of the DT creates an opportunity to actively improve ship operation and learn from the responses of the physical entity for future design and manufacturing.

Figure 22 provides a high-level overview of the tasks necessary between the virtual and physical entities to enable a DT:

- *Task 1:* The acquisition of data from the physical to the virtual entity obtained from employed sensors on the physical entity.
- *Task 2:* Perform a virtual test or optimization process in order to improve the performance or decrease the risk of malfunctions or failures of the physical entity.
- *Task 3:* Enacting corrective measures on the physical entity by transmitting data to the actuators of the physical entity using a specified protocol.

**Figure 22: Schematic representation of a DT with the interconnection between virtual and physical entities (Mauro and Kana, 2023)**

Sensors could measure characteristics onboard such as the engine room temperature, strain, pressure, electricity consumption or exhaust gas composition which will provide data that can be used to improve the efficiency of the operation of the ship to decrease GHG emissions. Also, environmental sensors can be deployed to measure for example the wind and sea state, outside temperature, sea salinity and GPS to directly respond to environmental changes for optimal operation in changing environments. In order to respond to such environmental and onboard changes task two is crucial to establish a corrective measurement. Lastly, this corrective measurement needs to be translated to the physical entity to alter the operation for improved performance. Such as reducing the speed during increasingly heavy sea state, winds or reducing noise pollution when entering certain (marine) protected areas.

From a ship design perspective, DT based design is not a term commonly used in literature. Especially not in the maritime industry where the concept of DT alone is underrepresented compared to other complex engineering industries (Mauro and Kana, 2023). Even in other industries such as aerospace, civil, and automotive the method for DT-based design is very premature and as a result, is inconsistent and does not have a standardized framework (Psarommatis and May, 2022). There are multiple reasons why it is so challenging to create a detailed DT framework focused on design for new builds. The main challenges provided by previous literature studies suggest three main reasons why:

1. Most importantly the definition of DT has been used inconsistently intertwining the concept of DT with other versions of digital entities.
2. The concept of DT-enabled design with the synchronised DT from Grieves (2014) is relatively new and in a very early stage of development globally.
3. The developments have mainly focused on the operation and maintenance stage and not on design (or retrofit).

This paper proposes an additional reason:

4. When designing a new vessel, the physical entity does not, by definition, exist yet. Thus, properly adhering to the DT definition requiring bi-directional communication between the physical and virtual entity is not possible. Thus, this paper discussed DT-based design to suggest a design process that eventually enables true DT capabilities once the vessel is built.

Mauro and Kana (2023) conclude that there is a large delay in the *design* and *retrofit* phase for DTs, and thus it is necessary to evaluate the state-of-the-art and limitations of DTs in these phases in more detail.

### ***DT-based New Build Design***

Currently, most research publications containing conceptual DT applications focus on parts of a ship instead of the total ship itself. A systematic review of the literature finds only two available publications which address a DT theoretical framework considering new-build methods, and of which only one is associated with the design of the whole ship (Xiao et al., 2022). The authors propose a DT framework proposing the use of a vertical-horizontal design method of a new-build regarding the total ship throughout its life-cycle phases. This framework is still under development. Even though it provides promising conclusions, it is still a theoretical framework with in-depth research still being conducted as mentioned by the authors. Nevertheless, no articles are available regarding concrete applications of DTs linked to new-build design methods, only for theoretical and conceptual cases.

The remaining articles concern mostly subsystems of a vessel and relate to conceptional applications or only provide a general description of such an application (Arrichiello & Gualeni, 2020; Nikolopoulos & Boulougouris, 2020; Pérez Fernández, 2021; Stachowski & Kjeilen, 2017). Erikstad (2017) has also identified this trend of subsystem DT application but indicated the potential of getting closer to achieving a DT of a complete ship when such subsystem DTs are merged.

Additionally, very few papers include essential information such as specific methods, input data, output data or reliability of the design. Following the classification by Tao et al (2019) and used by Mauro and Kana (2023) the current literature on DT-based ship design is in a so-called formation stage, meaning, “very few papers are published as the technological foundations are not mature enough to support effective applications”. As a result, it will likely be challenging to iterate and develop these methods further within the maritime community outside of the specific research groups where they were developed, hampering overall progress.

Finally, a distinction can be made between (1) the design of a physical entity while consequently designing a DT specifically tailored to the physical entity and (2) developing a virtual space in which DTs can be developed for different types of ships. A choice needs to be made to establish a development direction. This distinction has been pointed out by Wang et al (2022); however, they do not mention an argument to which development direction is favourable. This state-of-the-art report argues, nevertheless, for the second direction, as it provides the potential for generality and reusability of the virtual space, enabling greater usability potential.

### ***DT-based Retrofit Design***

Even though it is not performed for every ship and therefore not considered as a general life-cycle phase, retrofitting is common to perform when aiming to reduce emissions or to improve the onboard systems (RINA, 2020). There are limited available publications linked directly to DT application for ship retrofitting, which can be explained by the fact that the retire or retrofit phase (including multiple retrofits) is the last stage of a ship’s life-cycle and subsequently will also be the last stage to be fully investigated with regard to DTs. In order to fill this gap it is proposed to examine research done on DTs in the operational phase which will provide sufficient information on design decisions linked to retrofitting. With ship data acquired during the operational phase of the vessel and processed by a DT, design decisions for a retrofit can be derived throughout the DT.

Two publications have been identified which present a conceptual framework to integrate DTs with an existing ship (Zhang et al., 2022) and virtual system (Mouzakitis et al., 2023). Zhang et al (2022) propose the construction of a DT for an already existing research vessel, ‘Gunnerus’. Although the project is still ongoing, the article provides a DT architecture including the data-driven design building block method using the Open Simulation Platform, an open-source simulation platform. Even though a unique vessel is being considered, the authors aim is to provide a standardized DT concept for the maritime industry.

Additionally, Mouzakitis et al. (2023) address the importance of using high-performance computing together with big data analytics to develop, and therefore contribute to high-level digital products for the maritime industry. The DT architecture includes a proposed data integration into the existing unified system within the ‘VesselAI’ project. Additionally, the Digital Twin for Green Shipping (DT4GS, 2024) project aims to develop DTs for existing commercial vessels, with applications in container ships, bulk carriers, tankers, and RO-PAX ferries. This project is still ongoing.

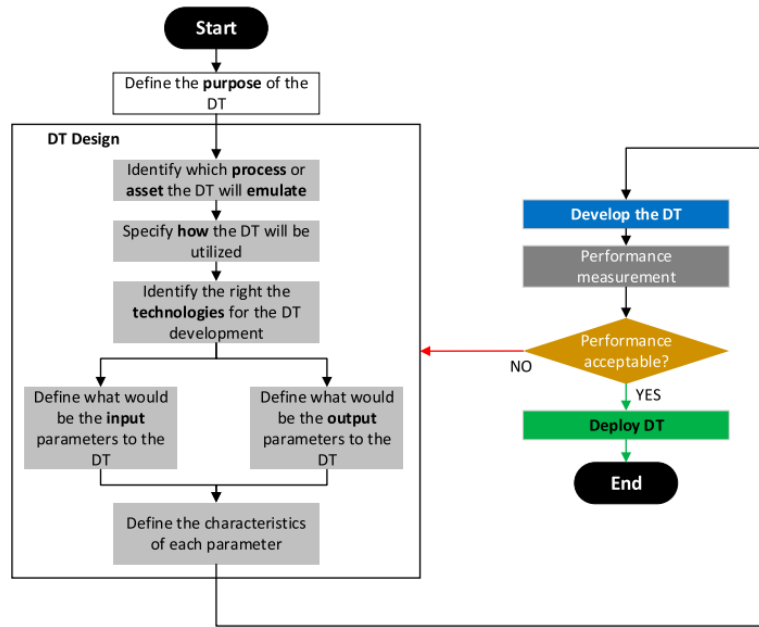

With maritime DT applications still being relatively new, it is logical to assume publications regarding retrofitting will become available in the future. This paper argues for additional research on DTs in the operational phase to support information regarding a possible retrofit, given the fact retrofitting is being performed to extend the life-time (e.g., operational phase) of a ship.

For both new-build and retrofit designs a clear research gap is identified regarding the application of DTs. When examining the current state-of-the-art of DTs for ship design and retrofit, the literature showed that scientific research into maritime DT applications is still in the early stages of development but is rapidly growing. Regarding new-builds, publications only cover conceptual DTs or consider a subsystem of the ship, not the total ship. Furthermore, limited available publications were found regarding DTs for retrofit design. A research gap is identified for DT application of new-build design considering the total ship and retrofitting in general.

## **Lessons Learned from Other Industries**

In other industries, there are DT-based design challenges that have been researched but have not been addressed yet in the ship design industry. A large amount of literature referencing DT-based design is not specifically aimed at a certain industry. As a result, the proposed design methods are not very detailed. However, some important frameworks have been developed which could influence ship design as well. For example one of the ship design challenges stated by Fonseca and Gaspar (2020) is the complexity of determining the business value of the DT. Newrzella et al (2022) propose a method to define a selection of use cases and data sources to start a pilot phase, derived from the market needs and the most impactful data sources. Since the shipping industry is relatively sensitive to market needs and business value, an approach to determine what DT use cases to develop from the early design stage is fundamental.

Additionally, in the literature review by Psarommatis and May (2022) it is concluded that the manufacturing industry, which is furthest ahead of other industries, also encounters the same problem as the ship design industry specifically related to the research gap exploring DT-based design methods. The majority of DT-based design papers either develop technologies for only one-time occurrences or are not stated. The definition of the communication within the DT has been categorized as unstated or manual, with manual being the most common, which is in contradiction to the formal definition of DTs proposed by Grieves (2014). The large majority of the papers do not verify their methods nor include input and output parameters. As a result, most methods are only suitable for one-time use and cannot be further developed. Thus, it appears that the manufacturing industry has similar challenges to ship design. Psarommatis and May (2022) propose a flowchart of the design decisions needed before the DT can be developed (Figure 23). This targets shortcomings in the current literature that the maritime industry also encounters. These steps are general and can be integrated into the ship design process with minor modifications, depending on the intended application.

**Figure 23: Proposed DT-based design method by Psarommatis and May (2022)**

Finally, the aerospace industry has more experience in the application of DTs and proven effectiveness in quality improvement. NASA is working on the integration of model-based systems engineering (MBSE) and DT design (Weiland, 2021) which has also been explored in the shipping industry (NAVAIS, 2022). MBSE enables the inclusion of contributors and stakeholders, facilitating collaboration throughout the product life cycle, and resulting in more efficient data exchange and shared model information compared to traditional methods (Lopez and Akundi (2022)). MBSE can also handle fast changes, and improve the collaboration of engineers and digital machines by providing knowledge-sharing infrastructure, automating designs, and simulating system behaviour (Weiland, 2021). This paper thus argues for additional research effort within the ship design community in the application of formal MBSE to support DT-based design and retrofit as it provides a promising framework to develop a virtual space in which digital twins can be developed for different types of ships.

## Digital Twin Modelling for Ship Design and Retrofit

This section provides a high-level DT modelling process that can support DT-based design. It is designed to be generic and thus also be coherent with the application of MBSE stated above. Before starting the process, the objective of a DT must be determined which covers the composition and modelling process of the DT. The DT objective will indicate which virtual models are required for the DT. The DT output is based on performing simulations, using available operational data. The composition of the virtual part of the DT depends on this data, as this will determine the feasibility of modelling certain parts within the DT, and thus drives the modelling process (Giering & Dyck, 2021). By investigating the available data, the virtual models which are feasible to construct are identified. Finally, the overlap between the required models (derived from the DT objective) and the feasible models (derived from the available data) provides the models to be selected for the final DT (see Figure 24).

**Figure 24: Selection process for DT models (Hermans, 2024)**

After establishing the DT's objective and the model selection process, the modelling phase involves the following general steps:

1. **Set-up the data acquisition:** To acquire the data for the DT, a data acquisition system needs to be established, which collects the information required to model the DT, and functions as a collector for the bi-directional data connection.
2. **Establish a data pre-processing framework:** The data needs to be pre-processed in order to be of use as input for the virtual models. García et al (2016) discuss key data preprocessing techniques in the field of computer science, which can also be leveraged for DT modelling, such as data cleaning and normalization. A preprocessing framework depends on the chosen modelling approach, and consequently on the type of data. By establishing an effective framework, redundancies are reduced regarding connected features within the DT (Autiosalo et al., 2019).
3. **Choose modelling approaches for virtual models:** The three different modelling approaches adopted in standard data-science literature are: black-box, white-box, and grey-box. Black-box models are digital models purely based on statistical techniques in order to find relationships between a set of empirical input data and a set of desired output data. White-box models are the exact opposite, and are constructed based on physical principles, theoretically derived set of equations and experimental-derived data. A grey-box model aims to achieve the advantages of both model types by combining the analytically and experimental-driven methods of a white-box model to achieve physical accuracy, and the statistical techniques of a black-box model to identify patterns (Ehmer & Khan, 2012).
4. **Perform model training in case of statistical-based models:** Through training, the model is calibrated in order to achieve the acceptable accuracy. Model training is required for black-box models.
5. **Verify and validate (V&V) the virtual models:** When the chosen models are constructed, and trained in case of applying a black-box or grey-box approach, they need to be verified and validated to ensure the accuracy and reliability of the chosen modelling approaches
6. **Integrate the virtual part with the physical part:** After the models have been verified and validated, they can be integrated into the DT infrastructure. Following the DT definition by Grieves (2014), the output of the virtual models needs to be connected in an automated way to the physical ship. As it is related to the physical vessel, this output can directly be received and used by the respective vessel. In the case of a DT for retrofit purposes, the output will relate to recommendations regarding design decisions. It is considered that the output of the models will drive the retrofit design, and after the retrofit has successfully been performed, the virtual models will represent the modified vessel. Thus, after the retrofitting occurs, the virtual-physical integration can take place. With the integration completed, the DT is established and can be used for operational purposes, such as performance monitoring.

Figure 25 shows a schematic representation of the transition towards a DT for retrofitting. The integration step is performed at the end and can occur simultaneously with the completion of the retrofit (step 5). The final retrofit DT originates from a digital model which represents the ship (step 1), and which is further investigated for possible retrofit options (step 2). The chosen retrofit design (step 3) will then be used for the actual retrofitting of the respective vessel (step 4).

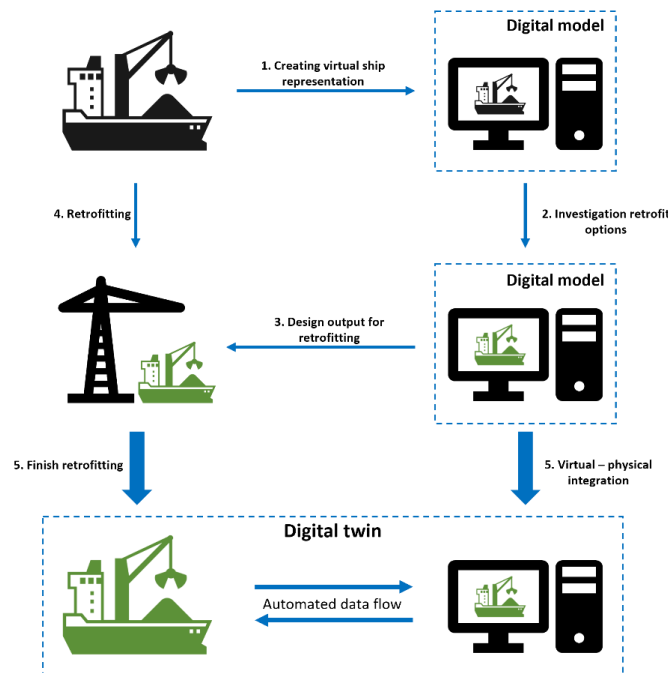

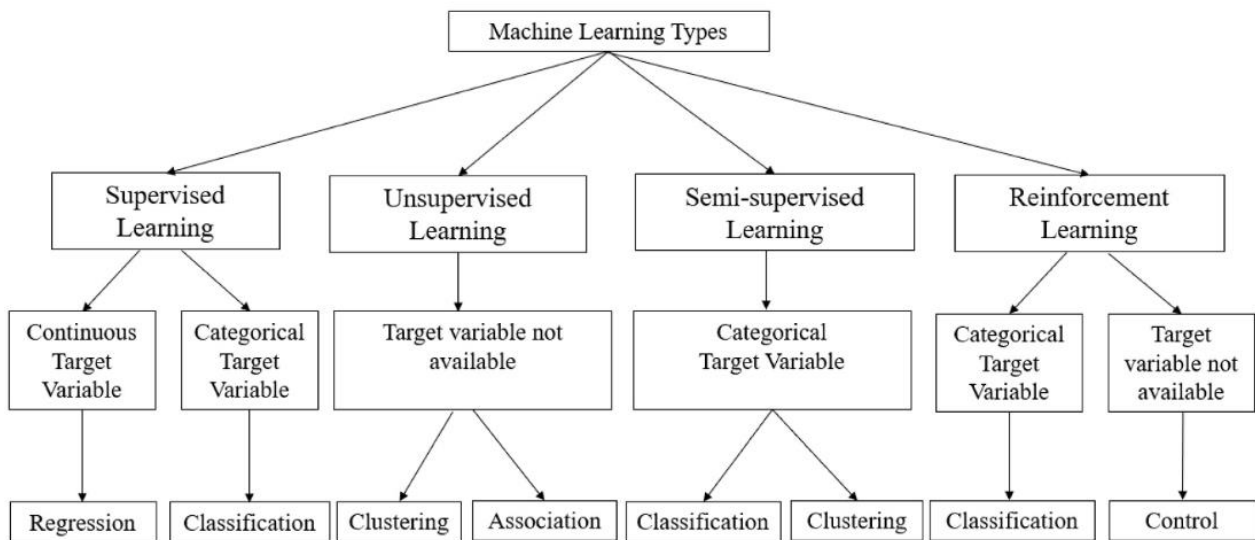

Figure 25: The development of the digital twin for retrofitting (Hermans, 2024)

## ARTIFICIAL INTELLIGENCE

Erikstad and Lagemann (2022) have already addressed the introduction of artificial intelligence (AI) in ship design in their IMDC 2022 State-of-the-Art report. However, it was a few months later that the world was astonished by the release of OpenAI's Chat Generative Pre-trained Transformer (ChatGPT) at the end of November 2022 (Wikipedia, 2024). Since then, the research on the potential benefits, limitations and challenges of the application of AI in the ship design field has intensified.

According to the definition adopted by the European Commission in 2018 (Boucher, 2020) “AI refers to systems that display intelligent behaviour by analysing their environment and taking action – with some degree of autonomy – to achieve specific goals”. There are many attempts to classify the key technologies that are associated with AI. According to Boucher (2020) for EC there are three main stages of development. The first was the symbolic AI (or Rule-Based AI) that included expert systems, Artificial Neural Networks (ANN), deep learning and fuzzy logic. The second stage includes the introduction of machine learning (ML) algorithms such as surrogate models and data-driven intelligence. The third wave includes ‘strong’ or ‘general’ AI (AGI) that shows intelligence in a wide range of problem spaces. This includes Natural Language Processing (NLP) algorithms and in the future artificial superintelligence (ASI).

Huang et al. (2022) have attempted a review of the research addressing ML's application in sustainable ship design and operation. Their classification of ML models was inspired by Sarker (2021).

**Figure 26: Classification of Machine Learning according to Huang et al. (2022) inspired by Sarker (2021)**

AI accelerating applications in ship design provide solutions to several challenging problems. These include hull optimisation, performance prediction, holistic design optimisation; accelerated structural analysis and material selection; energy efficiency, decarbonisation and environmental impact; safety analysis and compliance with the applicable rules and regulations; and prognostics and diagnostics for predictive maintenance.

### Hullform optimisation

Yu and Wang (2018) introduced a Principal Component Analysis (PCA) methodology to compress the geometric representation of a group of existing vessels. The resulting principal scores are used to generate many derived hull forms, which are evaluated computationally for their calm-water performances. A Simple-Source Panel Method (SPM) based on potential flow theory was used to calculate the wave resistance, accelerated by a Graphic Processing Unit (GPU). The results were used to train a Deep Neural Network (DNN) establishing the performances of the different hull forms. Based on the DNN's evaluation, a large-scale search for optimal hull forms is performed very quickly and with increased flexibility. However, the authors note that the pool of parent hulls should be expanded and CFD and EFD results should be included in the training to increase the accuracy of the DNN predictions. Additional performances should be evaluated to establish a more comprehensive optimization process.

Panchal et al. (2019) in their guest editorial for the special issue on ML for Engineering Design, argue that machine learning algorithms have an evolutionary impact on mechanical design, uncovering hidden patterns in data and developing autonomous systems. DNN and other modern ML techniques are enabling progress in AI. Examples include ANN, Gaussian processes,

clustering techniques, and Natural Language Processing. They also point out that engineering design research has more recently benefited from the introduction of deep learning techniques such as convolutional neural networks (CNNs) and generative adversarial networks (GANs). The research they present in the special issue introduces a first taxonomy of the area: (i) ML techniques to support surrogate modelling, design exploration, and optimization, (ii) ML-supported design synthesis, (iii) extraction of human preferences and design strategies utilizing ML, and (iv) ML-informed comparative studies and research platforms from design researchers support. The editorial team recognizes that ML has already applications in modelling human decision-making, market system design, human or surrounding environment interactions with products, design for reliability, informing the design using of real-time data from products (design-for-X), where a particular aspect of the lifecycle or across several aspects of the lifecycle are benefit for the analysis of data gathered. Security, privacy, cyber-resilience, trustworthiness and other non-traditional design challenges in engineering design, arising from smart products and systems, present emerging opportunities for the use of ML.

Grigoropoulos et al. (2021) presented a mixed-fidelity method to optimise hullforms combining genetic algorithms (GA), hydrodynamics potential flow numerical codes and a surrogate model based on ANN to account for the viscous effects. The ML tool is trained to capture the impact of viscosity on the flow around the stern of the vessel by analysing the results of a series of Design-of-Experiment (DoE) runs with a Reynolds-Average Navier-Stokes (RANS) solver. The approach accelerates the evaluation of the calm water resistance of the various designs and reduces the computational time required to reach an optimal hull design. The final design was evaluated with the RANS solver and the accuracy was satisfactory. The authors note that the exact number of neurons in the network are less important than the quality and quantity of the input data used for training the ANN. However, they recon that full-scale simulations at large Reynolds numbers are still challenging.

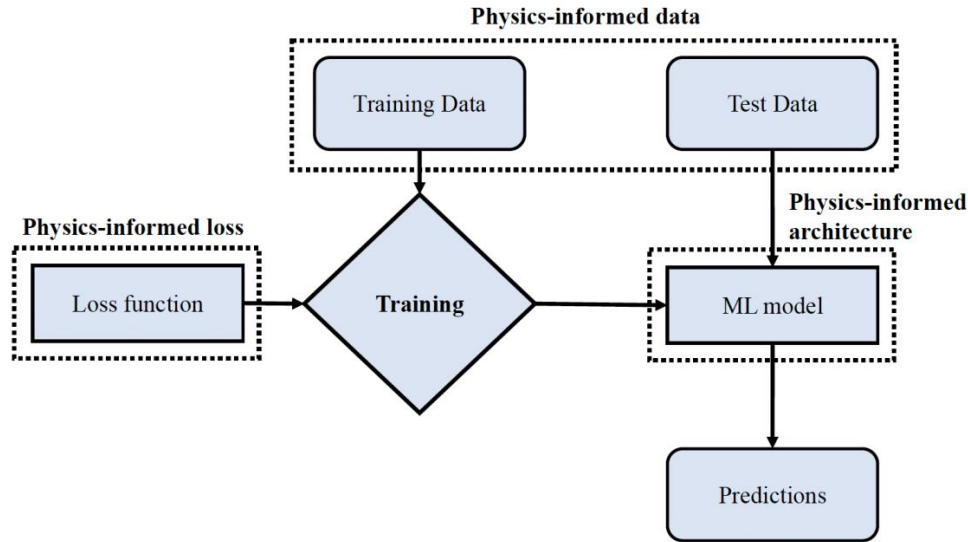

Ao et al. (2022) presented a data-driven multiple-input neural network (MINN) model to predict the total resistance of the ship's hull with the objective of avoiding inconsistencies from input parameters. It utilised three Fully Connected Neural Networks (FCNNs). The authors argue that the developed AI-based ML algorithm can assist the ship hull design process in real time by accurately providing the total resistance. They validated their results against a potential flow resistance prediction method. Through their validation studies, the authors have shown that a well-trained ANN can accurately estimate the hydrodynamic performances of a hull based on its geometry modification parameters. Therefore, the authors claim that the approach gives an accurate and fast AI-based method that provides optimum estimation accuracy in the entire design space.

Bagazinski and Ahmed (2023a) proposed a generative AI model based on a guided diffusion algorithm for parametric ship hull generation. They used a denoising diffusion probabilistic model (DDPM) that created the tabular design vectors of a ship hull. The model managed to improve performance through guidance. It utilised the dataset of 30,000 parametrised hull forms called Ship-D (Bagazinski and Ahmed, 2023b). Utilising 45 hull parameters and 49 algebraic feasibility constraints and guidance from performance prediction models, the algorithm was able to generate high-performance designs with only information learned from the low-performing hulls in the dataset. However, the significant reductions in wave drag were calculated using Michell's integral and they were not confirmed by more precise tools (e.g. VOF CFD) and the impact of other design changes (e.g. increased displacement) was not compensated by changes to other design parameters such as lightship, deadweight, stability etc.

Khan et al. (2023) introduced the generic parametric modeller ShipHullGAN. Deep convolutional generative adversarial networks (GANs) were used for an adaptive representation and generation of ship hulls. The model is trained on a dataset of more than fifty-two thousand physically validated designs. They included a variety of different ship types, such as bulkcarriers, tankers, container ships, crew supply vessels and tugboats. All training designs are converted into a common geometric representation using a shape extraction and representation strategy. They have the same resolution, as typically GANs can only accept vectors of fixed dimension as input. Right after the generator component, a space-filling layer was placed. Its purpose was to confirm that the trained generator could cover all design classes. The designs are provided in the form of a shape-signature tensor (SST) during training. It harnesses the compact geometric representation using geometric moments that further enable the cost-effective integration of physics-informed components in ship design. The authors argue that comparative studies and optimisation cases have shown that ShipHullGAN was capable of producing designs a broad spectrum of designs, both traditional and innovative, with geometrically sound and practically viable configurations.

Sharma et al. (2023) review Physics-informed Machine Learning (PIML) and how it integrates ML with domain knowledge. The authors suggest that higher data efficiency and more stable predictions can be achieved. Therefore, high-fidelity numerical simulations of complex turbulent flows can be augmented or even replaced. The authors categorise ML into unsupervised, supervised, and semi-supervised. Unsupervised learning refers to algorithms that learn from unlabelled data, This is opposed to supervised learning where algorithms recognise patterns of input-output relationships from labelled data. In semi-supervised learning, algorithms contain characteristics of both unsupervised and supervised learning. Regression and classification problems are typical applications of supervised learning. The PIMLs are the most recent step in the evolution of ML towards their applicability in fluid mechanics problems as they combine ML techniques with physics knowledge, and model loss

functions as can be seen in Figure 27: **Methods for incorporating knowledge from physics into supervised learning framework models** (Sharma et al., 2023)

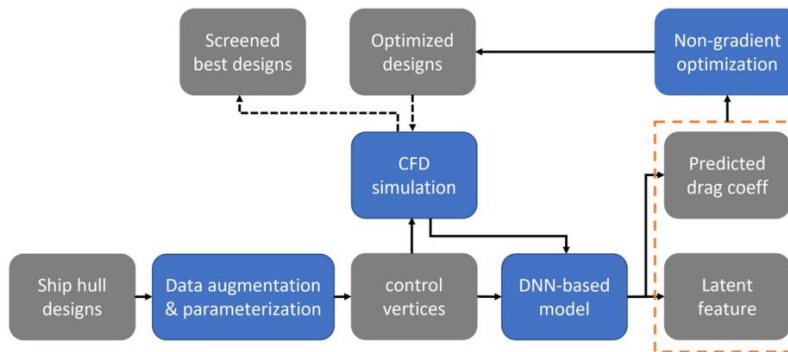

**Figure 27: Methods for incorporating knowledge from physics into supervised learning framework models** (Sharma et al., 2023)

Majnarić et al. (2024) investigated the use of ML-based determination of a containership’s main particulars at the early design stage. They applied a synthetic data generation technique for generating a large amount of synthetic data points regarding container ships’ main particulars, utilising a multilayer perceptron (MLP) regressor on both original and synthetic data mixed with original data points. The models were validated based on real data showing very good agreement.

### Performance Prediction

Wang et al. (2022) present a deep neural network (DNN)-based approach to convert hull designs to condensed representations, generate innovative designs, and based on their hydrodynamic performance, optimize the synthetic design. The DNN-based 3D ship hull encoding and optimisation framework is shown in Figure 28: 8. It consists of three components integrated with CFD simulations: ship data augmentation and parameterization, VAE, and design optimization with virtual screening.

**Figure 28: Overview of the data-driven ship 3D hull encoding and optimization framework** (Wang et al., 2022)

A variational autoencoder (VAE) equipped with a hydro-predictor has been developed to reconstruct the geometry of hulls by reconstructing the Laplacian parameterized hulls. It also encodes the CFD-simulated resistance. Perlin noise mapping and free-form deformation (FFD) data augmentation algorithms generate the training set from a parent hull. This VAE model is then used to search efficiently through a vast array of generated hulls to identify those with minimum resistance. The most promising hulls are verified using CFD calculations. Numerical experiments verify the ability of the framework to reconstruct the input geometries and predict their resistance accurately using a convolutional neural network (CNN). The authors note that it has

produced new hull designs showcasing a 35% resistance reduction compared to the parent design. However, despite its adeptness, it is limited to intraclass ship design as the VAE reconstruction network is highly model-specific.

Hodges et al. (2022) utilized Siemens' NX CAD software to parametrize the hull form of MV Regal with 12 independent geometrical variables. They determined the powering requirements of the designs using the CFD solver Simcenter STAR-CCM+. Then, utilizing the results, they created in Simcenter ROM Builder and Monolith surrogate models. The workflow of the methodology is shown in Figure 29. The outputs of the models include torque, total resistance, powering, and propulsion metrics. These were then supplemented with additional ML CFD predictions for local field results including the wake fraction at the propeller, the generated wake, and the shear and pressure loads on the hull. The authors depict the capabilities of ML models to predict accurately the local field (see Figure 30), and their potential of enhancing the hull optimization pipeline.

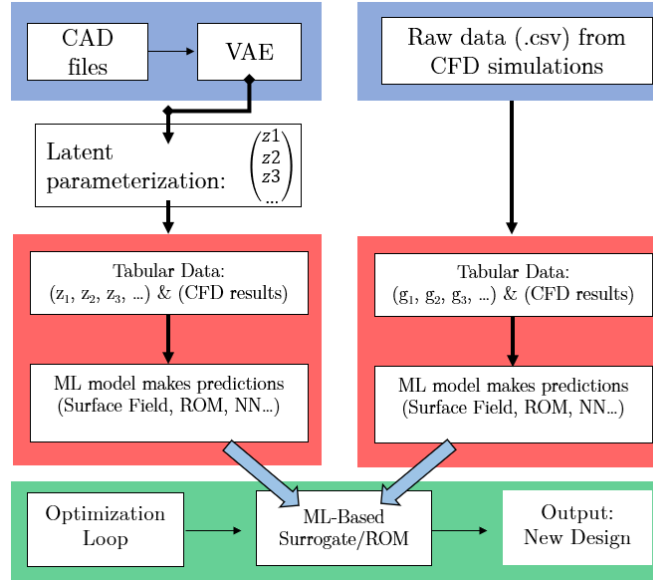

Figure 29: The different workflows used by Hodges et al. (2022)

## Safety Analysis

Louvros et.al. (2023) described a novel approach that introduces a fast decision support tool which can provide information regarding the ongoing damage stability casualty utilizing prior knowledge gained from simulations. Case-based reasoning and Machine Learning methods are used, providing real-time predictions based on “analyzing” a dataset of pre-run damage scenarios. In this way, the lengthy and costly computations that describe the actual flooding phenomena can be bypassed. Case studies simulating realistic scenarios are presented to showcase the performance and practical application of the methodology.

## Holistic Design Optimisation

Nazemian et al. (2024) presented a Machine Learning (ML) tool for calm water resistance prediction and used it to develop a systematic series for battery-driven catamaran hullforms. Furthermore, they employed the ML predictor for design optimization using a GA. For the dataset training, three regression models were tested, namely, Regression Trees (RTs); Support Vector Machines (SVMs); and Artificial Neural Network (ANN). The authors use the framework for the optimization of several catamarans, including dimensional and hull coefficient parameters based on resistance, structural weight reduction, and battery performance improvement. Lackenby transformation is initially used to explore the design space, and then, a novel self-blending method generates new hullforms based on two-parent blending. Finally, the generated data of the case study are encoded in an ML model. The ANN algorithm has shown a good correlation with the expected resistance. Accordingly, by choosing any new design based on owner requirements, GA optimization obtained the final optimum design by using an ML fast resistance calculator. The design of a 40 m passenger catamaran vessel was optimised in a showcased study. The framework achieved a 9.5% improvement proving that combining ML and GA optimization may accelerate significantly the ship design process.

### **Energy efficiency, decarbonisation and environmental impact**

Nikolopoulos and Boulougouris (2023) presented a Robust Holistic Ship Design Approach (RHODA) using voyage simulation and surrogate models. The authors deployed the framework for the optimization of Zero-Emission Ships. They implemented the simulation-driven optimization in the case study of an NH3-fuelled Large Bulk Carrier. The framework was adapted to cover the ship and fuel-specific aspects of the design of the Zero-Emission ship configuration

Zhang et al. (2024) utilize a deep learning method for the prediction of ship fuel consumption. Their approach makes use of big data from sensors, voyage reporting and hydrometeorological data, summing up to a total of 266 variables. Their model is trained based on results from sea trials of a Kamsarmax bulk carrier. Using a Decision Tree (DT), patterns are recognized within the available dataset. Implementing a deep learning model, the influence of variables such as sailing speed, heading, displacement/draft, trim, weather, sea conditions, etc. on ship fuel consumption (SFC) is established. This is achieved by incorporating a DLM based on Bi-LSTM with an attention mechanism. The methodology is validated using k-fold cross-validation and implemented in a case study. The author concluded that the method could be useful in the context of a decision-support system for environmentally friendly operations, subject to further testing and validation.

### **Other areas**

Mikulić and Parunov (2019) presented an overview of the AI and ML state-of-the-art in different areas of the maritime industry. This included design, structures, hydrodynamics, forecast of environmental factors, corrosion, production, and machinery. The authors concluded with recommendations for potential implementations.

AI and ML algorithms have also found their way into the integration of ship design and ship production in the form of the recently started Horizon Europe Project ESY (2024), where digital tools will support sustainable shipbuilding practices.

## **CONCLUSIONS AND WAY AHEAD**

### **Conclusions**

In today's era of smart digitalization in the frame of Industry 4.0, recently introduced digital/software tools and systems have increased the efficiency and quality of the life-cycle ship design process. Parametric optimisation and simulation-driven design, product lifecycle management, digital twins and artificial intelligence are nowadays frequently used by the maritime industry during the commissioning/quality control activities and in the various phases of ship design, ship operation and ship production.

Classical and novel concepts of ship design and the assessment of life-cycle operation are nowadays implemented in versatile, integrated design platforms, offering the user a vast variety of options for the efficient development of alternative ship designs by use of tools for their analysis and parametric, multi-objective optimisation with respect to all relevant (ship) design disciplines, as well as virtual prototyping. Some design software systems (e.g., as developed in HOLISHIP) adopt an open architecture that allows for the continuous adaptation to current and emerging design and simulation needs, flexibly setting up dedicated synthesis models for different application cases. The exploration of the huge design space is enabled by the use of automated parametric models of significant depth, which are processed with reduced lead time.

Simulation-driven ship design has become an important part of today's design teams and the authors believe that it will play an even more decisive role in the future. As presented in sections *Parametric Ship Design Optimization*, *Simulation-driven*

*Ship Design and Artificial Intelligence* the trend is to address more complex design tasks while doing so with higher efficacy. SDD campaigns increasingly accommodate more objectives and several disciplines. This is because competition continues to be high, calling for better products, while the need for sustainable shipping has become evident as is now also reflected in recent legislation. Furthermore, the environment in which design teams need to make decisions has become more complicated over the last years. Potential solutions for energy-efficient shipping are developing more rapidly – with some that are just emerging – while the prediction of available fuels, trade patterns and retrofits for ships in service is presently rather difficult, adding uncertainty and calling for flexibility as elaborated in section *Ship Production and Lifecycle Management*.

We believe lifecycle aspects of marine systems design will become even more important in the coming years. Our common ambitious goals for net zero 2050 will be the main driver. Business-as-usual is not an option. Nor are currently available technology, energy carriers, concepts of operations and regulatory framework sufficient to solve this problem. Thus, innovative and even radical measures are needed – but what this will turn out to be is not yet known. For the maritime industry, this is a severe risk for most, but also an opportunity for those who are able to make and implement the best lifecycle strategies for business development, fleet renewal, retrofits, and operations. For the marine systems design community, it poses a challenge for the years ahead to develop the necessary models, methods and tools to foster change built on a holistic, lifecycle perspective.

A review of the state-of-the-art of digital twins in the design and retrofit of ships concludes that there is currently no standardized design method or approach for DT-based design or retrofit within the ship design industry, or even in other relevant industries. Thus, this state-of-the-art report argues for four points. First, ship design literature should be consistent with their terminology when researching and applying DTs. This paper argues for the DT definitions proposed by Grieves (2014), and Kritzing et al. (2018). Second, the development of a standardized DT-enabled framework, applicable to both new-builds and retrofits, which is flexible, reusable, and verifiable, and includes, among others, specific methods, input data, output data and reliability of the design would help with the research and innovation in this domain. This should be done to support the development of a virtual space in which DTs can be developed for different types of ships. Third, additional research and application focus should be placed on the use of formal MBSE to support DT-based ship design and retrofits. Finally, additional research focus should be placed on DTs in the operational phase specifically to support retrofitting to extend the lifetime of a ship, increase its energy-efficiency and improve its operation.

The integration of AI in ship design is set to accelerate, expanding from the conceptual phase where its benefits are already evident. AI's role is expected to grow across all stages of design, including hull optimization, performance prediction, and structural and safety analysis. Despite these advancements, engineers face challenges such as ensuring the transparency and verification of AI-generated results, as AI learning is ongoing. Additionally, the impact on the training and employability of future engineers is a concern. The adoption of these tools could significantly reduce task completion times, but there is scepticism about their potential negative effects on job availability in the sector. Naval architects and marine engineers must adapt to leverage AI's advantages while mitigating its challenges.

## Way Ahead

The complexity of solving multi-objective and even multi-disciplinary design tasks is intrinsically high since many free variables are involved and many high-fidelity simulations are needed. Surrogates and ML have been proposed to cope with high complexity and to more easily capture mutual influences. In order to provide the necessary training data Design-of-Experiments are utilized. There currently are several approaches to reduce the number of variants that need to be run along with the computational effort that has to be spent: (i) The reduction of the number of free variables by dimensionality reduction, see for instance Diez et al (2015), (ii) the mixture of simulations of different fidelity, see for instance Pellegrini et al (2022), and (iii) the adaptive sampling of design spaces, see for instance Serani et al (2019).

The abundance of data produced during SDD campaigns should and could be utilized more intelligently and more systematically in the future, see section Digital Twins in the Design and Retrofit of Ships. The various levels of digital representation (i.e., model, shadow and twin) can certainly benefit from design data and vice versa. Here, one challenge lies in ship hydrodynamics where full-scale simulations by means of CFD are very resource-intensive and, unfortunately, are difficult to verify by means of reliable measurements while sailing in accurately known weather conditions. Here, the industry at large appears to be still at the beginning of developments.

There are naturally several trends that have not been discussed in this paper so as to deliberately limit its scope. Yet, some of them should be briefly mentioned as they may influence the not-too-distant future in ship design: (i) Cloud solutions, even though still looked at with a certain skepticism when it comes to sensitive data, (i) web-based applications and micro-services that could help increase access to more design teams and “democratize” the usage of high-fidelity simulations at acceptable costs while ensuring results of high quality.

Last, but not least: the complexity of the employed design methods, software tools and design platforms has created an increased demand for proper training of users of software platforms in information technology and beyond traditional naval architecture. This calls for an urgent adaptation of the curricula of university education in naval architecture and marine technology. Ship design is a synthetic, multi-disciplinary field and only properly trained naval architects will be able to assess the validity of results of simulation tools/design software platforms and take proper decisions on the way ahead in stages of the ship design process.

## CONTRIBUTION STATEMENT

**Author 1:** Conceptualization; supervision; writing introduction and chapter on parametric ship design optimisation; paper consolidation; review and editing. **Author 2:** conceptualization; writing chapter on Artificial Intelligence – review and editing. **Author 3:** conceptualization; writing chapter on Life Cycle Management– review and editing. **Author 4:** conceptualization; writing chapter on Simulation-driven Ship Design – review and editing. **Author 5:** conceptualization; writing chapter on Digital Twins - review and editing.

## ACKNOWLEDGEMENTS

The support of the presented research by the European Union’s Horizon research and innovation program, Projects HOLISHIP (Grant Agreement No 689074), TrAM (Grant Agreement No 769303), Orcelle (Grant No 101096673) and DT4GS (Grant Agreement No 101056799), is acknowledged.

Dr. Harries has been partially supported by the Horizon Europe project “RETROFIT55 – Retrofit solutions to achieve 55% GHG reduction by 2030”, grant agreement 101096068 (see <https://www.retrofit55.eu/>).

Prof. Boulougouris has been partially supported by the Horizon Europe project “ESY-EcoShipYard”, grant agreement 101138730. He also acknowledges the support from RCG and DNV, sponsors of the Maritime Safety Research Centre at the University of Strathclyde. The opinions expressed herein are those of the author and does not reflect the views of EC, DNV or RCG.

The authors would like to acknowledge Julien Hermans (Hermans, 2024) and Isabel van Noesel (van Noesel, 2023) of Delft University of Technology who provided significant contributions to the digital twin section of this paper. The authors are also grateful to Mrs. Aimilia Alissafaki (NTUA), for her support in edition of the paper.

# THE EXPANDING SCOPE OF SHIP DESIGN PRACTICE

Professor David Andrews<sup>1,\*</sup>

## ABSTRACT

*As the former International Chair of IMDC, the initiator of the continuing series of IMDC State of Art (SoA) Reports and the lead author of most IMDC SoA Reports on design methodology from 1997 to 2018, the author has both pioneered and observed an increasingly broader scope in the practice of the design of particularly complex vessels.*

*The paper commences with reviewing some key publications, not just to recent IMDCs, that have tracked the manner in which “ship design” (in the broadest sense) has become more sophisticated – especially in the crucial early stages of design. The diversity of ship design practice, not just due to computer-based methods, is readily observable. Moreover, the impact of computer aided design in ship design has not just been to better analyse ship performance (e. g. in hydrodynamics, strength and ship infrastructure systems behaviour) but also in the increasing use of graphical tools and design methods to enable “better ship design”. In a growing number of, mainly, academic centres, but also in some government agencies and design consultancies, there is a clear desire to better understand how to design “ships” and to manage the ship design process, especially for the most complex and novel classes of vessels. In particular, the objectives being sought when conceptualising and synthesising a range of ship options (as part of the requirement elucidation approach) in an ever-increasing scoping of the relevant issues, amounts to developing a more holistic approach. This is not just due to an increasingly complex ship acquisition and ownership environment, but also due to environmental and socio-economic (especially system safety) concerns. Overlaying all this are the opportunities or the spectre of Artificial Intelligence (or perhaps more immediately those of Machine Learning) and its likely impact on engineering practice as well as those other professions in the “marine design enterprise”. The paper concludes by emphasising that while ship design has distinct differences, when compared with most other large scale engineering design practice, the lead ship design profession of the naval architect has somehow to deal with this expanding scope in the practice of “ship design”. This means the education and on the job development thrust must broaden if the ship design profession is not to be side-lined into acting as mere hull engineers. It is argued, such a specific role will be more vulnerable in an increasingly Machine Learning dominated future, than the holistic ship creating and systems architectural alternative. Finally an ambitious vision for future ship designers is given alongside a summary of the specific main contributions by the author to ship design methodology.*

# 1. INTRODUCTION

## 1.1 Preamble

It is the opinion of the author, from a close involvement in the triannual IMDC conferences for more than the last two decades, that the scope of the practice of ship design has expanded in recent years. This is investigated by looking back even beyond this timeframe to the commencement of such considerations, which could be said to have been initiated by Stian Erichsen, the first chair of what was first designated as the International Marine Systems Design Conference series from the inaugural IMSDC 1982 conference in London. This conference resulted from a precursor symposium in 1979, called by Erichsen in Trondheim, with contributions from twelve eminent practitioners in the field of “marine design” (Erichsen, 1979). After the initiation of the IMSDC series, the first conference followed a similar pattern to that of 1979 with eleven invited authors to present their versions of the state of the art in, essentially, ship design, which was seen as the essence of “marine systems design practice”. The term ‘marine systems’ reflected Erichsen’s particular view that the bulk of merchant shipping can be seen to be part of larger transportation systems, for bulk goods, like petroleum products, or containerised manufactured items. The conference title also reflected a wider engineering design paradigm, that of systems engineering, which was first adopted to manage large military programmes (including submarines and surface vessels) in the post Korean War NATO-Warsaw Pact conflict. A similar paradigm may shortly arise with the design practice for complex systems due to current rapid developments in Artificial Intelligence (AI) or at least Machine Learning (ML) and so it seems necessary to address the expanding scope of marine design at this point.

IMDC conferences have been a good (if not perfect) mixture of input from industry as well as from academia involved in “marine design” and with a focus on the ship design process and practice. Thus, we should take Erichsen’s “whole systems” stance as a broad measure and also go beyond classic naval architectural views of ship design. The current author introduced the distinct conference feature of State of Art (SoA) reports into the 1997 IMDC, under the IMDC chairmanship of Erichsen’s successor, the late Pratyuch Sen. The SoA reports were seen as a way of reflecting, not just rapid advances in computer aided design but also scoping the increasing diversity of “ship” types (including floating offshore structures) and many design approaches being introduced, including a realisation of the widening scope of what “ship design” should encompass. This broadening scope came from a view by the author, who having had two short (four years each) “secondments from the UK Ministry of Defence (MoD)” to academia, which included authoring a ground-breaking PhD (Andrews, 1984), while teaching at UCL, returned permanently to UCL in 2000 after a career of three decades in naval construction in the UK Ministry of Defence (MoD).

Thus, the author also presented at IMDC conferences over more than two decades several IMDC Keynote papers, including one in 2012 asking “Is Marine Design now a mature Discipline?” This issue of the emerging discipline in naval architecture of ship design was in part behind the initiation of the wider SoA Reports and specifically those on Design Methodology. Two years before that 2012 Keynote, I reviewed for the RINA Anniversary “150 Years of Ship Design”. Both perspectives drew on 35 years designing a very wide range of vessels for the British Royal Navy followed by over two decades leading research on an innovative “inside-out” approach to the design of complex vessels, which culminated in 2018 with writing a Special Edition of the RINA Transactions (Andrews, 2018a). This was uniquely commended by the RINA Council and still provides the basis for me to argue that not only have the types of marine vessels continued to become ever more diverse, but also the practice of “ship design” has expanded well beyond traditional (apparently simple) approaches to ship synthesis, such as the ubiquitous “design spiral” that I have criticised as being simplistic and misleading.

While naval ship design might seem to be a rather specialised experience of “marine design” (especially when that includes the highly demanding and specific domain of nuclear submarine design), in terms of the types of designs undertaken, it can be seen to be highly diverse. This is because those “ship” types range across naval combatants, submarines, specialist large naval vessels, naval auxiliaries (with tanker and cargo carrier characteristics) and novel vessels, such as a royal yacht and procuring the first ocean going trimaran ship. My “naval ship” design experience also encompassed all phases of ship design “from cradle to grave”, including being the Design Authority for a large part of the Royal Navy’s surface fleet (SAOS, 2020). This range of experience is summarised in Appendix A at Table A1, where my role for each of 18 separate designs for the Royal Navy is identified and gives my view as to “what drove each design” and the “key lessons learnt from each of those design involvements”. The latter set of summary statements was produced to reinforce the message that such ship design practice is already highly diverse in scope.

I was able to undertake relatively early research in CASD (1980-84), when still practicing “ship design”, while a permanent move to academia in 2000 enabled more extensive research to be conducted into ship design methods, types of ship design and design issues, many of which have been presented at IMDC conferences over the last two decades. This research is briefly summarised, with appropriate detailed references in the major monograph on the early-stage design of complex vessels

produced as a Special Edition of IJME/RINA Transactions in October 2018 (see Sections 6.2 and 6.3 of Andrews (2018a) for example UCL projects). A further justification for the current paper focusing on the expanding scope of ship design is due to the likely impact of the advent of the specific form of Artificial Intelligence (AI), namely, Machine Learning (ML). The implications for the practice of managing the design and build of Physically Large and Complex Systems (PL&C) Systems has already been outlined for the architectural profession (Bernstein, 2022). Possible implications for the design and project management of acquiring complex vessels are addressed later in the paper, where the future practice of ship design is considered once the nature of the postulated expansion of ship design practice has been explored.

## 1.2 Lessons from IMDC State of Art Reports

Having persuaded the IMDC chair to introduce the SoA Reports, the first set of reports in the VI IMDC (Andrews et al., 1997) was clearly scene setting and of an overall reviewing nature. Consequently, the process was not revisited until the IXth IMDC (Andrews et al., 2006), and since then, there have been SoA Reports at each IMDC (Andrews et al., 2009; Andrews et al., 2012; Andrews and Erikstad, 2015; Andrews et al., 2018; Erikstad and Lagemann, 2022). The first SoA Report on Design Methodology (DM) consisted of ten separate sections in two halves: the first five could be considered generic (e.g., general design theory, systems engineering, preliminary ship design methods, safety) while the remainder covered the design of specific vessels, from passenger ships, unconventional vessels, offshore structures, to naval ships and submarines). Notably, the latter sections did not include sections on bulk carriers and container ship design, despite that being the original intent. Subsequent SoA reports covered “ship design methodology” as well as specific ship design issues that were usually on topics of particular interest to the maritime sector of the hosting country (e.g., Offshore Engineering for the USA in 2006, Arctic Design for Finland in 2018). The introductions to the 2015 and 2018 SoA reports on design methodology provide more detailed summaries of the various previous SoA reports, each of which included copious lists of key publications.

Before passing on from the IMDC SoA (DM) reports and the extensive source they provide on marine design practice and how it has expanded in scope over recent decades, it is worth recalling the nine issues that the first SoA DM report raised when presented. These were in brief: -

- *(There are)* “Different models of the *(ship)* design process;
- Models of design/design practice *(are)* too academic;
- Concept tools too often ignore context;
- Design on the *(computer)* screen needs traceability;
- Concept design *(is)* vital, noting *(the)* role of decision-making methods;
- Concept *(Phase)* in commercial ship design is too short;
- Method vs. methodology needs defining;
- *(It is wise to)* look at the Science of Design, elsewhere;
- A formal taxonomy *(would help)*, while avoiding rigid design procedures.”

This set of concerns can be contrasted with the last SoA report (Erikstad and Lagemann, 2022), which saw four “main evolutionary tracks” in marine systems design methodology: a holistic optimisation strategy; a systems engineering based approach; a set-based strategy; and configuration based design. Each of these tracks were then allocated to 34 PhDs in “marine design” completed from 2016 to 2022 in nine universities in Europe and USA. Erikstad and Lagemann’s four tracks are revisited below, as are the nine bulleted issues above, at the end of the paper, to see if they cover the extent to which it is surmised that the scope of marine design has truly expanded.

## 1.3 Is Marine Design now a Mature Design Discipline?

A paper with this title was presented by the author to the XIth IMDC (Andrews, 2012a) after thirty years of IMDC and some fifteen SoA reports. This keynote started by asking “why this question needs to be posed, both as a general issue and at this time at IMDC”, furthermore, asking “haven’t ship designers been perfectly happy designing ship for centuries?” This was addressed (through reviewing key IMDC papers and certain other selected publications) by answering the following points: -

- a. What actually is marine design?
- b. Has three decades of consideration (in the tri-annual IMDCs) established marine design as a coherent and accepted body of work and practice, vis a vis the other two naval architectural sub-disciplines (those of ship structures and ship hydrodynamics – *with their own regular international conferences*)?
- c. If ship design is a mature discipline, is there a clear route towards marine design’s future development with the assumed aim of providing “better ship designs” undertaken by “better ship designers”?

In fact, the last issue has been more recently addressed in a more satisfactorily manner, at least for naval vessels, in Andrews (2022) which followed on from the last IMDC. A summary of the 2022 discussion of “good ship design” is covered in Section 4.3.

The 2012 IMDC paper on whether marine design was now “mature” reviewed IMDC conferences, not just from the State of Art reports, but also considering several keynote papers, such as Andreasen’s (2003) vision of design methodology which he spelt out as threefold: -

- “By what methods do we design?
- What are the theories, and
- Scientific basis for this?”

Also, the 2012 IMDC paper drew attention to Nowachi’s (2009) IMDC Keynote on “Marine Design Methodology -: Roots, Results and Future Trends” from over five decades of involvement, to which it seems appropriate to return, when this paper ends by consideration of the future of ship design. The 2012 keynote also discussed several publications that had been recently produced that were seen to be highly pertinent to the already wide scope of ship design practice. Two of those were lecture texts made available to the ship design fraternity (Lamb (2004a) and Yang (2004)). Both provided extensive lists of “key references” and can still be seen to be useful in parallel with the IMDC SoA reports and their copious references. The first of these sets of lecture notes were by the editor of the two volume multi-authored SNAME book “Ship Design and Construction” (Lamb, 2003, 2004b), which also addresses some fundamental design issues, while Yang’s presentation gives a historic timeline (reproduced in Andrews (2012a) IMDC keynote at Figure 5) of “Design Theory” on the “practical design of ships”. This starts with Baker (dated 1942) and ends at 1995, which now poses the question as to whether we need an up-date. Finally, mention should be made of the 26 “models of the Ship Design Process” collected in the X IMDC SoA DM Report (Andrews et al., 2009).

#### **1.4 What can be learnt from “150 Years of Ship Design”**

The above title refers to a RINA Transactions paper (Andrews, 2010a), which (as part of RINA’s 150th anniversary) reviewed 150 years of ship design published in the longest series of naval architectural articles. This review pointed out that there had been immense changes in ship design in that period. This was ably reinforced by the companion paper by Buxton (2011) entitled “Enabling Technology and the Naval Architect 1860-2010”. Notably papers in the first 100 years of that review were seen to be largely descriptive of the many technological advances of the day, however there was seen to be a distinct broadening of considerations of ship design in more recent years. Thus, in the latter part of that 2010 review it was seen as sensible to draw a distinction between the earlier and more recent papers on ship design – not least due to the radical change in ship design practice arising from the advent of electronic computers. Six specific categories were thus adopted to review the progress of ship design in the last five decades (up to 2010): -

- i. General design reviews, where developments across a range of ship types were undertaken, such as naval reviews (e.g., Purvis 1974) to the evolution of the modern cruise ship (e.g., Payne 1990, 1998);
- ii. Specific merchant ship designs, with probably the most notable being Meek’s series (1964, 1969, 1970, 1972) outlining, through four series of designs, the epoch-making transition from his “ultimate cargo liner” to the modern container ship;
- iii. Specific naval designs ranging from the first GRP MineCounterMeasures Vessels (Harris, 1980) to submarines (Wrobel, 1985), new aircraft carriers (Honnor & Andrews, 1982) and the Danish Fishery Protection Vessel (Watson & Fritis, 1992);
- iv. Novel ship types, showing the explosion in types of marine vehicles from LNG vessels (MacGregor et al., 2006) to a wide range of unconventional hull forms (e.g., Semi-Submersible Drill ships (Winters et al., 2001));
- v. Specific design issues, ranging from economics (e.g., Goss, 1965 and Rawson, 1973) to accommodation (e.g., Cain and Hatfield, 1979 and Andrews et al., 2008) and the impact of electronics (e.g., Gates & Rusling, 1982);
- vi. Design methods and practice, which given the stance of this paper, deserves more extensive consideration here and can be seen as a direct consequence of the computer’s ubiquitous impact on ship design practice and (in recent years) the parallel need, or desire, to better understand the ship design process.

While these six categories are useful to see the expanded scope of ship designing over recent decades, in design methodological terms it is the last of these that is now considered. The early consideration of CASD was noticeable for considerable discussion from the RINA membership of each development. From 1977 (almost commensurate with IMDC’s origins), papers on ship design methods and design approaches were in the RINA Transactions: notable on the merchant ship side was Watson and Gilfillan’s (1977) “Some Ship Design Methods” to be seen in contrast with both Canadian and British naval originated papers, including the author’s early ‘configurationally/inside-out’ synthesis proposals (Andrews, 1981, 1986, 2003a). There were also

papers on thematic design, such as Brown's (1993) "History as a Design Tool" and Woods' (2008) yacht design paper. Also worth mentioning are the seminal papers by van Griethuysen (1992, 1994), on "monohull warship geometry" and the most detailed presentation of the early-stage design of a specific naval combatant option, using the UCL Design Building Block (DBB) approach (Andrews and Pawling, 2008), which also provided an extensive bibliography of preliminary ship design methods. The final group of papers on the practice of ship design cover the years 1993 through to 2009 and are mainly on naval ship design practice internationally but also includes one on maritime rescue craft (UK RNLI paper: Cripps et al., 2005).

The brief outline above, with a few selected examples from the fuller listing in the 2012 paper, is seen as further justifying the immense scope to be encompassed by any consideration of the nature of marine design as currently practiced and, by implication, the difficulty in arriving at any clear understanding of marine design methodological assessments. It needs to be said there are other summary articles that also provide similar reviews of ship design to that in the 2010 RINA review, such as Benford (1993) (see also TransSNAME 1993 Vol.101 for various Centenary papers, not just on ship design) and Nowachi's (2010) paper in a general CAD publication. However, as the rest of this current exposition suggests, there is no reason why common themes should not be identified, if we are to look forward to future needs and developments in our discipline, as suggested by the third of the issues identified in Section 1.3.

## 1.5 Initial conclusions on the expanding scope of ship design practice

Even before the main disposition in the rest of this keynote, it is possible to discern the degree to which ship design methods and practice have already expanded greatly from the traditional design approaches used by shipping companies (and then shipyards), for merchant shipping, and by navies and naval yards for warships, even prior to the immense changes in very recent decades. However, there still seem to be some constants in the maritime sector, that may or may not finally change. I have in mind the fact (aside from some very few radical designs touch upon in the fourth category in the previous sub-section) that the following are still relevant: -

- i. The implications in not resorting to full-scale prototypes, unlike automobiles and aircraft design and manufacture, though some might argue that the advent of the Digital Twin facility means we now have virtual prototyping?
- ii. The lack of investment in ship design, when compared to the development of naval combat systems and even general ship equipment (especially for recent main machinery developments driven by carbon reduction pressures);
- iii. Both of the above points can be seen to be consequences of ship design being characterised by risk adverse shipbuilders, who undertake the bulk of ship design, if this is to be judged (perhaps questionably?) by the extent of engineering construction resources deployed. This applies across the ship design domain and has been made worse in the naval sector by the adoption of Prime Contractorship (Andrews, 2018b). While there has been some signs, such as the adoption of alliances (as for the UK Queen Elisabeth Class aircraft carriers (Coles, 2007)), it is the case the merchant shipping sector has not adopted the Cost Reduction in the New Era (CRINE) strategy (Cox and Newland, 2000), that the UK Offshore Industry introduced over two decades ago, to reduce cost risk margins being accumulated down the sub-contracting ladder, which had led to such projects becoming unaffordable.

## 1.6 Outline of the rest of paper

This consists of five main sections, each divided into several sub-sections: -

- Diversity of ship design and impact of computers and CAD;
- Trying to understand ship design and the ship design process;
- Seeing the objectives in ship design as holistic;
- The future impact of AI on design;
- Conclusions – four main topics with two appendices.

# 2. DIVERSITY OF SHIP DESIGN AND IMPACT OF COMPUTERS AND CAD

## 2.1 Types of "ship" roles

One reason why ship design has continued to increase in scope is the ever-expanding types of "ships" (or better marine vehicles/vessels/structures). As ever we are presented with a typological challenge. Erichsen (1998) talked of marine systems design, and this was right in so far that all marine entities (ships) are part of some larger marine system (such as bulk cargo transportation or naval fleets). But when it comes to designing, our focus (hopefully with a growing awareness beyond – because that is part of the expansion in the scope of ship design) is largely on the 'ship'. It is clearly a floating vessel (and not

a platform – see argument in Andrews (2022)) and could be a (mobile) vehicle from a systems perspective, ‘though hardly to be seen as similar to much smaller land and air supported vehicles. The latter two types of vehicles have comparatively limited endurance and sustainability, while offshore structures have limited mobility, but they do float and so are not civil engineered fixed structures, even if “planted in an inhospitable seaway”.

“Ships” are often divided up into consideration on the basis of their owners’ motivation for such a large investment in money and human resources. Thus, bulk carriers, container carriers, passenger carriers (blurred by the difference between essentially acquired for entertainment or ferrying) are about delivering “a cargo” ocean wide through ports, while other ships (including the highly diverse set of very expensive naval vessels (see Table A1)) are designed to provide a service “at sea”. That “service” is often motivated by a need to deal readily with unpredictable events, be those supporting offshore floating/fixed facilities or the extremes of disasters ashore/policing at sea/outright warfare. Thus, in simple terms there are ships which are designed to be part of a larger transportation system and those (often more highly diverse and without clear measures of merit to guide design choices) which are essentially service vessels, where the design problem could be said to be more “wicked” (see Section 3.3).

This very wide range of “roles” has expanded over recent decades to deal with new markets and needs, by largely newly emerging national and commercial imperatives. It is likely with growing world trade, challenges of environmental change and political upheavals, that further discrete “ship types” will emerge. Not least, ship design is driven by the current search to mitigate the effects of carbon (and other environmental impacts), while there remains the general motivation (with the somewhat bizarre exception of mega yacht owners) to maximise the capability (however that is defined – see Section 4) for the expenditure able to be provided in order to acquire and operate new vessels.

## 2.2 Types of “ship” forms

Having said there are many roles that ships undertake, which perhaps justifies the need for a better understanding of ship design, there is an aspect of ship design, which can be said to add to the complexity of the ship designer’s challenge. It can be argued that few other designers of complex systems seem to have, alongside general engineering design demands, the level of choice that the ship designer has in the form of their mobile floating structure. It needed an engineering design theorist, with no marine design background, to reveal this explicitly at the second IMSDC. The late Stuart Pugh, author of many publications on “Total Design” (Pugh, 1996), presented a paper entitled “Systematic Design Procedures and their Application in the Marine Field” (Pugh, 1985), which is still worth reading, however I particularly want to quote his view that for some industries “true conceptual design in totality is no longer necessary”. Such designs are what Pugh called conceptually “static” and this applies to the design of automobiles and aircraft but, much to Pugh admitted surprise, this is not the case for ships.

Why this investigation of the “dynamic choice” of form is not done as a matter of course in most ship design is worth debating and in my seminal monograph of 2018 (Andrews, 2018a) I strongly suggest the Concept Phase for complex vessels should, as a matter of course, explore the solution space and do so much more widely than is usually the practice. It should also, in so doing, recognise that different conceptual options require different approaches to obtaining the first balanced “ship” concepts. Thus, clearly there is no single ship design process, if we are talking of synthesising a ship solution that may be subsequently developed. This is discussed further in the next sub-sections.

## 2.3 Types of “ship design” practice

Depending on who wants/funds a new “ship” and who undertakes the design process and whether they are involved throughout the subsequent ship design process, including the build/assembly of the completed vessel and maybe even through in-service to disposal, it seems clear that ship design practice varies greatly. Furthermore, the appropriate ship design practice in each new ship acquisition is fundamentally dependent on the intent behind the acquisition process for each design considered.

In the IX IMDC State of Art Report (Andrews et al., 2006), of the 26 models of the ship design process already mentioned, there were six versions of the Design Spiral. When it comes to most textbooks on naval architecture dealing with the initial design of a new ship, they resort to the “Design Spiral”, as do many designers writing of ship design. This is in a way odd in that its originator, Harvey Evans, was an American ship structural academic and presented, in what he edited as a text launching the modern (probabilistic) approach to ship structural design (Evans, 1975a), a figure, which is not of the ship design process but a ship structural design process, which he showed as a spiral. Evans had already produced a wider ship design spiral seeing “structural design itself is but a part of a larger whole made up of spirals within spirals” (Evans, 1975b). So, the structural spiral is just one of many? That this was taken up by designers of whole ships and applied as a single spiral to not just initial ship design but often the whole ship design process through to build, without much obvious debate, seems a little odd to this author (see Pawling, et al., 2016) and to other actual design practitioners, given actual ship design is nothing like that.

The attraction of the Ship Design Spiral seemed to be that a spiral shows the observed iterative steps undertaken, apparently in a sequential manner, in order to size a new design option through balancing weight and buoyancy, powering and resistance, and, probably, just initial intact stability. Thus, the spiral implied a fixed sequence, one that at best was strictly only applicable to certain conventional monohulls, took no account of any external activities, including inputs (or even decisions) from various stakeholders (including sub system designers), and proceeded in a fixed sequential manner without any decisions or changes to the proscribed sequence. All of which is clearly unrepresentative of real ship design practice – certainly at the more sophisticated end of the spectrum of “ship design”. This highly simplistic view of ship design will be compared with both the author’s decision-based strategic process and a more holistic human centred process originating from the author’s more philosophically based vision of ship design (i.e., Requirement Elucidation driven and “inside-out” focused (Andrews, 2018a)).

## 2.4 The Impact of computers on designing “ships”

It was an eminent Dutch naval architectural academic Gallin (1973) who quite early on said “ship design without computers is no longer conceivable”. I take it that he was referring to the fact that most engineering analysis, which I, like most engineers of that ilk in my earliest “calculating posts” (see Table A1), learnt to do engineering analysis using mechanical calculators. However, this century old practice rapidly transitioned when the author acquired the UK MoD’s first hand-held “pocket calculator” (using Reversed Polish notation). This enabled me to carry out the necessary calculations on site while conducting the Trim and Inclined Experiments on submarines coming out of major refits, an evolution that almost rebuilt each vessel’s internal outfit. Just a few years later, we were using large “main frame” computers to undertake finite element analysis (FEA) of whole ship structures (Honnor and Andrews, 1982), while still hampered by the lack of pre-processors and post-processors to facilitate the management of what then seemed to be a vast amount of data. Clearly, engineering analysis has come on by leaps and bounds and has fundamentally changed how we do the analytical side of engineering design.

One issue concerning modern presentation of results of what can seem to be “black box” analyses, is the apparent plausibility of superb results presentations, that leaves the designer with the need to understand the veracity of their modelling of reality. Furthermore, there is the question as to whether the specific sophisticated analysis undertaken is appropriate to the investigation of that design for the likely environmental behaviour, to which the overall ship system will be subjected when in service. When it comes to the specifics of, say, designing a hull form and checking that form is right for the likely response of the whole system (rather than just specific strength concerns addressed by (say) FEA) we can, for example, now impose the likely statical stability response at the press of a keyboard button. While the geometry of the underwater form is now easily modelled, the assumption (until quite late in a design) as to where the mass centroid of the complete vessel lies (particularly vertically), remains a “guess” by the human designer, a typical example of ship design uncertainty.

## 2.5 The impact of computer-aided ship design on “ship design”

I have observed through my career, as firstly a designer of naval vessels (see Table A1) and latterly as an academic engineering researcher and design philosopher, that the advent of computer graphics, linked with the appropriate mathematics and physics applied to each design, has enabled the designer to open up the ship design process. However, this immense capability will only work to produce “better” designs if we resist the misapprehension that CAD doesn’t mean the computer does design but rather it **Aids** the designer. Thus, the naval architecturally aware designer has to provide the creative input into the design evolution of a new whole ship design and do so from a true position of understanding the ship as a whole. To do so means other players in the ship design process must accept that the ship design experienced naval architects is **the** designer, being the one who makes most of the crucial ship design decisions. Those key design decisions at a generic level have been spelt out several times through extensive appendices in the author’s key papers (Andrews, 2012b, 2018a).

Given a broad view of the development of ship design since the advent of CAD, and the increasingly ubiquitous implications of Data Driven Design (D3) (Gaspar 2018) with the further implication of using Machine Learning tools, this future needs to be debated. This D3 view was made as one of the published responses to my major exposition by on the sophistication of early-stage ship design (ESSD) (Andrews 2018a). The effect of CAD and project management techniques (such as systems engineering) on how ships are designed have not been broadly debated. A clear exception to this is in the naval ship design field where the series of papers (in SNAME Transactions and US Naval Engineers Journal) over several decades by Keane and his colleagues (Keane et al., 2009, Keane and Tibbitts, 2015, 2018) have addressed US naval ship design practice. To a degree, this has been matched by various (largely RINA) papers by the current author looking at the procurement practice for UK naval vessels (Andrews, 1993, 1994, 2016, 2018b). Both sets of publications on this topic were drawn on in a recent SNAME SMC paper (Andrews, 2022) and some of the relevant arguments are also addressed in the current exposition.

It is provisionally concluded from this opening review of the current state of ship design, that ships and their design should be seen as a highly diverse set of engineering endeavours, and furthermore that the diversity of product and process is becoming ever greater. So, are there lessons to be learnt as to how we, as ship design practitioners and researchers in pushing the

boundaries of these endeavours, might better understand what we do and thus how it can be made more resilient to cope with future challenges?

### 3. TRYING TO UNDERSTAND SHIP DESIGN AND THE SHIP DESIGN PROCESS

#### 3.1 Ship Design is part of Engineering Design which is part of wider Design Practice

Seeing marine design in a broader design context has been part of the IMDC approach since 1997, when State of Art Reports were introduced, and particularly the Design Methodology series, which has included consideration of developments in the wider design community. This was consistent with earlier IMDCs inviting theoreticians in engineering design to present their broader perspectives (see Pugh (1985), mentioned in Section 2.2, and Andreasen (2003)). Such wider design visions were also reflected in my first methodological paper (Andrews, 1981), which looked at a range of design tools and techniques as part of a “creative approach” to future ship design. Thus issues, such as design thinking (Engholm, 2020), or which see design as a creative process (Nelson and Stolterman, 2012) and design philosophy, beyond marine design, are considered worth keeping an eye on. This is not just in case some insights from designers in other challenging domains could provide insights but also that (given this paper’s theme) the likely developments in general computer aided design will have impact on our design practice.

This all comes under the umbrella of “Design Methodology”, where the use of the term methodology is not the adoption of a fancy word for a new method but “the science of method in scientific procedure” (Chambers, 1971), which means consideration of such methods at a meta-level. Given many engineering design practitioners “just want to get on with designing” and thus too readily adopt the first convenient model (e.g., the ship design spiral), there has been some questioning of this broader view of design methodology. As a view from two eminent engineering thinkers, I have previously presented Finklestein and Finklestein’s (1983) four specific rebuttals to those objecting to this intent to raise the intellectual and philosophical vision of engineering design. This I presented to IMDC 2012 (Andrews, 2012a) with my response addressing the relevance of these issues to ship design, and is reproduced as Table 1 in order to discuss it further in the light of the theme of the current paper and the major changes expected to engineering (and architectural) design practice from AI related developments.

**Table 1: Finklestein and Finklestein (1983) Justifying Design Methodology and Andrews (2012a) Comments**

	Objections to Design Methodology	Finklesteins’ Answers	Relevance to Ship Design
1.	Design is intuitive and creative any methodology stifles creativity.	Design not purely intuitive, it is amenable to understanding.	Good ship designers often intuitive but have clear approach – a Methodology.
2.	Methodology constrains the designer.	Methods are sets of rules and alter the context.	Rules are used but awareness is important.
3.	All methodologies have inherent value systems.	Value systems are inherent the important thing is to be aware (of their influence).	Value systems lead to different design solutions by different designers.
4.	No evidence of applicability of design methodology.	There is a wide number of design methods used in different fields.	Ship designers still naval architecture dominated (S <sup>4</sup> ) and need ship architecture.

Taking each point in Table 1 in turn: -

1. While a good ship designer (however that might be defined and determined - see next section) can be intuitive (probably enhanced by experience), they need to adopt a clear approach, which ought to be based on methodological awareness. This becomes harder given changes to both the constraints (see Table 2 of Andrews (2018a)) and to the practice of ship design, which is seen to be happening ever more rapidly;
2. Ship design “rules” have been used, especially when new projects have significant uncertainty. While databases are increasingly available, they also introduce dependencies on “black box” tools and on databases with likely opaqueness. Awareness by designers of such issues becomes more essential and hence it seems even more necessary to adopt my decision-making strategy, which is summarised by Figure 1 at Section 3.2.
3. So as ever, value systems (inculcated by each designer’s culture and education, which need to be seen in the widest sense, not just in university degrees obtained) mean there is a distinct “style” (which is discussed in the next item) implicit in each design solution, or, at a minimum, the (unquestioned?) adoption of a default style and practice.

4. Currently ship designers approaches to a new ship design are, for very good historic reasons (i.e., both of safety and a designer's limits to understanding), still dominated by the traditional naval architectural sub-disciplines (i.e., the first four of Brown and Andrews "S<sup>5</sup>" issues - see Figure 1 in Brown and Andrews (1980)). However, a significant portion of this is becoming highly amenable to Machine Learning (see Section 5) and therefore the less ML amenable internal architectural drivers will become a greater focus for the ship designer. The growing need to put the ship internal configuration together more coherently, further justifies my advocacy of an "inside-out" approach (Andrews, 2018a). This is not just to achieve a better design synthesis but also to guide the development of the subsequent design's full definition.

Previous IMDC SoA design methodology reports have reported on what seems key wider design discussions beyond the maritime domain to provide potential insights, as the scope of ship design continues to broaden. Beyond such insights also lies the unease motivating this author regarding the understanding of the nature of ship design by the broader stakeholders (Andrews, 2022). That is to say that few of the other players in the ship design process seem to comprehend the unique nature of ship design. In part this may be due to the vast bulk of ship design (especially in the commercial field of transportation vessels – see the distinction made in Section 2.1) just following a basic evolutionary or even a "type ship" based approach. However, it could be argued that not just "service vessels" but ships in general will have to be designed in a more questioning and responsive manner to cope with the likely complexity of the future "market" and design environment (see also Section 4.3).

Thus, further design methodologic insights of a philosophical stance will arise beyond those brought to recent IMDC DM presentations, such as by Love (2000) (see Andrews et al., (2006) for discussion) and Nelson and Stolterman (2012) and even critiques of questionable views, such as those due to the philosopher Parsons (2016), who in his "philosophy of design" excludes engineering design entirely from consideration. Both of the last contrasting texts were reviewed in the IMDC 2018 DM report (Andrews and Erikstad, 2018) as it was considered discussing such different views serves to counter narrow understandings of design as well as to where ship design sits, both in wider engineering design practice (Andrews, 2010b) and with regard to similar design fields, such as architecture. This is not just due to the need to look to the human factors' component in ship designs and the nature of the ship design process, especially now AI developments are "around the corner", but also because the architecture of ships has parallels with (and clear distinctions from) the architectural design of "bespoke" buildings. Finally, it is worth mentioning, alongside the quantum physicist, Rovelli's (2018) defence of thinking philosophically (see Andrews 2022), an eminent design engineer, Ove Arup. Arup, interestingly went from studying philosophy to becoming the greatest structural engineer of the late 20<sup>th</sup> Century, in complete contrast to Ludwig Wittgenstein's opposite journey (Sterrett, 2006)), thus Arup wrote strongly about his philosophy of (engineering) design (Arup et al., 2012) which he saw as holistic.

### 3.2 Ship design issues

In their excellent IMDC 2022 Design Methodology State of Art report, Erikstad and Lagemann considered there to be four "evolutionary tracks" typifying strategic approaches to characterise the "high level plan(s)" that are adopted to organise the ship design process. Despite also criticising the ship design spiral's limitations (as in Section 2.3 above) they see it as the origin of the four tracks: model-based systems engineering; set-based strategy; configuration-based approach; and an optimisation strategy. One or more of these tracts were used by them to identify the design strategy used by each of 34 PhDs produced in 2016 to 2022 from the 10 universities, which can be said to be the centres of academic research in "marine systems design".

As the originator (Andrews, 1981, 1984) of the "configuration based" (or inside-out/architectural) approach to ship synthesis, I would question whether these four "tracks" are all comparable as approaches to ship design or even strategic in the same sense. The difficulty as I see it is that (as Erikstad and Lagemann acknowledge) there cannot be a "one-size-fits-all" model of ship design (Andrews, 2018a) and the four "tracks" together don't necessarily address the same level of ship design process. Rather than the configuration-based approach being "strategic", I see it as a more sophisticated approach to ship synthesis (than just a simple numeric balance sometimes called "point-based design" (Singer et al., 2009)) that can be chosen instead of a purely numeric (weight and space balance) or even a fixed sequential one (as implied in the design spiral). This is particularly appropriate to "complex and novel mono and multihull forms" (including naval submarines and configuration driven surface vessels), especially where the internal configuration is complex and actually drives the sizing of the vessel (see Sections 6.1 and 8.1 to 8.4 of Andrews (2018a)).

Is also worth, when considering possible ship design "tracks", comparing both Andrews seven types of ship design for increasing design novelty (Andrews, (2018a) Table 3 and Section 5) with Papanikolaou's (1997) four types of "fundamental initial ship sizing methods" or ship synthesis: -

- The parent ship "by interpolation but un-innovative" i.e., "type ship";

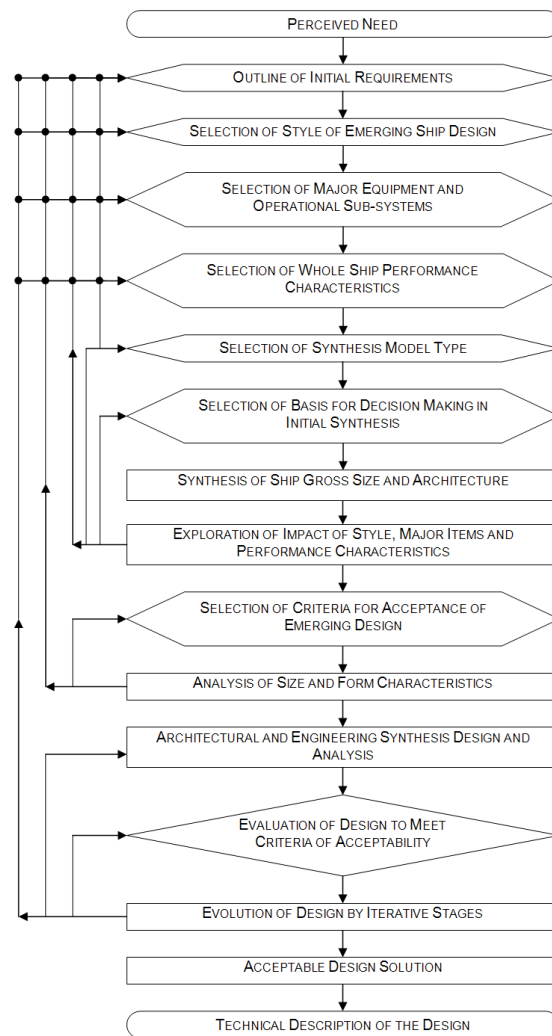

- Regression data “averaging empirical values for specific ship types” i.e., akin to design lanes and “evolutionary design”;
- Density approach “empirical coefficients – “crude” formulae for payload fraction, vessel density and weight coefficients” i.e., akin to a numeric synthesis (item 4 of Andrews (2018a) Table 3) built into student design exercises and many spread sheet approaches (Hyde and Andrews, 1992);
- Parametric variation “first principles “versatile” CASD algorithms for innovative designs”.

However, I would argue that for true innovative design outcomes, just varying hullform coefficients and dimension parameters (even with CASD driven algorithms) without being combined with an inside-out (DBB) approach (Item 5 of Table 5 in Andrews (2018a)) results in a configuration, constrained by possibly inappropriate choices and, even, by algorithms (invisible to the CASD user), that is hard to layout and hard to work up to meet modern multi-dimensional design aims and constraints.

The strategic track appropriate to such “configuration-based synthesis” can draw on system-based, or optimisation techniques and even set-based design process strategies. However, I prefer a higher-level strategic approach to (complex) ship design, by which I mean the concept designer should follow a clear decision-making strategy, that is knowingly making significant choices about each of several design options, rather than all too often “just doing what we did last time”. I have simplified this strategic decision-making process for a single design option – in a wider solution space (see Figure 4 of Andrews (2018a), with each step spelt out in that paper’s Appendix A and reproduced here as Figure 1). A version, appropriate to tackling multiple design options, using the decision-making overview/strategy is given by the “rich picture” representation (with, in that case, showing just four concept options) by Andrews and Andrews (2021), which was reproduced as Figure 13 at the end of the 2022 DM SoA Report (Erikstad and Lagemann, 2022) and also is here as Figure 2, presented at the end of Section 4.

There could be said to be related ship design issues associated with one other of Erikstad and Lagemann (2022) design methodological “strategic tracks” – that which comes under the umbrella of “optimisation”. While this can be seen as a design strategy appropriate to the marine sector, as it is for example the basis for Papanikalou (2022) EU HOLISHIP project, optimisation has also proved attractive at a ship sub-system design level, particularly applied to structural weight minimisation. To me, the latter is seen as a common error often used in much of engineering analysis, where optimisation poses as a design approach, thereby exhibiting the flaw that “we have a good technique” (meaning highly mathematically amenable) “so let’s use it here”. This is too often done and called “optimisation” or an optimised solution, when at best (in whole ship terms – or even more so regarding a whole maritime transportation system) it is minimising a sub-system (say, steel weight). As such it is a classic version of sub-optimisation of the intent of the ship or worse the fleet or wider business system.

The argument for optimisation can have even worst implications if applied to designing service vessels, where both the wider system is likely to be ill-defined and, often, the ship’s purpose is to deal with the unexpected (e.g., Offshore Support Vessels (OSVs) or naval vessels – see the discussion on what is a “good (ship) design” in Andrews (2022) and summarised in Section 4.3 below, where both Brown’s (2000) analysis of the performance of the British Navy ship designs in World War II is covered and the quite different approach to designing OSVs by Ulstein and Brett (2015). In fact, these two cases can both be seen to be facing up to the subtleties that most optimisation approaches don’t properly address. I think it would be of concern if AI/ML enhanced ship design was to go down a “black box optimisation” path rather than be used to help address the key decisions flagged up by Figure 4 and the associated exposition in Andrews (2018a), which Figure 1 summarises.

**Figure 1: A Representation of the Overall Design Process for PL&C Systems Emphasising Key Decisions (see Andrews (2018a) including its Appendix A that describes each step, in detail)**

### 3.3 Ship Design is Decision-making

Although the characteristic that is seen to typify ship design – that of making major or key decision(s) has already been highlighted (and emphasised in my key publications, including IMDC design methodology SoA reports) this section specifically addresses this. This is because this was seen as the key message of the 2018 Special Edition (Andrews 2018a), where the heart of the message of that extensive publication is at its Section 3. This section, which was entitled “The fact that the concept phase is unlike the rest of design”, can be summarised: -

1. There are many views of early stage/concept phase ship design: This suggests that each study is different and searching for a set approach (even for different options of the same concept) in a concept process is questionable?
2. For the design of physically large and complex (PL&C) systems the design practice of wider engineering and other sophisticated design fields (like architecture) provide insights but also raise distinct issues of their own.
3. The concept phase is different to the subsequent phases of design – as it is about big decision-making: While all design involves making decisions (see Ferguson’s (1992) “dozens of small decisions and hundreds of tiny one’s”), those, often made by default or without question, in the Concept Phase are almost always the most important and hard to go back on beyond that phase.
4. Different (ship) design processes are distinguished by the nature of each potential option’s novelty as shown by the table of increasing novelty (Andrews (2018a) Table 3) where each type is spelt out in that paper’s Section 5.
5. The motivation for the concept phase is to undertake Requirement Elucidation (because of the nature of the design issue is that it is a “wicked problem” (see Rittel & Webber (1973) and full comparison of this urban design term with ship design practice is in Appendix B of Andrews (2018a). Again, it is necessary here to point out the term “wicked”

does not mean such design is complex, but rather the “wickedness” lies in determining what is actually the objective or set of balanced objectives that the new design is intended to meet through a Requirements Elucidation activity.

6. Why the concept phase (particularly for complex vessels) has a different design motivation/objective to all subsequent phases, which are focused on working up a chosen and initially balanced ship design to construct, assemble, set to work, operate, maintain, and to be disposed. So, the concept phase does not have the same design focus but rather a meta-design stance, that leads post-concept to what many seem to see (falsely) as “design proper” i.e., engineering analysis of the progressively worked up solution and build description.

The above list, apart from reinforcing the 2018 paper’s assertion of the sophistication of ESSD for (certainly) complex vessels, also should have demonstrated that the design spiral is a simplistic and inaccurate summary of such sophistication and is no more than a reminder (sort of) of the iterative nature of much of design, which is used to achieve and maintain ship design balance. But, with the expanding scope of design tools and methods, not to mention CASD’s ability (already the case before further AI advances) to inform the sophistication spelt out in the summary above, leaves both CASD developers and users with the responsibility to question those design decisions. These range from the strategic to the myriad (see Ferguson, 1992) and their potential impact on each design option being explored. The range of options covers both those being further pursued and those, perhaps, rejected with insufficient further consideration. The latter approach remains all too common a procedure, due to the pressure to “get through concept” and “get commitment” to work up the (crudely in design exploration terms) chosen concept design, which is then taken into feasibility and subsequent detailed design and build.

The author, in several of the examples of his “real” (as opposed academic) design projects (see Table A1 for top level summaries of each project’s distinct design drivers, constraints and outcomes), was forced to revisit the chosen and developing concept-based design, not just in the subsequent feasibility phase but very late in the contractual phase or even in detailed design. Sometimes this was due to a design “flaw” emerging, but more often it was due to “the need to reduce initial build cost” (below that best costed in concept design) or to cases of late major changes that the “end customer” declared were “more important to incorporate than keeping the ship (usually the first of class, sometimes seen as a sort of prototype) to the contracted programme and cost”. This might not often occur outside the very resource intense and politically charged (meaning politics in both senses) naval “ship” procurement environment, but I would hazard that when this does occur elsewhere this is due to commercial pressures to proceed to build, despite it often being obvious that a “better” design could have been worked up with emerging hindsight?

I have already criticised use of the design spiral and, given the theme of this paper that the scope of the ship design process is ever expanding, this critique also relates to an all-too-common view that design is merely “working up the specification”. To some extent this is the approach in architecture and civil engineering for complex “one-offs” – once an architect’s concept has been selected (after, say, an architectural competition). Of course, the question is “who writes the spec?”. I would argue much that is covered in the outline of a sophisticated concept phase in the six points in the first paragraph of this sub-section (summarising Section 3 of Andrews (2018a)) needs to be well addressed and should underpin any coherent specification. This would still be the case even if the decision is to select an “as previous/type ship” option, if that has been coherently arrived at through proper Requirements Elucidation (Andrews, 2011).

Certainly, any properly evolved concept phase should follow the process undertaken for most service type vessels and, I hazard to guess, that in the uncertain future for the design environment in which many more commercial ships may emerge, that their acquisition is likely to be more exposed to such decision-making implied by my six points above. I would contrast the exposition in Andrews (2018a) to that of, say, Watson’s (1998) detailed and informative “practical ship design” text. Watson’s exposition of commencing ship design with a detailed specification and then working up a clear (specification detailed) concept, is contrasted with commencing much earlier in the design process with a true *ab initio* ship design, as called for and outlined in Andrews (2018a). So, the former will more likely end up with an incoherent concept than one following Andrews (2018a) outline. This is discussed further in the next main section addressing the changing nature of the objectives in ship design practice.

### 3.4 The Ship Design Process is a human endeavour

As the design tools and data driven design (D3) becomes ever more capable, what remains then of the role of the human designer? This begs the question that we can define a measure of design system capability, when for many designs we cannot define an adequate measure of performance in comparing each design solution, particularly through its life in an uncertain future. If we believe that designing a PL&C system, such as a complex vessel, remains a human driven process then how do we ensure that control and decision making is not subsumed by ML/AI capabilities that are likely to come on stream, as is considered in Section 5?

It is a fundamental belief that a properly sophisticated approach to ship design (especially in ESSD) for complex vessels, requires full human engagement, such that using CAD systems as assistance to the designer, can be followed through despite more advanced methods increasingly drawing on the data mining and analysis of what is called Artificial Intelligence. The description of the ship design process I favour is one that is a series of high-level decisions addressing the basis behind that design process with as wide a sense of the full practice being undertaken. This must cover exploring widely, not just the solution space but questioning the sequence of design investigations and the basis for design decision making (see Figure 1). It must also question, or at least acknowledge, that any design approach is biased by the design education and experience of the ship design team, the methods, tools and data they choose (or are constrained to use) to adopt on each design study, or possibly each individual design option, they select to populate the solution space. This selection should be motivated by being part of a Requirements Elucidation (RE) philosophy (Andrews, 2003b, 2011) and should lead to insights into each particular design's main design driver or drivers, which then focus the subsequent design evolution.

This RE approach includes the major decision for each significant option of the style of that design leading to the appropriate design synthesis type dependant on the novelty of each option, as is spelt out in Section 5 (and Table 4) of Andrews (2018a). That this can be seen as a very human process has been humorously captured by the 'Rich Picture' by Andrews and Andrews (2021) of the naval SDP example in Figure 2. This human endeavour is further emphasised by the need for the ship design naval architect/ship design manager to lead the decision-making, that only they (or in a worst-case practice, the CASD synthesis system/creator) can holistically direct in arriving at a balanced concept design and a coherent set of requirements to take forward through the requirements elucidation dialogue. This ought to involve all the necessary stakeholders – but more likely just the ship owner or requirements owner. Relevant to this is the insight of those software engineers that based their systems approach, known as Systems Architecture (Maier, 1998), on what they perceived was the creative, balanced and integrative approach to the whole design, from initiation through to acceptance (and even in-service), by the “first systems architects”, that Maier calls naval architects (see Andrews, 2015).

The exercise of this “system architecting” to maintain the coherence of the original concept design has been seen in major defence projects as the task of that project's named individual chief engineer, acting as “the Design Authority”. (See Gates (2005) for argument for the UK Type 45 Destroyer contracted project exercising Design Authority and Betts (2006) and Andrews (2006b) arguments against that case study's viability.) This further shows the very “fuzzy” nature of the endeavour of designing and procuring such complex vessels. In reality, that endeavour is achieved by an initially small group of individuals, but for most of the design process, then undertaken by a large number of detailed designers in discrete (contracted) teams, hopefully united by the project intent. This is a social and human endeavour, with all the psychological complexities of such activities, hinted at in Figure 2 and reflected in histories, such as Hughes (1998) for four major US technological projects and Johnstone-Bryden (2018), on the origins of the UK Post-Falklands War's Amphibious Replacement Fleet. In the latter case, Johnstone-Bryden records the current author's pivotal early role in ensuring the project for the new assault ships survived its early progress against “administrative animosity”.

### 3.5 Conclusion on Ship Design & the Ship Design Process

In spelling out the nature of ship design and the process at the most complex levels it is practiced, I now argue that this also means (given the theme of this article) that the task of better understanding what a new ship design is intended to achieve and how all those involved might best be engaged, needs to be debated. Another aspect of the expanding scope of this practice is the extent of those involved, namely, intended users (i.e., sailors); owners (be that government or shipping operators); the other disciplines, beyond our focus on the whole ship designers; the wider set of stakeholders, which goes beyond the shipbuilder and a host of systems and equipment vendors to include commercial, insurance, classification and consultancy sectors and, often, wider society and if things “go wrong” both public and media involvement (see Yule & Woolner, (2008) on the Australian Collins Class Submarines).

The other immediate conclusion is that this involvement of a growing set of organisations, is changing the process. This then suggests that any consideration of ship design and the SDP must recognise the need for multiple levels and types of dialogue, especially in the crucial earliest stages in the most sensitive ship programmes. I have long argued that any such dialogues are better facilitated by architecturally based descriptions or sketches of potential design solutions. This is part of seeing the concept phase as drawing on the right set of tools, given the object in the concept phase is not doing better “classical naval architecture” (i.e., S<sup>4</sup>) but undertaking: -

- a better exploration of the solution space (see Figure 8 of Andrews (2018a));
- questioning requirement assumptions in the light of design implications;
- and (initially) searching for unknown synergies (such as a Trimaran combatant solution being better at facilitating enhanced organic aviation assets with less total ship impact than a monohulled “equivalent”).

This need for wider exploration at concept led the author to question CASD tools that “provide faster concept design” (de Winter, 2018). I said this because “faster concept design” would be at the price of coming out of the concept phase with apparent insights that appear to give solutions with “better naval architectural definition” but lacking a robust exploration of the solution space and of a demonstrated coherence between design and requirement (Andrews, 2019).

## **4. SEEING THE OBJECTIVES IN SHIP DESIGN AS HOLISTIC**

### **4.1 The Issue of Human Factors in Ship Design**

The traditional view of what is wanted in exploring the role(s)/ performance/cost of even the most complex service vessels, such as naval combatants, has emphasised the operational needs in terms of incorporating into the design equipment (e.g., weapons/sensors/command and control (for a combatant) or towing capacity/manoeuvrability (for an Offshore Support Vessel)) or providing facilities onboard (e.g., a flight deck and organic hangar (combatant) or stowage of rig supplies or spare wind turbine blades (OSV)). However, this leaves out consideration one significant aspect of the total “system of systems” (Andrews, 2022) that can be said to constitute a complex vessel, which is that of adequately integrating into the ship design the personnel onboard. This is a challenge as the personnel, who work the vessel, also live on the completely constructed and mobile environment, which is something that is not replicated in the designing of onshore architecture or urban constructions.

Despite the fact that RINA, as the major international institution for the profession that leads ship design, has for several decades held specific conferences to address ‘Human Factors’ (or ergonomics) in regard to ship operations and hence ship design (RINA, 2023a), little progress seems to have been made in putting this key aspect of the “system of systems” into the design process as an integrated part of designing ships. When the contents of such regular HF conferences are inspected, one finds many papers by ergonomists, that are relevant to ship design, bemoaning the fact that their emphasis on a scientific approach to designing ships so the crew can work onboard efficiently and also live for long periods on the vessels which are effectively their homes, is poorly considered in the ship design process (Cook, 2017; Schumacher and Banks, 2019). The reasons for this, like much of how ship design has been taught to naval architects and practiced in detailed design (where ergonomic relevant issues have largely been addressed, if at all), usually in the shipyard drawing offices, lie in the origins of modern ship design and procurement practice. When ships are compared with (say) aircraft, the maritime approach has been one of “cheap and quick” initial design combined with the highly significant absence of prototypes or extensive production runs, in favour “bespoke acquisition”. This has led, since the beginning of time, to nearly all ship owners to both directly influence “their” ship’s design and any consideration of ergonomics in it. Thus that consideration has been regarded as secondary by all involved except engaged Human Factors experts and those directly concerned with the welfare of the sailors onboard.

I was asked by the UK Nautical Institute, as the professional institution for mariners, to contribute to their most recent publication entitled “Improving Ship Operational Design” (The Nautical Institute, 2015), which was said to be primarily addressed to the naval architect “to improve your design”. Thus, I spoke for the ship designer in two introductory sections: on the evolution of a ship design through to its final design (using a naval vessel as a very complex case study with high density of personnel onboard); and on the general (ship) design process, including the role of the naval architect. So, I sought to disabuse the HF experts as to why ship designs largely fail to be ergonomically designed. There are of course exceptions, particularly modern ship bridges and machinery control rooms in most ships and high intensity combat compartments (such as the Operations Room/Combat Information Center (CIC)) in naval vessels. However, the vast bulk of the spaces in a ship inboard (such as the key main passageways) and on most of the upper weather decks, where physically demanding operations are largely carried out, are not subjected to intense ergonomically driven design. This is because the scale of the product, the lack of a full-scale prototype (to iron out poor ergonomic design), and the manner in which shipyards win contracts (by the lowest price bid). Thus, at the level of detailed design, the focus is primarily on production aspects to meet contracted cost and time. So it must be admitted (as my section in the Nautical Institute 2015 publication tried to explain to the disappointed HF experts), detailed ergonomic concerns come low down in priority when compared to those aspects that have dominated ship design, which remain the naval architects’ primary concerns. The latter have to ensure the ship design (as agreed at the end of the concept phase/bid acceptance) remains balanced and stable, structurally intact, achieves contracted power/speed/endurance, and (maybe) is appropriately seaworthy. So traditionally, any detailed ergonomically good features are addressed by the detailed designers with appropriate inspections, but only if “an expensive” acquisition process has been contracted. Otherwise, anything more than “usual practice” is unlikely and also to be low on the naval architects’ priorities, needless to say, this has been (rightly) ill received by HF experts.

If we assume both greater levels of automation in future vessels and fewer highly trained personnel at sea, then perhaps (outside exceptions, such as the US Navy’s Zumwalt Class combatants with extensive automation to reduce ship’s complement (Feege, and Truver, 2016)) more attention ought to be paid to HF, as yet another sub-discipline for the naval architect to master. This was the question I posed at the 2018 IMDC: “Does the future ship designer need to be a human factors expert?” (Andrews,

2018c). There is some useful guidance (beyond the papers in the RINA HF conferences already mentioned) by authorities such as Sherwood-Jones (2005) and Cook (2017) as well as the contributions from several authors in the Nautical Institute (2015) publication. One can even look at urban design, where terrestrial architects have long given attention (at least in the best designed buildings) to the needs of their human occupants. A comprehensive example of this was summarised in my (2018c) paper, namely Broadbent's (1988) seminal text which "places (the role of) the psychological and cultural aspects" at the centre of building design. Thus some 21 human sciences (from Anatomy to Sociology) are outlined for architects, some of which Broadbent considered provide useful information to designers. While it might be argued (as indeed I largely did in Andrews (2018c)) that there is little scope in a naval architect's current education for acquiring in-depth ergonomic skills, some might see AI as about to readily "assist" by performing much of the naval architect's traditional "engineering" computational role. This could then leave room for more creative and "human centred design" capabilities? Once more, the author's emphasis on a graphically and architecturally centred "inside-out" ship synthesis approach (Andrews, 2018a) provides the scope to foster a holistic HF consideration more readily, right from the initiation of any ship design study.

## 4.2 Broadening the set of Ship Design Objectives

Beyond the likely increased scope in ship design for HF aspects, there have already been quite a few approaches over recent decades to essentially broaden what has been traditionally seen as ship design objectives. This broadening can be seen as a wider mix of specific objectives, in terms of improving performance against cost. Defence procurement organisations in democracies, where the underlying objective can be seen to be achieving the best capability or set of performance characteristics for an acceptable impact on the defence or national budget, might be considered a basis for making procurement decisions for specific major (naval vessel) programmes. However actual practice is far from that straight-forward and is probably an explanation as to why major naval acquisitions are so politically sensitive. Thus, the placement of orders for individual vessels for a nation that has several comparable shipyards (a diminishing situation for even major naval powers) can result in the allocation of a batch of vessels between several yards for political reasons, despite usually being economically less efficient. Or a major feature in a design can be imposed to sustain a specific national industrial capability. (A clear example of this was the French Government's insistence that the CHARLES DE GAULLE aircraft carrier be fitted with two nuclear power plant to maintain that production line for the French Navy's nuclear submarine fleet. Such pragmatism, beyond the individual procurement of that vessel, also occurred when the build duration of the same vessel was deliberately stretched because the government facility, in which it was built (Brest naval yard), did not increase the workforce but "built more slowly" to keep continuity of labour force demand. This meant that individual programme's total procurement cost was greater but the "cost" to the national budget was more efficient year on year and the wider national naval shipbuilding capacity (in continuous build and constant workforce) better maintained.)

That wholistic French approach, outlined in the above paragraph, can be contrasted with somewhat parallel UK programmes in which I have been involved, where a project "silo mentality" of just considering "your project", was demanded of individual ship projects at the risk to a coherent national industrial capability. Such examples justify my view that the constraints on such sensitive national programmes need to be recognised for their potential impact on key early design decisions (see Figure 3 and Table 2 in Andrews (2018a) for further discussion on the importance of the three types of constraints on the ship design process). So, while there can be sophisticated ways of compounding a set of detailed objectives for a new design (such as multi-criteria approaches (see IMDC DM reports Andrews et al., 1997, and Andrews et al., 2006), cost effective presentations (see Hockberger's (1993) critique) and Pareto Front presentations (see Purton, 2015 and Burger and Horner, 2011)), such methods are best used to provide insights, reveal broad trends and to be seen as advisory, rather than obeyed without question when making design choices (Andrews, 2021a).

A non-naval and government driven practice, that faces up to the broadening scope of assessing the basis for judging the right mix of capabilities to achieve the best design choices for multi-role service vessels in an unpredictable market, has been produced by the research of Gaspar (2013) and the associated investigations reported by Ulstein and Brett to the 2015 IMDC. Both Gaspar's adoption of the M.I.T. Epoch Era approach and Ulstein and Brett's (2015) division of the aspects that a complex vessel design needs to address, have been proposed in preference to simplistic summing of performance metrics weighted against build or, even, predicted through life costings, which are inevitably high risk. Thus, the latter authors' three elements of ship design objectives consist : -

1. Design for Efficiency: namely, Technical (over the design's life cycle); Operational (for different missions); and Commercial (systems influencing valuation, preferences and exploitation regarding Return On Investment (ROI);
2. Design for Effectiveness: namely, Safer, Smarter, Greener;
3. Design for Efficacy: namely, Flexibility, Robustness, Agility.

In many respect one can see this more comprehensive basis for assessing a "better ship design", as comparable to the current author's separation of the purely technical (historic ship design) issues, summarised by "S<sup>4</sup>" (Brown and Andrews, 1980) from

the more holistic issues under the 5<sup>th</sup> term “Style”. (See Table 1 in Andrews (2018a) for the case of a naval combatant, Table 1 in Andrews, (2021a) for the “Style” items of a submarine and Table 1 in Andrews (2018d), comparing Style issues for a combatant with the Style breakdown for an Offshore Support Vessel, the latter being a comparable example with Ulstein and Brett’s typical shipyard products.)

Many of the “qualities/issues/capabilities” identified in Ulstein and Brett’s (2015) Design for Efficacy also occur in Andrews (2018a, 2021a, 2018d) style tables. Thus, Flexibility in a design is a measure of being adaptable to new conditions, and hence the Style term Adaptability (see also Andrews, 2001) is comparable – in fact I prefer the latter term as from a structural design stance I don’t want excessively flexible ship structures. Robustness is identified by Ulstein and Brett as being better able to resist failure modes or to accommodate changes in operating contexts and is repeated in my Design Style listing. (A classic example of responding to experience was the case of a “highly efficient” modern structural design found wanting when in the UK-Iceland “Cod Wars” in the 1970s, very expensive British frigates were damaged by “robust” Icelandic gunboats. Thus, the next class of UK frigates were specifically structurally beefed-up around their bows.) Agility was defined for a design as being more readily modified through life, whereas the Design Style listing assumed this was part of a wider definition of Adaptability. Achieving the latter often comes down to providing adequate (weight, space, and stability) margins, beyond the design margins. The latter reflect the designers’ need to provide sufficient allowances from the start of a design through to its completion to accommodate design uncertainties, in a manner that these margins are progressively absorbed in the budgets up to completion (Gale, 1975). The margins provided for mission changes and significant equipment additions through life are often excluded, against the ship designers’ advice, in attempts to “keep the design tight”. An example of this is the UK Type 42 Destroyers discussed in the next section.

### 4.3 What is Good Design?

It could be seen, for such complex service vessels as those focused upon above, that this clear broadening of scope in current ship design practice, is just making ever more demanding that complex decision process (such as that seen strategically by the author’s main SDP representation, which has been provided in many papers - see Figure 1). Another way of looking at this is to take Ulstein and Brett’s (2015) paper’s title question and see it in terms of identifying what is a “Good” design. This I see best done through the design of naval vessels, the justification being that (as Table A1 shows) these are many and varied, both in their several sub-types (e.g., combatants; amphibious vessels and craft; submarines and auxiliaries and even a royal yacht) and their different ship configurations, from Trimarans to nominally “commercial/utility” styled warships.

One way to investigate the nature of good design is to draw comparisons between broadly similar completed ships produced in a similar timescale. This was done by Brown and Andrews (1980) for a set of British warships produced over the last century. These five pairs of design comparisons were each of a “first-rate” design compared to one deliberately “second-rate”, in terms of comparable capability, the apparent logic being that more cheaper hulls could then be afforded. In every comparison the (relatively) marginal extra procurement cost for the “first-rate” was found to be better value for money, both in added performance and in longevity of service, the latter being seen as a measure of successful design. Specific design comparisons have been discussed in earlier papers (Andrews, 2022 and 2017b) thus the UK Type 42 (Air Defence) Destroyers have been compared to the “first-rate” Type 22 (Anti-Submarine) Frigates produced shortly after. The T42 was a tightly packed design to reduce procurement build cost, but this meant necessary up-grades through life of that class of ship became a very expensive exercise, leaving the ships’ overall performance significantly degraded. In contrast the T22s, having been designed with decent design and future up-grade margins, which initially led to accusations by operators that they were inadequately “armed”, were both more easily maintained through life and the design easily “stretched” twice to produce very successful further batches of the class. This suggests that if a more holistic approach to design choices had been adopted the British Navy might have lessened the shrinkage of its fleet, even before the end of the Cold War and the subsequent (premature) taking of a “peace-dividend”. The second example is of the UK and US comparable submarine designs, which revealed an interesting holistic insight into submarine design. Thus, the case of the UK SWIFTSURE Class when compared with the US THRESHER/LOS ANGELES Classes, as is debated in Andrews (2017b), where it was questioned as to whether the latter seemed to have been “sub-optimised” for high top speed rather than the more resilient and noise reduction configured SWIFTSURES and their second batch TRAFALGAR Class?

Considering the good naval vessels design debate above, alongside the offshore support vessels that were the focus of Ulstein and Brett (2015), then the clearest naval ship design analysis was by the naval ship designer and technical historian, David Brown (2000), who went back to the last extensive wartime example, that of WWII. Andrews (2022) summarises Brown’s analysis which concluded the (British) fleet’s overall design performance was “probably the best that was achievable within the UK’s marine industries capability to deliver”. Brown remarks that the best design according to “some naval architects (*is the design*) that meets the (*formal*) requirement at a reasonable price” but Brown disputed that, as being far too narrow a definition. He proposed a better definition lay in that by the 1842 UK Parliamentary Committee on naval ship design which

ends: “...to endeavour to produce the best effects with given means”. Thus, the basis of what is “good design” is consistent with the “Fleet” arguments in the following sub-section and sensibly leaves the issue qualitative and reflects my belief that ship design remains a subtle and sophisticated multi-faceted and, therefore, human directed process.

#### 4.4 Properly incorporating Readiness/Sustainability/Availability

One of the measures of a good design achieved by focusing on “design style” issues (see in the last column of Table 1 of Andrews (2018a)) would be a better recognition that the process is one of designing several complex vessels, which usually consist of a class design providing a “fleet capability”. This might be for a naval force or providing support to the growing number of large-scale offshore facilities (i.e., by OSVs), and therefore to move away from a traditional “good design” approach focused on an individual ship. Rather, the measure in such cases should be directly focused on a significant number (say six hulls) of units and their total fleet availability. This focus has only recently achieved prominence in the open organs for discussing naval ship design, such as the RINA annual “Warships Conferences”. At the latest of these devoted to submarine design, Availability was headlined (RINA, 2023b).

The reason for this emphasis on availability could be said to have arisen due to the extensive press coverage in Australia and the publication by the Australian Government of several reports on the very poor operational availability of their six COLLINS Class conventional submarines (Coles, 2012). This then led to the topic for the 2023 RINA Submarine conference (RINA, 2023b), namely “Capability and Availability in Submarine Design”. I took that title and turned it into a question (Andrews, 2023) and concluded, from reviewing some four decades of papers on submarine design in such conferences, that most submarine design presentations have been on how the design of these unique vessels is different to that of the most complex surface ships. Thus Andrews (2017b) is entitled “Submarine Design is not Ship Design” and like many of those papers is on the design of both non-nuclear and nuclear-powered submarines (the latter being the most important and costly distinction in submarine capability and design), and it does so largely in terms of the design of an individual vessel. Whereas, Coles and his team in investigating for the Australian Government why their “current level of availability *..is...poor*” (both absolutely and relatively to comparable submarine fleets), provided some five main issues and 25 recommendations to achieve better fleet availability than those of comparable forces. Most of these identified improvements came down, not to the direct submarine design aspects but the wider management by three sets of participants:-

- “At a national level combining the main government responsibilities (such as funding and overall ownership authority);
- The Australian Navy and wider Defence organisation.
- The related submarine industry, especially the designer and builder (the Australian Submarine Corporation).”

Andrews (2023) saw this expanded scope of “submarine design”, which ought to focus on sustainability/availability/readiness of a whole class/fleet to achieve through life performance for the number of “available hulls” to the Fleet Commander, to be a paradigm shift (to use Kuhn’s (1962) term for scientific revolutions) in the design of such complex products. This clearly is a major expansion of the way in which design of such complex vessels is addressed, namely, by focusing on designing such vessels and seeing the capability sought from a class/fleet perspective, rather than just producing a good technical solution for a single vessel. Thus, the traditional approach has the danger of failing to give sufficient attention to through life (TL) availability of the whole enterprise. So, it is necessary to design for “support” from the start and, once again, an “inside-out” synthesis can best encourage this from the concept phase.

The above term, enterprise, was adopted in recent conference paper by Macdonald and Nicholl (2022) entitled “Nuclear Submarines – the most complex endeavour in defence” and directly addresses the Australian intent to acquire a fleet of SSNs, with the active involvement of the USA and UK. These authors argue, from their experience as senior UK MoD engineers and in subsequent leading roles in the naval acquisition industry, that the wider aspects are what make the design and acquisition and through life (TL) ownership of nuclear submarines such a demanding and unique activity. This complexity is seen to be the joint involvement of players from: industry; finance; military; societal; legal and regulatory; and political, and they highlight that “not everyone understands all this”. Looking to the nuclear submarine endeavour that the Commonwealth of Australia is commencing to embark upon, they identify three critical success factors:

- “The right mindset;
- An enterprise approach;
- Continuous investment, indefinitely.”

While not arguing with their strategic analysis, acquiring such a broader whole system understanding from those involved in submarine design also requires this national commitment. Thus, as a designer, teacher and researcher in submarine design and

bearing in mind the insights from the analysis in my 2023 paper that the key capability of Fleet availability needs greater prominence, I consider Macdonald and Nicholl's paper should also have had a greater emphasis on the unique demands required of submarine designers when designing such a demanding system of systems. Given specifically, that military submarines have to operate for extensive periods in extreme physical environments, this requires submarine designers, in addition to all that "normal" naval ship designers need to appreciate, to further understand two unique sub-specialisms regarding the physics of these large and relatively fast vehicles, that are not necessarily obvious from the wider ship S<sup>4</sup> issues (see Section 3.1 Item 4 above): -

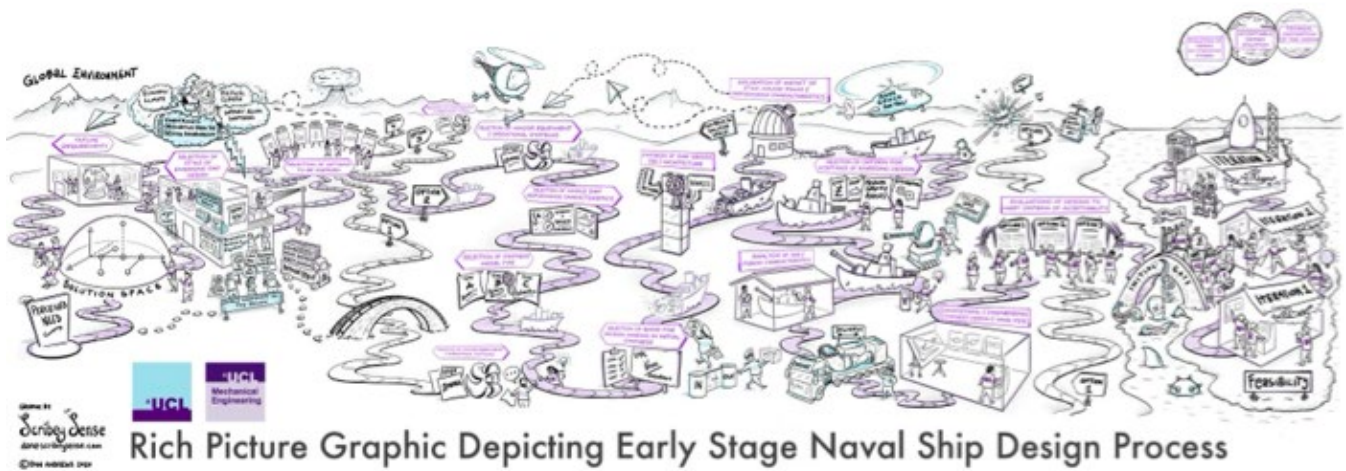

- the physics of pressure hull collapse (see Faulkner, (1983) for an overview and key references), and,
- manoeuvring at speed in three dimensions, which is more akin to modelling aircraft behaviour than that of a ship (see Chapter 8 of Burcher and Rydill (1994)).

I have taught both these subjects, at master's level, from first principles. When this extra understanding is added to general naval architectural principles and the skill of integrating the many sub-systems (from nuclear power plant through combat systems to the many fluid service systems in a densely packed and finely balanced vehicle of several thousands of tonnes (see Mukti, 2022), which is also home to some hundred or so highly trained sailors, then this truly can be seen as a pinnacle of engineering design. This specifically requires producing and sustaining an engineering cadre, with that submarine naval architectural knowledge and experience, if this "indefinite" endeavour is to be successfully pursued at a national defence level of capability. So at least for the most complex of maritime vessels, the scope of "ship design" practice now has been recognised as a further expansion of ship design endeavour. Furthermore, this expansion might become more of the norm for general ship design practice, given the growing complexity to be expected of future of maritime endeavours plus the added question of what this might mean in an AI impacted future, which is explored in the next main section.

## 4.5 Incorporating a Better Systems Awareness

Given that a systems approach was the fourth of Erikstad and Lagemann's (2022) strategic tasks used to identify recent academic research in "marine design" when considering the broadening scope of ship design (see Section 3.2), it is sensible to consider both why a systems approach has been seen to be attractive in ship design practice and how that also has become a less purely technical management "philosophy" in recent years. Erichsen's systems approach has already been referred to in a formative approach to consideration of marine design. Alongside this consideration of the maritime transport "system", in Andrews (2022) I recently challenged the ship design applicability of systems engineering (S.E.) to an American (and largely naval) audience that has a long history of considering defence procurement as systems engineering and even synonymous with "naval ship design". Specifically, Andrews (2022) questioned whether, for complex ship design, S.E. is more of a management philosophy or even just a systematic procedure for managing such acquisition, rather than actually a method of ship design.

The latter question, regarding S.E. as ship design management practice, was argued in Andrews (2022), by referring back to van Griethuysen's (2000) IMDC paper and to an even earlier systematic rebuttal of S.E. as the solution to future ship design by Rydill (1978). The specific UK MoD obsession with the false "god" of Requirements Engineering was first rebutted in the 2003 IMDC (Andrews, 2003b – see also Andrews, 2011) by proposing a more open approach, namely that of design centred "Requirement Elucidation" (item 5 of Section 3.2) and drew on support provided by a strong argument against solution-less based Requirements Engineering by the systems engineering expert John (2000). Rather than repeat the argument for requirements elucidation, which I am pleased to observe is now common thinking, at least in marine design academia, I draw attention to my IMDC 2015 strong call for "Systems Architecture" (S.A.) as a better reflection of the systems philosophy. This has recently been further broadened and "softened" by ICOSE's new initiative (RAEng, 2021) under the banner of "Elegant Design" (see Andrews (2022) summary). This return to Checkland's (1981) "soft systems" approach can be said to better reflect the needs of managing a more complex world than the very technocratic "hard systems" vision of the past and seems a more general version of Ultstein and Brett's (2015) holistic design approach for OSVs. That S.A. also includes focusing on human factors, both from designing for people to be fully accommodated through making new systems for them and, separately, recognising the human nature of the design process (see Figure 2). It can also be seen to be more consistent with concerns regarding the engineering discipline's response to the potential impact of AI developments on future engineering design practice.

**Figure 2: Rich Picture Graphic of a Typical Naval Ship Design Process (Andrews & Andrews 2021)**

Finally, from a systems stance, which I consider to be a strategic management philosophy rather than a direct ship design approach, I remarked in Andrews (2022) that the US Navy, as the largest procurer of naval vessels, had concluded that it needed to take back control of ship design and construction, as a reflection of the complexity of such activities (Winter, 2008). This then had implications for how naval ship design is to be undertaken and how the engineers who will do this are educated and career managed (see also that this is one of the example significant constraints on how ships are designed, as listed in Table 2 of Andrews (2018a): “Specialisation and training of design team”). The best summary of how the US Navy’s ship designers are addressing this is given in the pithily entitled paper: “Ready to Design a Naval Ship? - Prove It!” (Keane et al., 2009), which presents three tables summarising the skill set and career experiences seen to be required by future Ship Design Managers. That this should be appropriately read across to all ship designers to meet the challenging future for ship design, I consider irrefutable.

## 5. THE FUTURE IMPACT OF AI ON MARINE DESIGN

### 5.1 Current state of art

While AI seems to be the current preoccupation for many involved in the design of technological products, it is not that design, since the advent of electronic computation and then CAD systems, has not been, with the continued existence of Moore’s Law, trying to cope with the changes to design practice that have been “assaulting” us for over half a century. It is worth tracking recent indications that suggest what might be the issues with the Machine Learning (ML) systems already upon us and furthermore how future AI developments will possibly impact on the more creative/human capabilities used to control complex design activities.

Data driven design (D3) was the response by Gaspar (2018) to my lengthy exposition on the sophistication of ESSD (Andrews 2018a), which the current paper on the expanding scope of ship design practice has heavily drawn upon. Thus, in Gaspar’s “technical paper” he proposes a D3 approach to “extract information and knowledge”, which sounds very like current ML proposals. He connects sophistication and complexity to Rowley’s (2007) identification of: data; information; knowledge; and wisdom (DIKW) and lists a common set of processes reflecting the description of the design of complex vessels (as outlined in Andrews (2018a)). He concludes with six key topics taken from Andrews (2018a), which Gaspar considers provides the challenge to implementing a D3 future: -

- “Quantifying Style;
- Comprehensive Synthesis;
- Success Factor for Ship Design;
- Design as a Learning Process;
- Aided versus Automatic;
- Architecturally Driven Data.”

All these issues and Gaspar’s related concerns, need to be seen alongside Bernstein’s (2022) ML analysis for urban architectural practice and Ruiz et al., (2023) similar view for the maritime industry, that are compared and contrasted in the next sub-section.

Before the ML comparison between urban and naval architecture is made, mention of Gaspar's (2023) paper on the "Past, Present and Future of CASD" is seen as pertinent. It is left to readers to go through Gaspar's excellent survey of the past and present and just briefly highlight his categories summarising the points relevant to the future of CASD: -

- "Hopes – problems that should be solved soon;
- Worries – problems that we may not solve;
- Fear – problems that we do not know that exist;
- Proposal for an optimistic future – A bias for data Driven Methods".

I am happy to note Gaspar calls for Andrews (2018a), as a comprehensive outline for ESSD, "to be implemented in design offices". This goes beyond the RINA Council's already unique commendation of Andrews (2018a) Special Edition publication as "a seminal paper, which sets the benchmark ...considered to be essential reading for all naval architects and marine engineers, and not just those working in concept design." I would be delighted if this were so but six years on from the Special Edition (which includes the five eminent contributions to its discussion) being published in the RINA Transactions, I doubt it. Gaspar concludes by quoting my post-PhD paper to RINA (Andrews, 1986) with its call for "The more sophisticated design description (*from adopting the inside-out synthesis approach*) ... makes the designer consciously address, as early as possible, many of the less tangible design issues. .... to provide an open, responsive, and 'softer' approach to CAD", which ML and, hopefully, AI developments will also foster. But this will only be the case if the profession rises to this (ultimate?) challenge as a response to the ever-expanding scope of ship design practice?

## 5.2 Insights regarding Machine Learning from Architecture and Maritime Engineering

Phil Bernstein (a professor at the prestigious Yale School of Architecture and previously a Vice President at Autodesk) was asked by RIBA to write a book "about the implications of AI for the architecture profession", which he (interestingly) called "Machine Learning: Architecture in the Age of AI" (Bernstein, 2022). The book is comprehensive with many insightful diagrams summarising AI and architectural practice (seen as a business undertaken by the profession of architecture and by other stakeholders), rather than a detailed speculation on the actual design process. Thus, ML is seen as already involved in architectural practice, such that there are chapters under Part 2 (Relationships) that consider the "fuzzy parts" of architectural practice (in a manner akin to Andrews (2022) response to Keane's (2018) comments to Andrews (2018a) Special Edition's holistic but more design specific outline of ESSD). So, Bernstein covers economics and value/laws, policy and risk/professionalism/education, where he sees ML having a profound impact. Rather than try to summarise his detailed analysis, which includes comparing US and UK architectural processes and issues, I want to just pick out some pertinent comments in that book before turning to our own profession.

Bernstein opens with a professional strategy that recognises a "preponderance of intelligent machines in every dimension of design, construction and built asset operation" and then asks what then is the "proper role for humans". He quotes Daniel Susskind (2020) pointing out "computers are increasingly becoming capable of tasks as opposed to entire jobs" and then hopefully proposes "a more intelligent route" where "computers assist in the critical, but more mundane, aspects of practice: those that drive project delivery, technical precision and performative predictability" (Bernstein, 2022). All this sounds sensible and should be able to be read across to complex maritime "jobs". It also re-enforces my strong emphasis on managing the SDP through strategic decision-making (i.e., Figure 1's process which is informed by human intervention, as is indicated by cartoon like examples in Figure 2). There is much that is worth pondering in Bernstein's thoughtful and informed proposal, including an AI taxonomy to cut through a lot of popular hype and a pertinent question thrown up by the AI challenge, which he considers to be: "what is professional knowledge?" The latter question is also one to be addressed by any engineering discipline, such as those undertaking ship design and construction (through life).

Turning to a recent maritime article that also addresses the implications of ML, this is by three authors from ETSIN at the University Polytechnique of Madrid (Ruiz et al., 2023). One of the co-authors is Professor Perez Fernandez, who gave the 2023 RINA President's Lecture (Perez Fernandez, 2023) entitled "Artificial Intelligence vs. Engineering Intelligence" with some pertinent conclusions for all maritime engineers, to be read directly across to ship designers. Firstly, the ESTIN authored article usefully gives detail on some nine ML algorithms, some of which are already used in the maritime sector and their Figure 8 breaks these down into three categories regarding their use. This scheme is then applied to analysing predictions for the propulsion system of a 9500 TEU container ship, addressing: Brake Power; Propeller Diameter; and material classification. Unfortunately, this seems a little prosaic alongside Bernstein's holistic review concerning architectural practice or possible ML applications with similar broad scope to whole ship design practice. Perez Fernandez RINA lecture was more of a grand overview and concluded, while software engineers may well be an "AI threatened species", naval architects and marine engineers were far less threatened, as the nature of their tasks and responsibilities were much more diffuse and he considered "the threat of AI is overblown". The latter was justified by Perez Fernandes because he considers that AI requires the human on top and he felt AI was a sub-set of "Engineering Intelligence". More likely AI might give engineeringly creative professions

(particularly in the complex and diverse maritime sector) more time to achieve “better ship designs”? However, given a more radical response to ML by Bernstein (2022) on behalf of the holistically design focused architectural profession, Perez Fernandez view could leave the ship design fraternity exposed, if we are too relaxed?

## 6. CONCLUSIONS

### 6.1 Why Ship Design is different to so much of Engineering Design

The first conclusion on the expanding scope of ship design is that even before this paper addressed the topic, the nature of ship design, when compared to most engineering design and other forms of large-scale design, such as architecture, is different, not just in the product (ships) but also the process. Both are particular and quite diverse across the maritime domain. There are other physically and large products/systems, as outlined before (Andrews, 1998), but both the ever-changing ocean environment and the mobile, long endurance, inhabitable entities we design, challenge many aspects of engineering analysis, construction and the design process. So, there is a need to train ship designers in naval architecture, not just on the traditional fundamentals (i.e., Brown and Andrews’ (1980) “S<sup>4</sup>”) but also the 5<sup>th</sup> “S” of Style issues. Furthermore, that knowledge has expanded and, while covering the fundamentals, advanced topics (like the examples given by the third set of bullets at Section 4.4) have to be formally understood from first principles. This is so that the over-arching ship designer can both quiz the growing bands of different deep specialists and ensure their inputs are incorporated appropriately within the whole ship design context. Reference has already been made to the issue of Design Authority (see Section 3.4 - third paragraph), which for ships can only sensibly be executed by a naval architect, not a generic systems engineer or domain knowledge limited manager. Thus, it is ethically wrong for ship safety certification to be signed off by senior (unqualified) personnel, as it is the senior most naval architect in a ship project with whom realistically the buck stops on most of whole ship safety (Andrews, 2021b).

Beyond the “S<sup>4</sup>” NA issues, there is the whole ship design (with Style issues summarising much of where the ship designer leads) covered by the six items listed in Section 3.3 and the three bullets of Section 3.5. If in addition the nine issues raised by the very first IMDC SoA report and listed at Section 1.2 are revisited, almost three decades later, it can be seen that many have been responded to over that time, not least in the subsequent conferences. Not all are resolved but most have been progressed and the remaining issues are appropriate (even with ML and current AI upon us) for future IMDCs to take forward. It was interesting that in the year’s delay to the XIV IMDC at Vancouver, due to Covid-19, the International Committee rejected a virtual conference in 2021. It was not just felt that a full physical conference was nice to have but rather it was essential for the next generation of new researchers in ship design to present in person and openly discuss their ongoing research with the marine design community.

### 6.2 The Future of Ship Design Practice

Although I have both called for a clear, if creative and non-prescriptive, approach to the manner in which ship design should be undertaken and, in this paper, which has discussed the growing diversity of ship/marine design, this is now considered in the forward-looking conclusion of this wide ranging and summary review. Thus, it is considered worthwhile to also list some of the questions I have proposed over the last decade in addressing future ship design and its practice. This is done in Table 2, which poses these questions, all of which are directly the titles for a set of recent design methodological papers. I leave it to the next IMDC in June 2027 to take up any or all of these questions, where my initial response to each question posed is given in the initial publication referenced.

### 6.3 An ambitious vision of Where Ship Design may Lead

One future vision for a better and more holistic approach to ship design, based on the issues raised in this paper, would be to apply the future ship design practice called for to future “physically large and complex systems”. The obvious maritime extension is to “inner space” or subsea habitats (Divemagazine, 2024). Perhaps not so obvious, unless my architecturally based approach to early stage design synthesis is seen as applicable beyond marine vessels to other PL&C systems, is future space “ships”, where the latter word is of course “a giveaway”. In fact, the architecturally DBB SURFCON module in QinetiQ’s Paramarine SD suite (Qinetiq, 2019) has been used in UCL student projects to design both a low terrestrial orbiting “Space hotel” (Bowditch, 2011) and an interplanetary “Spaceship” (Downton, 2023). It is argued that these large vessels are like many complex marine vessels, sensibly designed from “inside out” in a similar manner, and where achieving the naval architectural balance of the DBB “Master Building Block” (Andrews, 2018a) is replaced by the demands of the physics of terrestrial orbiting or interplanetary travel, respectively. The point being this is an extension of ship design methods and practice, which is more applicable than the aeronautical design approach (e.g., Mavris et al., 1998) used for current space “craft” (i.e., small vehicles for few people for short journeys). The ship type issues of no full-scale prototypes and bespoke design on a large scale, reinforce this analogy.

To round off this look at future ship design practice, I go back to my first formal publication on ship design, which led to my 1984 PhD thesis (Andrews, 1984), and was boldly entitled “Creative Ship Design” (Andrews, 1981). I would argue that the point behind that paper is more than ever relevant, given the “threat” of AI/ML. Thus, the routine approach to much of the practice of ship design would seem to be likely to be subsumed by tools driven by ML (and then AI) and the issues identified by Bernstein (2022) for urban architecture and planning will totally alter the human-machine design relationship. What will (hopefully) be left with the human ship designer will be the “creative” aspects of designing complex entities, hence the referral back to the 1981 “Creative Ship Design” paper, which originally argued for an architectural design synthesis (the inside-out approach) and thus to expand the ship synthesis from sizing, just to achieve “naval architectural balance” (i.e.,  $S^4$ ), into the harder challenge of the wider (e.g., HF driven) design needs. This challenge has been (at best) left by ship designers until too late in most current designs, namely well after the concept phase and thus when only highly constrained options are then practicable. Underlying this early creative call was a desire to make the design of ships better recognised (by the profession, our stakeholders and wider society) as one of the most sophisticated endeavours done by designers of complex systems and for that to be done to its best, requires a creative and open mind set.

### 6.4 Author’s contribution to Expanding Ship Design Practice

I am conscious that a new reader to this paper’s exposition of many previous voicings, of its messages on ship design, may consider there is too much presented of this author’s many ship design publications. However, I consider these are best encapsulated in the 2018 major statement (Andrews, 2018a) that permeates much of the current paper. As the originator of not just the architectural approach to ship synthesis (Andrews, 1981, 1984) but a strong believer in the fascination (Andrews, 2006a) and creativity (Andrews (1981, 2003a, 2012)) in the design of “ships” (of all types – so maybe vessels or marine design is a better term?), I attach at Appendix B a summary (Table B1) of my specific main contributions to the field of ship design

methodology. This tabulation is presented as it summarises the innovations originated in a career in ship design, covering practice (Table A1), teaching and research (Table B1). As such this paper may well be my last IMDC contribution. It should, therefore, be seen as making the argument for the expanding scope likely for future ship design practice, and as such leaves a clear challenge to my current colleagues and future successors.

Given I have always considered that a good designer ought to look to those beyond their own ilk, I have attached two prescient quotes above my Introduction, which ought to be taken to heart, regardless of the future posed by ML and AI for our profession.

## ACKNOWLEDGEMENT

As already mentioned, this is likely to be the author's last major contribution to an IMDC, having been a contributor since the VI IMDC, member of the International Committee from then, initiator and lead editor for the SoA reports from 1997 to 2018 and International Chair from 2015 to 2022. So, I want to thank my past and present colleagues on the International Committee, past chairs of the Local Organising Committee of each of those nine wonderful conferences and, not least, the very many contributing authors, who efforts made each conference a success, and finally all the other attendees, who gave life to each conference and sustained we believers in the magic that is ship and marine design, in which I feel privileged to have spent my professional life, and met so many committed colleagues.

## APPENDIX A

**Table A1: A Summary of the Author's Involvement in Major UK Warship Designs as a Naval Constructor (1972-2000) (see Section 2.1 of Andrews (2018a) for further detail on most listed designs)**

UK Warship Project	Time span of Author's Involvement	Role played by Author	What Drove that design	Key lesson from design/project
SWIFTSURE SSN	1973-75	Assistant Constructor –Structural design + Cold Bent Frame Investigation	Combating Soviet SSNs – Acoustic Performance	Even the best designs can have critically unforeseen problems (e.g., Cold bent frames (Faulkner, (1983))) Building in generous margins can reap major benefits beyond that design
SSNOY (Became TRAFALGA R Class SSN)	1974-75	Assistant Constructor-Structural new design + lead calculator	Step change from SWIFTSURE Class – New sonar + new reactor	Ended up too ambitious, so replaced by very successful Batch 2 Swiftsure Class (Trafalgar Class); Could be seen as akin to USN SEAWOLF experience – but UK Changed to Batch 2 Swiftsure.
INVINCIBLE Class CVS	1975-78	Constructor (Air and Weapons integration)	Initially ASW helo carrier with provision for a few STOVL	Modern light but medium sized carrier; First all Gas Turbine propelled major warship saved 30% crew; FBNW STOVL modified while building to take new FRS Sea Harrier (author led on fit to CVS)
Type 23 Frigate	1978-80	Lead Concept Designer (TA Tug with CODLAG)	To provide GRIUK Barrier + Merlin Helicopter	Do not design to precise OA scenario (ISD 1989 – End of Cold War) Ships then became GP with gun and PDMS. Lacked margins for adaptation or enough accommodation
FORT Class AOR	1978-80	Lead Concept Designer (one stop logistics support to Type 23 in GRIUK gap)	Commodities + 4 Merlin Helicopters full Support	Became main fleet support when Cold War role collapsed. Trying to mix a warship capable AOR with RFA standards meant cost excessive.
SANDOWN Class SRMH	1978-80	Lead ship concept design	Cheaper version of Hunt MCMVs	Example where shipbuilders' competition led to real build innovation by Vosper Thornycroft Shipbuilders
Various Frigate/CV Studies	1978-80	Lead Concept Designer (series of Hilo mix studies)	Square the circle of affordability +Exportability	Need to explore options widely to provide better basis for naval decision making on future ships and ship Research & Development.
VANGUARD Class SSBN	1984-86	Head of Hydrodynamics + Structural Design	Provide national Nuclear deterrent Submarines.	Assembled “A Team” to do the design in-house with top priority to deliver fully to time, within cost, meeting national capability
LPD (Replacement ) Class	1986-90	Warship Project Manager for Replacement Amphibious Fleet	Concept studies on up lift capability ro-ro LCUs	Key Amphibious Units. Author forced to adopt Proc Strategy (build to specification by 3 industry teams) that then failed as MoD needed to lead design. Reverted to MoD led design.

UK Warship Project	Time span of Author's Involvement	Role played by Author	What Drove that design	Key lesson from design/project
ASS/LPH OCEAN	1986-90	Warship Project Manager for Replacement Amphibious Fleet	Cheap helicopter carrier Thought possible without costed studies by senior naval staff	Flawed concept by non-ship designers without concept/feasib design. Proc strategy: fixed price even non-naval standards unaffordable. Got un-survivable High Value Unit (12 Helos + 800 Marines + vehicles) not sensible (Andrews 2018b).
RFA ARGUS ATS	1986-90	WPM to “get out of shipyard” (major conversion)	Ro-ro Container ship converted to helicopter training	Example of how not to procure a warship (see Andrews (2018b)) even on an apparent Fixed Price contract. Used by senior staff to explore Hands-off, so Major cost hike.
HMRV Replacement	1988-89	WPM conduct one-year Special Design Study for Head of State	Replacement of HMRV for No.10 and Head of State	Find cost of Replacement to modern standards – electric power/reduced crew/enhanced Public Spaces/helicopter landing/modern comms & security
Wave Class AO	1990-91	Head of Concept Design	Replace existing Fleet Oilers	Staff (OPNAV equivalent) “awaiting Fleet Studies” so author produced concept design; first navy double hulled tanker. Do not need OA when in a hurry to replace fleet assets.
Future Surface Combatant - became Type 26	1990-93 and 1998-2000	Head of Concept Design then Project Director	Main ASW Escort + general combatant	Not driven by major weapon but Adaptability – which MoD system found hard to model/approve; MoD approval system built on weapon capability not TL adaptable naval presence.
FCV (became QE Class Carriers)	1991-93	Head of Concept Design	Strike carrier STOVL/ CTOL	Needed to get large carrier adaptable to STOVL or CTOL. Basis of internecine RN-RAF “warfare”. Navy finally got capability by Carrier Alliance of MoD with main shipbuilders.
CNGF (became the T45 Destroyer Class)	1991-92	Head of Concept Design as Member of Anglo-French Steering Group	Fleet AAD-PAAMS escort	Example of single weapon system (PAAMS) dominating design. But major Machinery and Accommodation needs also drove size. Collaboration (UK/FR/IT) not easy, so reverted to Type 45.
FASM (became FSSN)	1990-92	Head of Concept Design	New SSN: post-Cold War	Need to change design approach (SUBCON based on author's Building Block approach) to explore solution space widely.
RV TRITON First Trimaran Ship	1990-93 and 1998-2000	Head of Concept Design then Project Director for acquisition	2/3 <sup>rd</sup> scale Prototype Trimaran Destroyer	Needed prototype (on cheap) to explore novel hull form (with steel structural design) and “win hearts and minds” of operators – successful but through USN LCS programme.

#### List of Acronyms in Table A1 (in order of first usage in Table A1)

SSN – Nuclear powered submarine

SSNOY – OY was second class of “new” SSNs to follow the 1970s Swiftsure Class (SSNOX)

USN – United States Navy

CVS – (Aircraft) Carrier (Support) – not Fleet (Attack) carrier

ASW – Anti-Submarine Warfare

STOVL – Short Take-Off and Vertical Landing Carrier Aircraft

FBNW – For But Not With – Ship designed to receive (weapon) fit but not installed on build

FRS – Fighter, Reconnaissance and Strike – designation of the UK Sea Harrier STOVL Aircraft

TA – Towed Array – Passive Sonar Array for ASW

CODLAG – Combined Diesel Electric And Gas(Turbine) ship propulsion fit

GRIUK – Greenland, Iceland and UK Gap – Cold War ASW choke point

OA – Operational Analysis

ISD – In-Service Date – for naval vessels Acceptance into the Fleet

GP – General Purpose – Designation for combatants with all-round capabilities  
PDMS - Point Defence Missile System – last ditch AAD against missile attack  
AOR – Auxiliary Oiler Replacement – One stop fleet replenishment vessel  
SRMH – Single Role Minehunter – MCMV with single (detection) role  
MCMVs – Mine Counter Measurers Vessels – broad MCM designation  
CV – (Aircraft) Carrier  
SSBN – Ballistic Missile delivery nuclear powered submarine – Nuclear Deterrent armed  
LPD - Landing “Platform” (Dock) – Amphibious Warfare (LCU delivery) vessel and Force Command  
Ro-ro LCUs – Roll on/Roll off Landing Craft (Utility) – new LCU concept for 1980s RN LPD  
ASS/LPH – Aviation Support Ship became Landing “Platform” (Helicopters) – Amphibious Vessel  
RFA – UK Royal Fleet Auxiliary – RN ships operated by Merchant ship “company” rules  
ATS – Aviation Training Ship – RFA to train helicopter operations at sea  
AO – Auxiliary Oiler – Fleet support tankers for underway replenishment  
FCV – Future (Aircraft) Carrier  
QE Class – Queen Elisabeth Class UK Attack Carrier Class  
TL – Through Life  
CTOL – Conventional Take-Off and Landing (Aircraft operated from Carriers with catapults and arrestors)  
CNGF – Common New Generation Frigate – designation of Anglo-French 1990s AAD combatant project  
RN-RAF – UK Royal Navy and Royal Air Force  
T45 – Type 45 – designation of RN AAD Destroyer class replacing earlier Type 42  
ADD-PAAMS – Anti-Aircraft/Air Defence- Principal AA Missile System – fitted to Type 45  
UK/FR/IT – UK France and Italy combined project for AAD (PAAMS) combatants – became T45 (UK) and Horizon (FR/IT)  
FASM - Future Attack Submarine – UK replacement for current ASTUTE Class SSNs  
FSSN – Future SSN – later designation for FASM (1990s/2000s)  
SUBCON – SUBmarine CONcept - concept design tool developed by UK MoD/BMT Icons in 1990s using UCL DBB approach (BMT Icons– British Maritime Technology – Icons formerly BSRA now Aveva)

## APPENDIX B

**Table B1: Andrews Specific major contributions to Ship Design Methodology**

	Andrews’ contributions to Ship Design Methodology	Initial Reference	Subsequent verification in Ship Design
1.	Inside-out approach to ship design synthesis.	Andrews (1981)	Andrews (1984)/(1986)/(1987)
2.	DBB realisation of inside-out ship synthesis	Andrews & Dicks (1997)	Andrews (2018a), Andrews&Pawling (2003, 2008)
3.	The importance of constraints on SDP	Andrews (1981)	Andrews (2018a)
4.	The importance of Style in going from function to form	Andrews (2012b)	Andrews (2017, 2018a)
5.	Requirement Elucidation NOT Requirements Engineering is aim of the Concept Phase	Andrews (2003a)	Andrews (2011, 2022)
6.	Proposing a 3-D ship solution space	Andrews (1993)	Andrews (2012b, 2018a)
7.	Identifying that the level of Novelty requires different design approaches/methods/tools	Andrews (2012b)	Andrews (2016a, 2016b, 2018)
8.	Showing the fuzzy “half” of ship design is a human driven decision process	Andrews (2012b)	Andrews (2012, 2018a, 2018b, 2018c, 2018d, 2022, 2023), Andrews & Andrews (2021)

# The Impact of Maritime Decarbonization on Ship Design: State-of-the-Art-Report

Thomas A. McKenney<sup>1,\*</sup>

## ABSTRACT

*The maritime industry faces a critical challenge to decarbonize and meet the ambitious goal of net-zero emissions by 2050. This transition requires innovative ship design strategies to address the increasing complexity and multiplicity of technical solutions amidst dynamic regulatory, geopolitical, and market uncertainties. This paper examines the maritime decarbonization challenge's impact on ship design and decision-making under uncertainty, highlighting the necessity for collaboration between researchers and practitioners to tackle this emerging challenge. To navigate the uncertainty, stakeholders can integrate advanced design methods and decision-making processes considering the full lifecycle and fleet-level implications. This paper promotes taking a holistic approach that incorporates regulatory compliance, technological advancements, and commercial considerations, as well as a blend of methods to manage decision-making under uncertainty. Continued research in specific areas is essential to develop and refine frameworks that optimize design and operation for the industry's sustainable future.*

## KEY WORDS

Ship design; sustainability; maritime decarbonization; energy efficiency; alternative fuels

## INTRODUCTION

Sustainability has become a pressing concern in various industries, especially in maritime. The urgency stems from the ongoing climate crisis, highlighted in July 2023 at the International Maritime Organization (IMO) Marine Environmental Protection Committee (MEPC) 80 meeting where its greenhouse gas (GHG) strategy was revised, aiming for net-zero emissions by 2050, setting interim targets, and proposing measures. Further discussions at the MEPC 81 meeting in March 2024 confirmed the direction while discussing existing and mid-term measures needed to achieve the revised targets.

Maritime decarbonization is a complex challenge with no one-size-fits-all solution. Numerous alternative fuels and ship technologies, both existing and under development, complicate the landscape. Industry stakeholders also grapple with uncertainties and dynamics such as shifting regulations and geopolitical events.

The need for immediate action, coupled with numerous options and evolving conditions, requires a substantial shift in the approach of industry players, including ship designers. It is important to stay up to date on the latest maritime decarbonization developments and consider whether the maritime decarbonization challenge presents the need to think differently about how commercial ship design is conducted. This paper offers ship designers a comprehensive overview, combining industry advancements driving decarbonization and recent academic research on sustainable ship design.

Multiple industry reports are regularly updated and readily available on maritime decarbonization topics such as energy efficiency (EE) and alternative fuels as well as industry-level analysis on how the industry can achieve decarbonization by 2050 (MMMCZCS, 2022a; ABS, 2022; DNV, 2023). General decarbonization pathways are provided, and proposed scenarios can be presented to understand broad industry directions. Key stakeholders interested in this type of analysis are mainly regulators from the IMO, regions like the European Union (EU), and countries. This type of information is helpful background for ship designers and ship owners/operators but lacks specific or actionable direction.

At the same time, there is an increasing number of academic research in the areas of sustainability, decarbonization, and, most importantly, design methods, decision-making, and support (Trivyza et al., 2022; Mansouri, Lee, and Aluko, 2015). Most research on ship design is related to "complex ship design" that includes naval vessels, submarines, and specialist commercial vessels like cruise ships. Andrews (2022) describes complex ship design as a "wicked problem," where the

\* Corresponding Author: tmckenne@umich.edu

challenge is not only in the ship's inherent complexity, but in determining what is really wanted (i.e., defining the requirements). Andrews (2022) continues by identifying two types of ships: "those that are part of a wider transportation system and those that go to sea to do something." With the introduction of the maritime decarbonization challenge, ships like container ships, bulk carriers, and tankers are becoming more complex and difficult to define requirements.

With so much uncertainty and changes in how the industry operates, the energy transition presents a case for placing more emphasis on the early stages of design of even simpler ships. The decarbonization challenge also demands a broader perspective than a single vessel design to account for full life cycle impacts and fleet-level considerations affecting future regulatory compliance. This paper is intended to strengthen the collaborative bridge between research and industry by evaluating the need from industry for ship design and operational decision-support, what methods and tools already exist today, and why they are needed now more than ever to help achieve full decarbonization of the maritime industry.

This paper caters to both researchers and practitioners, providing actionable insights for their daily work. For researchers, industry developments are moving quickly, and help is needed to bring relevant use cases and ensure they are addressing the right challenges and applying their research in the most effective way possible to maximize impact. This includes clearly identifying the best applications for given methods available or under development. For practitioners, there is a need to bring ship design methods and decision-making processes into the normal way of working to best handle the inherent uncertainties and dynamics associated with the maritime decarbonization challenge.

## THE MARITIME DECARBONIZATION CHALLENGE

This paper focuses on the environmental sustainability challenge of reducing the maritime industry's GHG emissions and how this impacts ship design. In addition to maritime decarbonization, sustainability broadly covers social sustainability and governance for sustainability as well as other environmental sustainability topics such as air pollution and impacts on marine life. Ship designers should not overlook these other topics or how they relate to maritime decarbonization considerations and decisions. Some examples include:

- Reducing nitrogen oxides (NO<sub>x</sub>) emissions, which are an air pollutant, from an internal combustion engine usually requires an increase in fuel consumption, leading to increased carbon dioxide (CO<sub>2</sub>) emissions, a GHG impacting the climate.
- Black carbon is a type of particulate matter (PM), typically regarded as an air pollutant, that also can have regional short-term global warming potential.
- While ammonia as a fuel has no carbon, which can lead to low GHG emissions, its toxicity can potentially harm marine ecosystems if discharged into water.

Focusing on the maritime decarbonization challenge, projections indicate that emissions will continue to increase if we rely on current decarbonization efforts. Shipping has the least emissions intensity for freight transported, but the maritime industry's enormous scale makes it a noticeable contributor (approximately 3%) to global emissions (IMO, 2020). Moreover, maritime is a hard-to-abate sector. If maritime emissions are not reduced, the sector may be responsible for a greater share of global emissions by 2050, as other sectors decarbonize at a faster pace (e.g., power and road transport). Three segments - bulk, tanker, and container - account for around two-thirds of emissions, making them the key focus areas for future emission reduction pathways (IMO, 2020). Without additional decarbonization efforts, emissions will remain far from the Paris Agreement's 1.5-degree trajectory or science-based targets (MMMCZCS, 2021). It is crucial to act this decade to bend the curve and set the course for the 2030s and beyond.

Historically, the industry has been slow to change and has not dealt with major technological or regulatory disruptions. It remains the most cost- and emission-efficient mode of transportation, which creates limited incentives for competition with other industries. In the early 1900s, the internal combustion engine was introduced with heavy fuel oil (HFO) used for propulsion. HFO is now the dominant fuel with worldwide availability, and the two-stroke diesel engine remains the prime mover of choice for most vessels. There have been some disruptions and innovations, such as the introduction of liquefied natural gas (LNG) as a fuel and regulations including ballast water treatment and the 2020 sulfur cap. However, these have not significantly changed the industry's operations.

As shipping is globally regulated by the IMO, part of the United Nations (UN), decisions are made by consensus, which tends to result in slow decision-making. The initial IMO GHG strategy was only introduced in 2018, but ambition is now increasing. This has led to a regulatory disruption that significantly affects the industry, impacting both fuel and technology use. At the MEPC 80 meeting in July 2023, the IMO's GHG strategy was revised, aiming for net-zero emissions by 2050 and setting interim targets and proposed measures. Additionally, regional regulations, particularly from the EU, are driving significant regulatory compliance and financial risks for maritime stakeholders. Ships also have a long lifespan of 20-25 years or more in certain segments, meaning decisions made today will determine the industry's makeup in 2050.

There are at least five candidate groups for future wide-use alternative fuels, including hydrogen, ammonia, methane, methanol, and liquid biofuels such as e-diesel and bio-oils. Each group, in turn, contains different types of fuels,

distinguished depending on feedstock and fuel production processes. In addition, alternative energies include wind, electricity (energy storage), and nuclear.

Meeting the energy demands and optimizing EE onboard ships can be achieved through a diversity of methods. Every vessel has distinct performance needs dictated by its type, size, and operations. To satisfy these specific needs, there are numerous solution pathways for vessels, encompassing a variety of energy and fuel configurations, onboard technologies, initiatives for enhancing EE, and concepts for power and propulsion systems.

Key stakeholders, such as policymakers, technology developers, fuel suppliers, and ship owners/operators, must make decisions under uncertainty, including interdependencies across stakeholder groups. Uncertainty encompasses fuel/technology availability and cost, willingness to pay/finance, and policy and regulation. Dynamics result from politics, consumer behavior, disruptive innovations, and geopolitical events. The war in Ukraine is an example of an event that has significantly impacted the energy market and led to an acceleration of policy support and investment in renewables within Europe (IEA, 2022).

Vessel owners/operators must evaluate options and decide what they believe is best for their vessel. In addition to the standard newbuild vessel design, vessels can be designed to be adaptable for other fuels or retrofitted with different or new technologies throughout their lifespan. This adds another layer of decision-making complexity, especially with high uncertainty regarding the main future fuels.

In summary, the industry's decarbonization challenge is captured in three main statements:

- First, we need to act now in an industry that is not easy to change.
- Second, there are many options, most of which are not fully mature.
- And third, key stakeholders must handle uncertainty and dynamic conditions.

The need for immediate action, along with numerous options and evolving conditions, necessitates a substantial shift in the approach of industry players, including ship designers. Keeping abreast of the latest maritime decarbonization developments and their impacts on ship design is crucial.

The solutions to the decarbonization challenge are multifaceted and require development in three main areas: regulation, technical, and commercial. Psaraftis (2019) stated that the main obstacles are not technical or economic in nature but political, manifesting in regulations at global, regional, and local levels. Although the maritime industry has achieved significant EE improvements over the past decade, EE alone will not be sufficient to decarbonize (Cullinane & Yang, 2022). With EE falling short, the industry is turning to alternative fuels to bridge the remaining gap to zero. The number of publications related to alternative fuels in the maritime sector has surged since 2018, with a significant increase starting in 2020 (dos Santos et al., 2022). This heightened attention within academic research is promising and welcomed, but it must now be translated and applied within the industry.

## REGULATIONS

There are two main types of maritime decarbonization regulations impacting ship design: EE and emissions. Safety regulations associated with the introduction of new technical solutions to support maritime decarbonization should also be considered in parallel. Environmental sustainability rules and regulations affecting ship design and operation can be at the global, regional, or local levels, depending on where the vessel is intended to operate. This review will focus on global and select regional considerations, mainly related to the EU. An example of an impactful local regulation is provided; however, such local regulations should be considered on a case-by-case basis, depending on expected operations.

At the international level, the 2023 IMO Strategy for the Reduction of GHG Emissions from Ships is driving updates and the introduction of EE and emissions regulations (MMMCZCS, 2023a). The levels of ambition, on a well-to-wake (WTW) GHG emissions basis, include:

- A decline in the carbon intensity of the ship through further improvement of the EE for new ships,
- A 40% carbon intensity reduction by 2030, compared to 2008,
- The uptake of zero or near-zero GHG emission technologies, fuels, and/or energy sources to constitute at least 5%, striving for 10%, of the energy used by 2030, and
- Net-zero GHG emissions by or around 2050 (IMO, 2023).

Indicative checkpoints to reach net-zero absolute GHG emissions include striving for a 20% reduction in 2030 and aiming for a 70% reduction by 2040. Figure 1 provides an overview of the latest IMO efforts related to achieving the ambitions of the 2023 strategy. The IMO has already implemented short-term measures to reduce carbon intensity, including the introduction of the Energy Efficiency Design Index (EEDI) in 2013 and, more recently, the Energy Efficiency Existing Ships Index (EEXI) and Carbon Intensity Indicator (CII). These short-term measures will be revised in 2026. Mid-term measures, such as carbon pricing and a GHG fuel standard, are currently under consideration and are expected to be adopted in 2026, with enforcement planned for 2027.

	2023	2024	2025	2026	2027+
Adopted regulations	EEXI	Revised Data Collection System: CII Rating	EEDI phase 3 (all ship types)		
	Enhanced SEEMP & CII Rating	EU ETS for shipping	FuelEU Maritime: GHG fuel standard		
Regulations under development					IMO carbon price
					IMO GHG fuel standard
					Black carbon & VOC
Processes	IMO LCA guidelines for fuels (first version)	Comprehensive impact assessment	CII and EEXI review	Feasibility of incl. ships <5000 GT in EU ETS	
	IMO Revised GHG Strategy				

**Figure 1: GHG regulatory timeline, adapted from DNV (2023)**

This section does not aim to provide detailed descriptions of each regulation and how they function for the various ship types and sizes. It will present the increasing regulatory pressure placed on the maritime industry, necessitating further emphasis within existing areas and the introduction of new solutions, including design for efficient operations, the introduction of alternative energies and solutions, and financial considerations like carbon pricing.

Table 1 provides an overview of the main regulations, their current design impacts, and potential future design impacts. This summary is described in more detail in the following sections.

## Energy Efficiency Regulations

This section will highlight the main ship design impacts already identified for each main EE regulation, as well as project what potential impacts could be as these regulations are updated in the future to align with IMO's revised GHG reduction strategy.

### **EEDI**

The EEDI is a design-related hard regulation that is the one-time responsibility of the ship designer or shipyard to prove compliance. The EEDI formula either drives a reduction in CO<sub>2</sub> emissions or an increase in transport work, which mainly relates to the classic ship-engine-propeller matching process (Ren et al., 2019) and involves a balance between ship capacity, power, speed, minimum fuel consumption, and the smallest quantity of CO<sub>2</sub> emitted into the atmosphere (Constantin and Amaraitei, 2019). Optimization of main dimensions can also improve EEDI values (Calisal et al., 2022).

A working group at the Mærsk Mc-Kinney Møller Center for Zero Carbon Shipping (MMMCZCS) recently published findings (MMMCZCS, 2023b) related to EEDI compliance, stating, "The combination of derating and propeller diameter changes delivers increased efficiency by aligning the optimal operational point of the propulsive system more closely with the vessel's actual usage. Feedback from working group participants indicates that compliance with the EEDI can be achieved through power reduction alone, without implementing other EE gains (through engine efficiency, retrofits, etc.)."

While evolutionary improvements in hull forms and power generation efficiency have mainly contributed to EEDI compliance, the introduction of energy-saving devices (ESDs) on newbuilds has proven beneficial for business and the environment (Kenney & Palmejar, 2023). Most adopted ESDs are hydrodynamic improvements (e.g., twisted rudders, rudder bulbs/fins, pre-swirl stators, propeller boss cap fins) or engine-related (e.g., waste heat recovery, shaft generators) (EC, 2021). Members of the MMMCZCS working group attribute their introduction mainly to the risk of poor sea trial results.

**Table 1: List of regulations, current, and potential future design impacts**

Regulation	Type / Responsible	Current Design Impact	Potential Future Design Impact	References
EEDI	Design, Hard for New Vessels  Ship designer, shipyard	Evolutionary improvement of hydrodynamics, propulsion and power generation on newbuilds. Introduction of new ESDs.  <ul style="list-style-type: none"> <li>• Ship-engine-propeller: Derated engines (linked to slow steaming trends) + increase propeller diameter, streamlined hullforms</li> <li>• Energy saving devices: Mostly hydrodynamic improvements (increased speed at fixed power to ensure sea trial results) or engine-related (WHRS, shaft generator)</li> <li>• Introduction of LNG</li> <li>• Increased capacity</li> </ul>	Could change metric from CO <sub>2</sub> -centric to a power or energy basis or enlarge the scope of emissions. Increased reduction rates. Updating of reference lines to include newer (and usually larger ships).  <ul style="list-style-type: none"> <li>• Incorporation of more innovative ESD technologies including air lubrication and wind-assisted propulsion</li> <li>• Introduction of new main energy converters including hybrid arrangements, all-electric with batteries and fuel cells</li> </ul>	Ren et al. (2019), Constantin and Amaraitei (2019), Calisal et al. (2022), MMMCZCS (2023b), Kenney & Palmejar (2023), EC (2021)
EEXI	Design, Hard for Existing Vessels  Ship owner	Limited to no design impacts on existing vessels with limited operational (mostly speed) limitations.  <ul style="list-style-type: none"> <li>• Adoption of power limitation that reduces maximum allowable engine power output</li> <li>• Limited to no introduction of new ESDs unless already planned</li> </ul>	Older (less efficient) vessels impacted more by power limitation could lead to increased scrapping. Updating of EEDI can lead to updates of EEXI limits if additional phases are introduced or another metric is introduced.	MMMCZCS (2023b)
CII/SEEMP Part III	Operational, Soft (until 2026)  Ship owner, technical manager	Higher impact on operations, however, improved designs lead to more operational freedom.  <ul style="list-style-type: none"> <li>• Vessel monitoring system requirement</li> <li>• More efficient designs are able to comply with CII more easily</li> </ul>	First operational measures will be exhausted. Then consideration for advanced technologies. Newbuilds to be more energy efficient to give further operational flexibility. Design for efficient operation emphasized. Speeds will generally go down.  Wind-assisted propulsion, air lubrication, waste heat recovery systems, shaft generators, and hybridization of the engine room (e.g., using batteries or fuel cells).	MMMCZCS (2023b), Sun et al. (2023)
Fuel Standards (IMO Mid-term Measure, FuelEU)	Operational, Hard  Ship owner, technical manager	Major impact for new vessels with expected lifetime of 20+ years as readiness for alternative fuels needs to be considered.  Due to small short-term reductions, limited impact for existing vessels with benefits seen from introduction of LNG as a fuel and small modifications required to use liquid biofuels.  Use of fossil-based LNG provides compliance window up to at least 2030. Small modifications required for biofuels (to be discussed in next section).	With the anticipated increased reductions upcoming, all new vessels need to address this compliance challenge based on the solutions available (to be discussed in next section).  Fleet considerations like FuelEU pooling requires designers to think at vessel and fleet level.	EU (2023), MMMCZCS (2022d)
MBMs (IMO Mid-term Measure, EU ETS)	Operational, Hard  Ship owner, technical manager	Unclear as in short term it is a relatively small added cost of operation. Emphasized efficient operation and reducing absolute emissions from vessel.	MBMs more closely linking economic incentives and penalties to the technical description of the vessel. Cost of GHG emissions could become major driver of design decisions (techno-economic analysis).	IMO (2024), Hansson et al. (2023)

The introduction of LNG dual-fuel vessels has also contributed to lower EEDI ratings (around a 20% reduction) due to the tank-to-wake (TTW) carbon factor used to calculate CO<sub>2</sub> emissions. It is important to note that the EEDI formula only considers direct vessel emissions and excludes other GHGs, such as methane. While the primary decision to design a dual-fuel LNG vessel has most likely not been for EEDI compliance alone, it has shown to be an easy way to comply with the latest EEDI Phase 3 requirements. Another method to improve EEDI values is to increase capacity while keeping power low. A good example of this is raising the wheelhouse height on container vessels to accommodate more twenty-foot equivalent units (TEUs) without impairing visibility.

The implementation of EEDI, especially under favorable market conditions, has increased focus on EE and led to more efficient ship designs, including the introduction of ESDs (MMMCZCS, 2023b). However, the EEDI attained values of recent newbuild vessels have plateaued (EC, 2021), and its future is not clear, with discussions on Phase 4 postponed to later in this decade. The IMO is now discussing the development of mid-term measures focused on reducing absolute emissions, which could render aspects of the existing EEDI calculation redundant (MMMCZCS, 2023b). The MMMCZCS working group suggests that the metric could be changed from CO<sub>2</sub>-centric to a power or energy basis or expand the scope of emissions. This would coincide with increased reduction rates and the updating of reference lines to include newer (and

usually larger) ships. It could lead to wider adoption of more innovative ESD technologies such as air lubrication and wind-assisted propulsion, as well as the introduction of new main energy converters, including hybrid arrangements, all-electric with batteries, and fuel cells.

### ***EEXI***

The EEXI is a design-related hard regulation that is the one-time responsibility of the ship owner to prove compliance starting from January 1, 2023. It is based on EEDI reference lines and can be considered as an extension of EEDI to cover existing vessels in addition to newbuilds. Due to the limited time ship owners had to prepare for the introduction of EEXI regulations and the small periods of time vessels operate at higher engine loads, most vessels have adopted a power limitation, which reduces the maximum allowable output of the engine (MMMCZCS, 2023b).

Data suggests that vessels can achieve EEXI compliance with minimal impact on operations. However, EEXI imposes a technical limit if vessels are incentivized to go faster, such as under certain market conditions or when catching up on a schedule (MMMCZCS, 2023b). While having a more significant impact on existing and mostly older vessels, EEXI compliance confirms a trend towards lower installed power and slower speeds as a major EE measure contributing to an overall reduction in GHG emissions. EEXI is an initial example of why operational factors have become more important for ship designers to pay attention to and consider as part of the design process, especially when projecting throughout the lifetime of a vessel.

### ***CII***

CII is an operational EE regulation based on annual operational data. It came into effect on January 1, 2023, and will be effective until at least 2030, with a review planned in 2026. CII reduction factors relative to 2019 start at 5% in 2023 and increase to 11% by 2026. If a vessel has low CII ratings for periods of time, corrective actions need to be agreed upon and taken (MMMCZCS, 2023b).

Along with the CII, Part III of the existing Ship Energy Efficiency Management Plan (SEEMP) was introduced in 2023 to ensure proper documentation of each vessel's implementation plan to obtain the required CII ratings. As part of the SEEMP Part III, the recognized organization, often a classification society, needs to verify its implementation plan, including the use of a vessel monitoring system (MMMCZCS, 2023b).

While intended to improve the operational EE of a vessel, studies have shown that a more efficient ship design can provide additional operational flexibility and higher CII ratings (MMMCZCS, 2023b). Design can be a differentiating factor for operational EE regulatory compliance, placing more emphasis on energy-efficient designs going forward. It is also expected that CII modeling during the design phase will be requested, and an understanding of the impact of EE technologies and operational measures on CII rating will be needed during this phase. This is a new consideration for ship designers and shipyards that previously only had to ensure compliance with EEDI. Subsequently, this raises more awareness of operational considerations and the operational part of the ship's lifecycle during the design phase, which should further improve the EE of newbuilds.

However, delivering an energy-efficient vessel does not guarantee good CII ratings, as operational conditions mainly drive the final rating, over which the ship owner typically has little control. Very efficient ships can have poor CII ratings. In addition to a focus on vessel efficiency, vessel, port, and canal operations, as well as commercial considerations, can significantly impact a CII rating (MMMCZCS, 2023b). While the ship designer has control over designing an energy-efficient vessel, they should not overlook the other drivers and their relationship to a ship's design. This includes considerations like expected speed, cargo utilization, and deployment.

How do ship owners intend to achieve CII compliance? Owners expect to first implement as many operational measures as possible, such as performance monitoring. Once operational measures are exhausted, owners must consider introducing advanced technologies like wind-assisted propulsion, air lubrication, waste heat recovery systems, shaft generators, and engine room hybridization, such as using batteries or fuel cells (MMMCZCS, 2023b). Additionally, speed becomes an important parameter for CII compliance, understanding that commercial aspects also need to be considered (Sun et al., 2023).

## **Emissions Regulations**

Emissions regulations are essential for designers to understand, as they can be fulfilled in different ways, including through design and operational solutions. This further integrates the designer into the operational environment where the owner's requirements, including operational profiles and conditions, should now be more deeply explored in an environment of impactful regulatory and economic considerations.

### ***Fuel Standards***

GHG fuel standards are expected at the international level through IMO mid-term measures (with enforcement starting in 2027) and regionally in the EU with FuelEU for Maritime, starting enforcement in 2025. The main purpose of fuel standards is to promote the use of sustainable fuels. The measure, which is based on GHG emissions per unit energy on a WTW

basis, is independent of the vessel's EE, as a reduction in GHG emissions will also lead to lower energy consumption. As such, this measure requires the introduction of more sustainable fuels.

FuelEU for Maritime required reduction levels start at 2% in 2025 compared to 2020 levels and will increase to 6% in 2030, 31% around 2040, and 80% around 2050 (EU, 2023). FuelEU for Maritime also introduces the concept of pooling, which allows a company to compensate for non-compliant reductions with over-compliant reductions across multiple ships in their fleet for the same time period. This concept changes the focus from single vessel compliance to fleet compliance, granting shipping companies greater flexibility in developing their compliance plans. This also introduces a new consideration for ship designers when defining newbuild design requirements that will join a company's larger fleet. Instead of designing for expected reduction trajectories, designers can introduce near-zero or zero-emission vessels that can help offset emissions from multiple sister vessels within a fleet.

The IMO's GHG fuel standard, considered a mid-term measure, is expected to follow a similar structure as FuelEU for Maritime. However, it is not confirmed, and there will likely be some differences as the IMO targets its revised GHG reduction strategy levels.

While alternative fuels will be discussed further in the next section, it is crucial to highlight that existing vessels either need to introduce biofuel blending or benefit from pooling (as described above). Owners who have introduced alternative-fueled newbuilds, including LNG and methanol dual-fuel vessels, can benefit from the use of compatible fossil and sustainable fuels. Recent studies have shown that LNG-fueled vessels operating on fossil-based LNG can remain compliant with FuelEU for Maritime regulations at least until 2030, based on the regulation's current setup (MMMCZCS, 2022d).

Nonetheless, these fuel standards are effectively compelling owners to introduce alternative-fueled vessels, which are now an essential part of a designer's considerations, especially early in the design process when the vessel's requirements are defined.

### ***Market-Based Measures***

Market-based measures (MBMs) put a price on GHG emissions to provide an economic incentive to reduce emissions through ship design and operation. The EU has recently included the maritime industry in its Emissions Trading System (ETS), a cap-and-trade system. The IMO is considering a list of potential MBMs as part of their mid-term measures, ranging from contribution schemes for GHG emissions through an ETS to schemes based on actual ship efficiency by design and operation (IMO, 2024). Each of the ten proposed MBMs for the IMO's mid-term measure either requires a direct cost per amount of fuel consumed or emissions, the purchase of related allowances, or sets strict EE standards with associated penalties (IMO, 2024). How any collected revenue from such measures will be used or distributed is yet to be determined.

MBMs are fuel- and technology-agnostic and provide flexibility to designers and operators when selecting solutions to minimize financial impact. Cost-effectiveness and abatement become critical metrics when evaluating solutions. With the expected cost of EU ETS emissions allowances in the short to mid-term, the least-cost measures like increased EE of ship designs and EE operational measures are likely to be implemented first as these abatement costs are typically negative due to fuel savings (Hansson et al., 2023). With higher abatement costs, alternative fuels and technologies would require greater costs associated with a MBM. Lagouvardou et. al. (2023) studied the marginal abatement cost of alternative marine fuels to demonstrate the role of MBMs in helping bridge the price gap between the fossil-based fuels of today and the more expensive alternative fuels of tomorrow. Revenues from MBMs can also be used to fund scaling of alternative fuel production as fuel availability can become a major constraint in the uptake of alternative fuels (Lagouvardou et. al., 2023).

MBMs now link economic incentives and penalties more closely to the technical description of the vessel beyond typical metrics such as the required freight rate (RFR). Techno-economic assessments are now intrinsically linked to the ship design process, and will be in the future, even if MBMs will potentially have an outsized impact on technical decisions compared to typical RFR measures.

### ***Local Emissions Regulations***

A pertinent example of an impactful local regulation is the zero-emissions requirement for cruise ships, tourist boats, and ferries in the Norwegian World Heritage fjords by 2026 (NMA, 2023). In response to this upcoming regulation, Norwegian shipowners and designers have developed power solutions to allow large cruise ships to operate emissions-free for up to 12 hours and have conceived zero-emission cruise ship designs (Business Norway, 2024).

### ***Non-Regulatory Drivers/First Movers***

Although regulatory compliance is the minimum requirement for an existing or future ship design, some companies prefer to be first movers setting more ambitious targets, including substantial investments in advanced technologies and alternative fuels. First movers seek competitive advantages, such as strong brand recognition, technology leadership, and resource control, while also taking on increased financial, technical, and operational risks (Esau & Bentham, 2023).

These pioneering companies are trying to capitalize on current and expected future demand for "green" transportation. While the demand is currently low, it exists and is growing. While regulations will be the primary driver of the eventual decarbonization of the industry, first movers responding to the market demand for clean transportation have been the start of solution investigation. In addition, various organizations publish guidelines or best practices to be considered. For a ship designer, understanding the motivation and objectives as part of the ship requirements definition is critical.

## TECHNICAL SOLUTIONS

Technical solutions are available and under development to help achieve regulatory compliance or to meet individual company decarbonization targets. This section will focus specifically on solutions that impact ship design. Pure operational measures, for example, will not be covered; however, operational measures are in most cases the easiest to implement and should be considered, especially for existing vessels.

While most operational measures are purely operational or behavioral in nature, ship designers still need to understand what operations are expected and if any operational measure impacts ship design, or if the ship design can be optimized to maximize the impact of targeted operational measures. This section will briefly cover some of these operational measures to ensure proper coverage of solutions and ship design-related considerations.

Technical decarbonization solutions can be divided into three main categories:

1. Energy efficiency technologies,
2. Alternative energies and fuels, and
3. Emission reduction technologies.

These solutions will be introduced, but not discussed in detail, as there are plenty of good sources that provide more detail and will be referenced in the associated sections.

This section will provide evidence of a general increase in ship design complexity and more design challenges with the introduction of maritime decarbonization technical solutions. While some solutions can maintain complexity levels (e.g., a newer, more efficient engine), most introduce additional complexities and interdependencies with other systems onboard. This increase in complexity and a high-level identification of the main ship design impacts with examples will be presented and discussed.

Design complexity discussed in this section is focused on the design product, not the design problem or process. Complexity of a design product can be described by the product's structure, such as the physical arrangement, its function like the number and connectivity of systems, and its behavior, such as predictability (Ameri et al., 2008). When discussing the technical solutions in this section, increased complexity is demonstrated by the addition of systems and their connection or relationship to other systems and overall vessel performance. Cost can also be used as a complexity metric and will be indicated where possible in parallel with technical complexity descriptions. Systems with higher complexity generally have higher lifecycle costs (Ameri et al., 2008) and failure rates (Jones, 2021).

## Energy Efficiency Technologies

Energy efficiency technologies (EETs) reduce the vessel's energy consumption. MEPC.1/Circ.815 provides guidance on how EETs can be treated for EEDI calculation and verification, including categorization (IMO, 2013):

- "Technologies that shift the power curve, resulting in a change of combination of propulsion power and speed.
- Technologies that reduce the propulsion power but do not generate electricity, leading to increased propulsion efficiency.
- Technologies that generate electricity, leading to saved energy, typically in the form of reduced auxiliary power."

From a ship design impact perspective, three general categories of EETs can be defined:

1. Standard Practice: Low ship design impact baseline technologies that are (or should be) incorporated into any newbuild vessel.
2. Moderate Effects: Medium ship design impact technologies that might cost more and require integration but can be managed without significant design or performance impacts.
3. Systematic Integration: High ship design impact technologies that cost more, have larger systems and interconnections, and implications for the overall ship design and performance.

Table 2 provides an overview of the main EETs, their maturity level, cost and complexity, and ship design impacts. It also includes specific examples of ship designs operating with EETs onboard.

While general technology categories can be grouped by ship design impact level, any novel or new technology within any category might require a more systematic integration study and should be evaluated on a case-by-case basis. A good example of such a case is the novel gate rudder system (Tacar et al., 2020). While within the propulsive loss reduction category that is typically low design impact, being a new and novel system, a more thorough assessment is needed.

**Table 2: List of energy efficiency technologies, maturity level, cost, technical complexity, main ship design impacts**

Impact Category	Technology Category	EET Type	Maturity Level / Cost (\$)	Design Impact & Technical Complexity	Examples / References
Low-Standard Practice	Hullform design	Dimensions, hull, openings optimization, asymmetric stern, skeg shape training edge, twin skeg. Use of model-based simulations.	Mature <500k	Part of normal design process. Enhanced through advanced CFD simulations.	
	Structural design	Superstructure optimization (wind resistance), lightweight reduction. Use of model-based simulations.	Mature <500k	Part of normal design process. Enhanced through advanced CFD simulations.	
	Hull drag reduction	Low friction coating, heating, surface texturing, additives	Low friction coatings well-established (mature), new technologies under development. <1M	Minimal. Can be retrofitted. Part of normal drydocking schedule. Coatings have low impact. Any active system would require additional supporting systems.	
	Propulsive loss reduction	Controllable pitch, contra-rotating, tip raked propellers, propeller nozzle/duct, pre swirl stators, post swirl fins/stators, rudder bulb, thrust fin, twisted rudder, ducktail waterline extension, gate rudder	Mature <1M	Impact on ship performance, both from a propulsion efficiency perspective, but also other important aspects such as reliability, maneuvering, structural fatigue. Can be retrofitted. Usually requires drydocking. Loss of efficiency by designing for an existing hullform.  Usually well-known and demonstrated. Part of normal design process. New propulsion devices and rudders such as gate rudders requires integration studies (supporting systems, structural integration) with increased complexity.	Novel Gate Rudder system includes two asymmetric rudders at each side of the propeller (Tacar et. al., 2020).
	Machinery efficiency	Engine design	Mature	Part of normal design process. Improved fuel consumption while maintaining NO <sub>x</sub> compliance and other emission targets (e.g., low methane slip)	
Medium-Moderate Effects	Shaft generator	Power take-off (PTO), power take-in (PTI), front-end/aft-end, on-engine, on tank-top, shaft mounted, geared/direct	Mature <1M	Space is a consideration when placed aft of the main engine (could effect hullform), requires switchboard integration. Retrofit can be challenging due to space limitations.  Additional system needs to be integrated close to engine, frequency converter and couplings, electrical integration	
	Waste heat recovery	Beyond exhaust gas boilers incl. steam turbine, power turbine, organic rankine cycle	Semi-Mature. Demonstrated onboard vessels.  1-5M (more if combined)	Space/weight requirements, piping, switchboard integration. Retrofit can be challenging due to space limitations.  Additional system, piping, electrical integration	
	Solar panels	Solar panels	Not mature. Limited demonstrations <500k	Large amount of deck space needed. Only applicable to certain vessel types (e.g., car carriers). Can be retrofitted.  Additional system that requires large area. Electrical integration.	K-Line's Drive Green Highway car carrier installs large solar energy system (Haun, 2016)
	Energy storage/batteries	Peak load shaving	Semi-mature  1M	Additional system, requires space, electrical integration. Retrofit can be challenging due to space limitations.  Space requirements, control and automation integration, fire safety	
	Cold ironing/shore power	Cold ironing/shore power	Semi-Mature <1M	Additional system that requires space, access, high-voltage cabling, electrical integration. Can be retrofitted.  Space requirements and outside access/interface, switchboard integration. Containerized options exist.	
High-Systematic Integration	Air lubrication system (ALS)	Bubble drag reduction, air layer drag reduction, partial air cavity drag reduction	Semi-mature. Demonstrated onboard various vessel types.  1-5M	Interconnected with hullform design, additional support systems such as compressors requiring additional energy demand, piping. Can be retrofitted. Requires drydocking. Loss of efficiency by designing for an existing hullform.  Hullform and ALS system designed together - performance dependent on good match (e.g., location of air cavities). Additional power demand and space for supporting systems such as compressors. Risk of air bubble interactions with propeller and sea chests. More suitable for certain types of ships (e.g., draft considerations).	Kim & Steen (2023)
	Wind assisted ship propulsion (WASP)	Wingsails or rigid sails, square rig sail systems, towing kites, flettner rotor	Not mature. Demonstrated onboard a few vessel types.  1-5M	Additional system that has additional weight, requires deck space, supporting systems, structural integration. Can be retrofitted. Current share of retrofits is significant (EMSA, 2023).  Air draft restrictions (e.g., bridges), stability, change in operations (wind-based route optimization), visibility.	Pyxis Ocean bulk carrier (operated by Cargill) was retrofitted with two rigid sails (WindWings) (Neuman, 2023), EMSA (2023), Khan et al. (2021)

The EETs with the highest complexity are also the ones with the highest potential. Two good examples are the air lubrication system (ALS) and wind-assisted ship propulsion (WASP). Potential net power savings of ALS technologies can range from 2-22% (Kim & Steen, 2023), while WASP can provide up to 30% savings (EMSA, 2023).

ALS technologies are considered semi-mature and have been demonstrated onboard various vessel types. With high initial capital expenditure (CAPEX) of around \$1-5 million (M), ensuring sufficient savings to justify the investment is critical. Additionally, the ALS is interconnected with the hull form design, and performance will depend on a good match (e.g., location of air cavities). Additional power demand and space for supporting systems such as compressors are also required. The risk of air bubble interactions with the propeller and inlets like sea chests also needs to be managed.

WASP technologies are not considered mature yet, but demonstrators are currently onboard a few vessel types. Like ALS, WASP has high CAPEX (\$1-5M), and ensuring maximum savings is critical. With multiple WASP systems added to a ship design, the additional weight and deck space can be limiting factors. Structural reinforcement is also required (Khan et al., 2021). Air draft restrictions (e.g., bridges), stability with large weights on deck, and visibility need evaluation. WASP performance will also depend on operations, creating an important link between design and operations. For example, the vessel can deviate from the shortest route if additional WASP savings can be achieved.

ALS and WASP provide two examples of high-impact ship design considerations that require systematic integration. While "low-hanging fruit" with low to moderate impact do exist, significant savings will usually require acceptance of increased cost and complexity.

## **Alternative Energies and Fuels**

While significant EE improvements can and should be made due to their favorable emission abatement economics, EE alone is not enough. This has been highlighted by recent fuel standards being implemented or developed, as well as continued trade growth projections that will only lead to increased emissions without the introduction of other solutions (Cullinane & Yang, 2022).

To reduce the emissions per unit of energy required by ships, alternative energies and fuels have been proposed and introduced in the maritime industry to replace fossil fuels like HFO, diesel, and LNG. Along with the introduction and development of alternative energies and fuels, new and modified energy converters such as dual-fuel internal combustion engines and fuel cells are being developed.

The main energies and fuels currently under consideration within the maritime industry are listed in Table 3 and include wind, electricity, liquid biofuels (including biodiesel and bio-oils), methane, methanol, ammonia, and hydrogen. These energies and fuels can be produced or provided in different ways. Renewable energy is used to produce e-fuels, fossil feedstocks are used as a basis to produce blue fuels, while bio-diesel and bio-oils include a range of techniques that convert biological material into an oil-like substance. Depending on the feedstock and production process, each pathway has a certain level of WTW emissions relative to fuel oil. A WTW methodology that includes the emissions from fuel production and onboard the vessel is needed to unlock carbon-based fuel pathways like methane and methanol.

While the molecular makeup of fuels can be identical, their emission intensities can vary. From a ship design perspective, the integration of "green ammonia" versus "blue ammonia" is identical; however, it's important to properly account for the source and production method when calculating lifecycle emissions (on a WTW basis).

The main energies and fuels have different maturity levels and commercial readiness levels, as seen in the number of alternative-fueled vessels delivered or on order. Based on DNV's Alternative Fuels Insight (as of April 9, 2024), with over 1,000 vessels in operation and on order, methane-based vessel designs are the most prevalent, with only 16 ammonia-fueled vessels on order.

While technical complexity generally increases with the introduction of alternative energies and fuels, this is not always the case. Most of the design complexity for fuels such as methane, ammonia, and hydrogen come from their storage requirements and proper management of liquefied gases onboard the vessel. They also require dual-fuel engines with two fuel supply systems and additional support systems and spaces, such as ventilation, double-walled piping, and fuel preparation rooms. Methanol is more easily stored but still requires additional systems like inerting and dual-fuel engines. In addition to the typical NO<sub>x</sub> reduction after-treatment technologies that are required, ammonia-fueled vessels may require additional systems to mitigate ammonia slip and nitrous oxide (N<sub>2</sub>O) emissions, as well as ammonia release mitigation systems due to its toxicity.

**Table 3: List of alternative energies/fuels, maturity levels, technical design complexity, main ship design impacts**

Energy/ Fuel	Maturity Level	Design Impacts	Technical Complexity		
			Port Interface	Energy Storage	Energy Conversion & After-Treatment
VLSFO	Mature	-	Standard bunkering	Integrated tank	Mono-fuel engine. NO <sub>x</sub> reduction (EGR/SCR).
Wind	For more than EE, majority of energy demand to be met. Not yet mature for this application.	Class guidelines and incorporation into EEDI/EEI calculations available. Potential change in operations such as speed (wind-based route optimization). Deck space, air draft restrictions (e.g., bridges), stability, visibility.	-	-	-
Electricity	Semi-Mature	Class guidelines available, risk-based approval process. Relationship between endurance, energy density and space requirements.	Power connection	Battery	-
Bio-Diesel/ Bio-oils	Mature	Minor modifications potentially needed.	Standard bunkering.	Integrated tank. Small modifications potentially needed.	Mono-fuel engine. Small modifications potentially needed. NO <sub>x</sub> reduction (EGR/SCR).
Methane	Mature	Prescriptive rules in IGF Code. Well-established design considerations. Additional storage volume requires an evaluation of endurance and cargo loss. Locating key spaces like the tank connection space, fuel preparation room and vent mast important for arrangement.	Liquefied bunkering requires additional systems including vapor return line, safety measures, operational procedures.	Liquefied at -163 deg C, requires independent prismatic (Type A/B), cylindrical (Type C) or membrane tanks, stainless steel, aluminum or nickel steel, tank aeration, tank connection space, inerting, vent mast and piping, boil-off gas management (e.g., reliquification).	Dual-fuel engine. Two fuel supply systems. Fuel preparation room. Fuel heating. Ventilation. Double-walled piping. Pilot fuel consumption. NO <sub>x</sub> reduction (EGR/SCR).
Methanol	Semi-Mature	IMO Interim Guidelines with risk-based approval. Integrated tanks require cofferdams that impacts required space in addition to energy density difference. Alternative designs can be proposed to reduce the impact of the cofferdam requirement.	Usually requires additional bunker lines (due to higher quantities for same amount of energy), vapor return, safety measures, operational procedures.	Integrated tank with proper coating. Liquid under ambient conditions. Inerting. Vent mast and piping.	Dual-fuel engine. Two fuel supply systems. Fuel preparation room. Ventilation. Pilot fuel consumption. NO <sub>x</sub> reduction (EGR/ SCR/ water injection).
Ammonia	Not Mature	Class guidelines available, risk-based alternative design required. Gas dispersion and quantitative risk assessment analyses recommended. Additional storage volume requires an evaluation of endurance and cargo loss. Locating key spaces like the tank connection space, fuel preparation room and vent mast important for arrangement. Additional integration of emissions and safety systems to achieve equivalent safety levels to methane and meet emissions regulations.	Requires additional bunker lines (due to higher quantities for same amount of energy), vapor return(s), safety measures, operational procedures.	Liquefied at -34 deg C or 18 bar pressure, requires independent prismatic (Type A/B) or cylindrical (Type C) tank. Low temperature or high tensile steel. Tank aeration, Tank connection space, inerting, vent mast and piping, boil-off gas management (e.g., reliquification).	Dual-fuel engine. Two fuel supply systems. Fuel preparation room. Fuel heating. Ventilation. Pilot fuel consumption. NO <sub>x</sub> reduction (EGR/SCR), potential need to reduce ammonia slip and nitrous oxide (N <sub>2</sub> O) via additional catalyst. Ammonia release mitigation system.
Hydrogen	Not Mature	Class guidelines available, risk-based alternative design required. Additional storage volume can pose a significant design challenge that requires an evaluation of endurance and cargo loss. Locating key spaces like the tank connection space, fuel preparation room and vent mast important for arrangement.	Requires additional bunker lines (due to higher quantities for same amount of energy), vapor return(s), safety measures, operational procedures.	Liquefied at -253 deg C or compressed at above 200-300 bar, requires usually a well-insulated cylindrical (Type C) tank. Special low-temperature material that avoids embrittlement. Tank connection space, inerting, vent mast and piping, boil-off gas management (e.g., reliquification).	Large two-stroke engines not currently being developed. Most likely converter for direct hydrogen use is fuel cells. NO <sub>x</sub> reduction (EGR/SCR) if burned in an engine.

Main ship design impacts with the introduction of alternative energies and fuels include increased fuel storage volumes, additional space for fuel management and safety systems, as well as key integration challenges such as placement of vent masts and routing of fuel piping. Ship performance is usually impacted, and compromises need to be made in terms of endurance, speed, and/or cargo capacity. Typically, alternative-fueled vessels will not have the same endurance as their conventional-fueled counterparts, where fuel capacity is not as constrained. Methanol-fueled vessels have their own integration challenges, including the need for additional space around the fuel tanks for cofferdams. However, alternative designs can be proposed to reduce the impact of the cofferdam requirement.

Hydrogen-fueled vessels have significant ship design challenges, including the lack of internal combustion engine development and the need for large storage volumes (Ustolin et al., 2022). There has yet to be a large hydrogen-fueled deep-sea oceangoing vessel developed. Hydrogen as a fuel has been successfully implemented on smaller vessels, though (Comyn et al., 2022). All-electric solutions have been implemented for smaller vessels, while batteries are mostly considered an EET on larger vessels. Industry and academic studies have indicated the advantage of using batteries for smaller short-sea vessels such as ferries, like hydrogen (Wang et al., 2022).

Nuclear propulsion has also gained renewed interest with the development of advanced nuclear reactor technologies, including small modular reactors and microreactors. Benefits of nuclear-based technology and applications include a zero-emission, base-load power source with more predictable financials compared to other alternative fuels that struggle with both availability and high price concerns. While commercial nuclear for maritime applications shows promise, there are several concerns and barriers to implementation that would need to be addressed. In addition to the well-known concerns of non-proliferation, nuclear accidents, and public perception, there are barriers associated with maturing the technologies for maritime application, merging nuclear and maritime regulations to form a viable regulatory framework and pathways, as well as the need to rethink how risks are calculated. The broader societal and industry impacts of such applications can also not be forgotten.

While the technical design complexity discussion has mostly revolved around the use of internal combustion engines as the main energy converter of today and will likely remain well into the future, alternative energy converters such as fuel cells are under development and show promise for use with alternative fuels. The use of hydrogen directly in fuel cells or the use of a cracker or reformer with fuels like ammonia, methanol, and methane can provide increased conversion efficiencies compared to internal combustion engines (Herdzik, 2021). While fuel cell technologies and their applications onboard vessels are not fully mature, their ship design implications should be considered and can, in most cases, lead to a less complex design compared to an alternative-fueled internal combustion engine design.

The introduction of new alternative energies and fuels has also raised safety concerns and the need to rethink how risk assessments and risk-based approvals are done. Comparing alternative fuels with different characteristics, such as flammability, explosiveness, and toxicity, that can impact safety can be challenging and requires new types of analyses and updated risk-based frameworks.

## Emission Reduction Technologies

Emission reduction technologies or after-treatment technologies have been used within the maritime industry to address mainly air pollutant emissions but are now also being considered to reduce GHGs and other alternative fuel-related emissions. Figure 2 provides a high-level overview of the emission risks for the main fuels and potential solutions to mitigate these risks, originally introduced by MMCZCS (2022b).

**Figure 2: Highlighting emission risks for main fuels, reprinted with permission from MMCZCS (2022b)**

The most notable technologies used today include exhaust gas recirculation (EGR) and selective catalytic reduction (SCR) systems to reduce NO<sub>x</sub> and exhaust gas cleaning systems (commonly known as scrubbers) to reduce sulfur oxides (SO<sub>x</sub>) and PM from engine exhausts.

EGRs and SCRs are not going anywhere, as NO<sub>x</sub> compliance will still be required with the use of alternative fuels, and most of the fuels under consideration require after-treatment. SO<sub>x</sub> scrubbers will become a technology of the past as HFO use will decrease as the first fossil fuel impacted by upcoming regulations. HFO is also not expected to be used as a pilot fuel for alternative fueled vessels in the long term.

One of the main emission reduction technologies currently under development for maritime applications are shipboard carbon capture (SCC) systems that can, most commonly, capture CO<sub>2</sub> from engine exhaust onboard a vessel. There are different types of SCC systems, and each has its own integration challenges and considerations. More extensive studies have been completed on amine-based absorption systems, as they are the most mature and are already used onshore. While studies have shown SCC to be technically feasible, there are high energy requirements, significant CAPEX investment, and integration challenges on certain vessel types due to the space requirements for the capture system, liquefaction, and CO<sub>2</sub> storage (MMMCZCS, 2022c).

Finally, with the introduction of alternative fuels including methane, methanol, and ammonia, emission reduction technologies either need to be applied and developed to ensure compliance with air pollutant emissions while limiting other GHG emissions in addition to CO<sub>2</sub>, such as methane and N<sub>2</sub>O. Special regional considerations for emissions like black carbon (BC) should also be considered (MMMCZCS, 2022b).

## UNCERTAINTY AND DYNAMICS

With the understanding that future regulations will be stricter and that there are many technical solutions that can help fulfill these regulatory requirements, commercial decisions will ultimately be driven by economics. In addition to economics, the added complexity due to adoption of new technical solutions presents an integration challenge, especially as regulations develop and evolve. While techno-economic assessments can be completed, the ability to capture the broad and varying types of uncertainties and dynamics can be challenging.

Uncertainty exists due to upcoming policy and regulation, technology and alternative fuel advancements (Trivyza et al., 2022), fuel specifications and standards, customer demand, and finance sector mobilization (MMMCZCS, 2022a). Conditions are constantly changing as more knowledge is gained about potential solutions being developed and policy decisions are made, in addition to the occurrence of disruptive innovations like advanced nuclear reactor technologies or geopolitical events such as the war in Ukraine or Houthi attacks on ships in the Red Sea. Uncertainty levels are also higher because maritime decarbonization is a long-term challenge that is at least 25 years from its achievement and the regulatory, technical, and commercial solutions are not yet in place today (Erikstad & Lagemann, 2022).

Key decision-makers include policymakers, technology developers, fuel suppliers, ports, ship owners, operators, charterers, and cargo owners. Each decision-maker has its own objectives but must consider decisions being made by all others along the value chain and across the industry. A good example is the relationship between alternative fuel producers and ship owners/operators. Fuel producers might not be able to proceed with the financial investment of building a new fuel production plant without long-term off-take agreements from shipowners/operators, who are in turn reluctant to lock in high prices not knowing future market dynamics. This example highlights the uncertainty associated with customer willingness to pay the additional costs to decarbonize and the uncertainty regarding how the additional investments will be supported by the financial sector.

Questions that now need to be addressed include:

- What decarbonization targets can be realistically achieved, and by when?
- Which alternative fuels will be available, by when, and at what price?
- What can I do with my current fleet to accelerate decarbonization?
- Should I ensure my newbuilds are generically "future fuel-ready," or should I focus on specific fuels?
- What roadmap should I follow to implement the transition of my vessel or fleet?

The link between company strategy and understanding the various uncertainties and dynamics becomes more important than ever. One of the main alternative-fueled design considerations is the evaluation of optionality and conversion potential related to preparing a vessel to be converted to an alternative fuel later in the vessel's lifetime. This is mainly driven by the uncertainty around when and at what price alternative fuels will be available in the future, combined with the uncertainty around future regulations. For ammonia, it is also due to the onboard technologies not being commercially available yet, such as the engine.

Future alternative fuel availability, and associated pricing, for the maritime industry continues to be one of the main uncertainties that stakeholders need to understand and manage. To a large extent, the development of alternative fuel availability and pricing within the maritime industry will be externally driven as multiple sectors compete for a limited

supply of renewables. With renewables being a scarce resource over the next decades, Lindstad et al. (2023) suggests renewable energy should first be prioritized for replacing coal fired electricity production then to electrify road transport. Hard-to-abate sectors including shipping and aviation would be expected to continue fossil fuel use until more renewable energy becomes available.

The decisions do not stop once the vessel is delivered and is in operation, which is both a positive in the sense that there are options to mitigate any uncertainty or dynamics, but also options mean you need to constantly evaluate them and select the best for your current situation. Based on a selected baseline fuel pathway, you have options to use fuels directly onboard or decide to convert your vessel to change from one pathway to another. Especially with such long lifetimes and the aggressive industry-level targets being set, replacing newbuilds with alternative-fueled vessels will not be enough. This means that fuel conversions will need to play a role in maritime decarbonization.

One example is starting with the LNG/methane fuel pathway, you can use fossil liquid fuels like HFO, low-sulfur fuel oil, marine gas oil, use liquid biofuels like biodiesel or bio-oils, fossil-based LNG, or bio- or e-methane. Additionally, you can decide to convert to the ammonia pathway, for example. This optionality, even in operation, demonstrates the requirement to take a holistic lifecycle approach to ship design that can consider changes in operations and operational decisions (Erikstad & Lagemann, 2022).

With the tightening of EE regulations and the introduction of fuel standards like FuelEU Maritime that provides the flexibility to consider fleet-level operations and compliance, ship design will take on another dimension: fleet design. A larger system perspective that considers a fleet of vessels versus a single ship will become even more important (Erikstad & Lagemann, 2022).

When attempting to capture the main maritime decarbonization regulatory, technical and economic drivers related to ship design, the following uncertainties and dynamics should be considered:

- Timing and levels of global, regional, and local regulatory requirements related to EE, fuel standards, and market-based measures.
- Technical maturity, commercial availability, and pricing of alternative energies, fuels, and technologies.
- Customer demand and finance sector mobilization.

In addition, two key macro trends have been identified that need to be captured when attempting to better understand and model these uncertainties and dynamics:

- A holistic lifecycle approach including design and operation,
- Concepts of optionality and flexibility/changeability, and
- Fleet-level design, operations, and perspectives.

## DECISION-MAKING UNDER UNCERTAINTY

Decision-making under uncertainty and dynamics is a broad and thoroughly studied research area, as well as an activity most organizations engage in regularly. With the urgency to act in an industry not easy to change, combined with many technical solutions and the introduction of various uncertainties and dynamics, the obvious next question is, how should key stakeholders make decisions?

Zwaginga & Pruyn (2022) highlight the deep uncertainties of the maritime energy transition and that, while uncertainty is not uncommon in ship design, the maritime decarbonization challenge introduces such high levels of uncertainty that new methods to deal with them are needed.

In their 2022 *Design Methodology State-of-the-Art Report*, Erikstad and Lagemann (2022) present four main design strategies that have emerged from the design spiral model: optimization, set-based, system-based, and configuration-based. While this paper is not intended to be a complete review of all ship design approaches and their applicability to the maritime decarbonization challenge, a central theme is that ships like container ships, bulk carriers, and tankers are becoming more complex and difficult to define requirements for. Transitioning from the classic design spiral to more advanced design strategies as presented by Erikstad and Lagemann (2022) can be beneficial and this section will describe some of these along with other strategic approaches that can be taken to manage uncertainty with specific examples relevant to ship design and the maritime decarbonization challenge.

Garcia Agis (2020) provides a good structure that defines four types of strategic approaches, each with several methods that can be applied: ignore (not the preferred option if the uncertainties are known), delay, reduce/control, and accept/protect. The "ignore" approach will not be covered in detail in this section as the main argument of this paper is that the use of deterministic models and approaches is not sufficient. This section will cover each of the remaining three strategic approaches (delay, reduce/control, accept/protect). The final part of this section will briefly discuss further development areas related to maritime decarbonization and environmentally sustainable ship design decision-making under uncertainty.

## **Delay**

Delaying decisions while gaining knowledge can be a helpful approach, especially during ship design. Applicable methods include concurrent engineering, set-based design, or real options (Garcia Agis, 2020). Most uncertainties and dynamics will not go away during the design process and will continue into a vessel's operation. This is why delay methods can capture decision-making throughout the vessel's lifetime.

Pomaska & Acciaro (2022) propose a real option analysis approach to hydrogen as an alternative fuel. The analysis demonstrated the value of deferring investment decisions to get a better understanding of regulation, fuel price, and technology developments while benefiting from potentially decreased hydrogen prices in the mid-term future. Metzger (2022) presents the use of the fuzzy pay-off method for real options analysis to better understand the impact of market-based measures on the valuation of greening technologies. The potential level and timing of a price on carbon are one of the main uncertainties key stakeholders must consider. While set-based design has been proven within the ship design context, its principles could be extended to apply to a full lifecycle perspective where set convergence could continue after the delivery of a vessel on certain design and operational aspects.

## **Reduce/Control**

Reducing or controlling uncertainty by gaining more information and increasing communication involves using scenario planning integrated into a strategic decision-making framework, data analytics, simulation, and optimization (Garcia Agis, 2020). When attempting to understand and model decision-making under uncertainty, the main goal is to increase knowledge so that uncertainties can be reduced or controlled as best as possible. Two main approaches that have been applied to the maritime decarbonization challenge are the use of scenario thinking and simulation and optimization with sensitivity analysis.

### ***Scenario Thinking***

Scenario thinking evaluates changes in specific values or metrics under different scenarios. For this type of analysis, specific scenarios need to be defined that include different values for defined variables. This could be a baseline scenario, a best-case scenario, and a worst-case scenario, for example. Scenario analysis promotes a holistic big-picture perspective that can focus efforts on important and relevant areas.

Scenario thinking is a tool that helps manage uncertainty by looking into the future and building a structure used to assign priorities (Bentham, 2023a). A good starting point for an individual stakeholder or company is to adapt broad scenario definitions such as those by Lehmacher & Lind (2022) to their specific decision-making situation and circumstances:

- “Storms: A world of nationalism, geopolitical conflicts, and a worsening climate crisis. Both the Paris climate goals and the IMO 2018 decarbonization ambitions are missed.
- Swells: Initially, businesses and governments concentrate on growth and decarbonization advances slowly. Then, as the climate crisis intensifies and disrupts shipping services and ports, quick, abrupt changes are needed and finally initiated. These are costly and cause significant disruptions. Accelerated decarbonization is late but eventually meets the Paris goals...
- Clear Sky: Politicians, business leaders, citizens, and investors worldwide align to meet the Paris climate goals...”

Mestemaker et al. (2020) presented a scenario-based life cycle assessment (LCA) method that incorporated variable fuel prices and emission costs. Scenario thinking has also been associated with improving a business's competitive advantage by acting earlier (Bentham, 2023b).

### ***Simulation and Optimization***

Multi-objective optimization and multi-criteria approaches, decision-support systems, and simulation models have been studied but have not fully addressed the need to move from deterministic to stochastic modeling while managing the increased complexity of the decarbonization problem (Mansouri et al., 2015; Frangopoulos, 2020; Frangopoulos, 2018; Trivyza et al., 2022). Methods like LCA can be used to quantify the environmental impact of a fuel or ship over its lifetime (Trivyza et al., 2022); however, LCA is a deterministic method that does not capture inherent uncertainties, for example, fuel specifications and standards. Typically, LCA is used to calculate the climate impact (in terms of GHG emissions) of an alternative fuel over its lifetime (i.e., WTW emissions).

Various decision-support tools have been developed to help evaluate and compare technologies and their impact on ship design (Robertson et al., 2022). Wei & Liu (2022) proposed a multi-objective optimization method based on a parametric ship model to reduce the negative impact of regulatory uncertainty that identified, in some cases, a ship design can be too eco-friendly based on a given regulatory scheme.

When using optimization methods and simulation models, it is important to incorporate uncertainty either by conducting sensitivity analysis or considering uncertainties during the optimization (Trivyza et al., 2022). Lagemann, Lindstad, et al. (2022) developed a deterministic model to optimize a ship's lifetime fuel and power system but identified that there is significant uncertainty related to the fuel prices and retrofit costs assumed. This highlights the need for sensitivity analysis when utilizing optimization within a decision-making framework. Lagemann et al. (2023) followed up this work with a

two-stage stochastic optimization model that considers uncertain fuel and carbon emission prices while also capturing the ability to convert to other fuels during a vessel's lifetime.

### **Accept/Protect**

Another approach is to accept the uncertainty and develop strategies that can handle uncertainties, including adaptive control, use of margins, resilience, robust design, optimization under uncertainty, Markov Decision Process (MDP), and fuzzy decision support (Garcia Agis, 2020).

Ship design concepts of flexibility/changeability, modularity, and robustness have been studied extensively and demonstrated to be effective under uncertain lifetime conditions (Rehn et al., 2018; Choi et al., 2018; Schank et al., 2016). Lagemann, Erikstad, et al. (2022) describe the introduction of agility as a parameter for fuel-flexible ships, including preparing vessels to be converted later in life. Agility, a characteristic of flexibility and changeability, can help mitigate future unpredictability and uncertainty, for example, related to emission regulation compliance. Niese (2012) introduced a ship-centric MDP (SC-MDP) that can improve early-stage design decisions related to uncertain environmental policy and non-technical disturbances. SC-MDPs are now used in long-term strategic decision-making and can help better understand key decisions (Garcia Agis, 2020). Kana & Harrison (2017) presented a Monte Carlo approach to SC-MDP to analyze whether a containership should convert to LNG to comply with Emission Control Area regulations. The results demonstrated how variations in uncertainties can significantly impact optimal decision strategies.

While most previous case studies have been applied to ballast water treatment and air pollutant emissions like SO<sub>x</sub> and NO<sub>x</sub>, the same methodologies are applicable to the maritime decarbonization challenges today. A good example of this approach is the introduction of dual-fuel internal combustion engines that can utilize a mix of conventional liquid fossil-based fuels as well as alternative fuels like LNG, methanol, and ammonia. While the push for dual-fuel capability is rooted in the need for a pilot fuel for alternative fuels, it provides fuel flexibility that allows the owner to maintain the use of conventional fuels until they want or are required to use alternative fuels.

### **Further Development Areas**

As part of a state-of-the-art review of decision support methods for sustainable ship energy systems, Trivyza et al. (2022) identified eight areas for future research, including uncertainty & stochasticity and the expansion of borders: holistic ship design and supply chain analysis. Trivyza et al. (2022) conclude their paper by noting that the maritime industry faces huge challenges due to the explosion in technological developments, the complexity of marine systems, and its conservatism, all while operating within an environment that is becoming increasingly sensitive and demanding.

While basic frameworks exist to consider maritime decarbonization decision-making under uncertainty, the latest research has also shown a need for further research in certain areas, particularly what decision-making strategies for managing uncertainty should be used for the maritime decarbonization challenge or, more likely, what strategies should be used for certain aspects of the overall challenge and how do they all connect to form an overall strategy. A comprehensive evaluation of ship design strategies and methodologies as they relate to the maritime decarbonization challenge is needed.

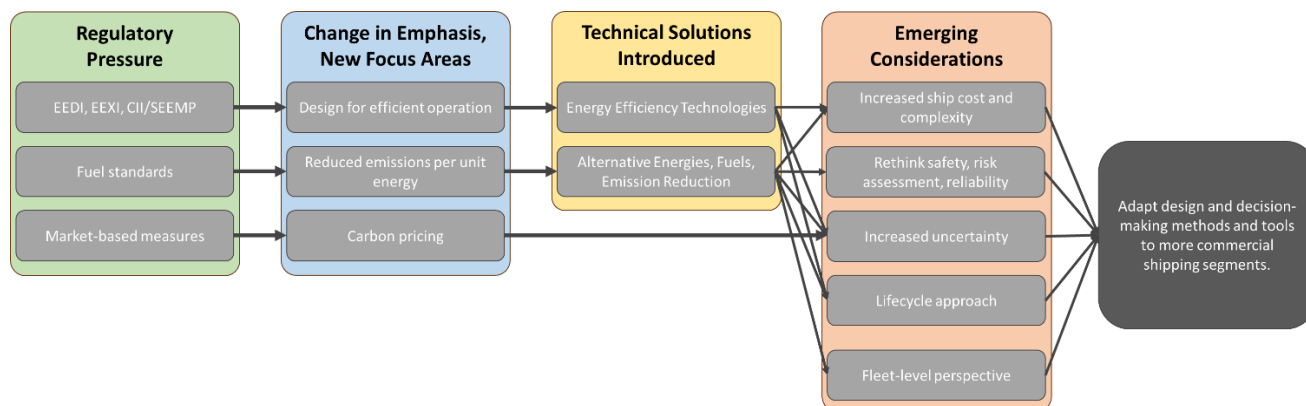

The methods identified above are usually best used to manage decision-making under certain types of uncertainty. This leads to the belief that there will not be one solution that fits all the challenges of the maritime decarbonization problem, but a collection of multiple strategies under an overarching framework. With increased pressure to change the way we have done things for a long time, combined with the increased complexity of the available solutions and the increased uncertainty they bring, there is a need to expand existing design strategies, approaches, methods and decision-support tools to a wider segment of the maritime industry where in the past design has not been a distinguishing or competitive advantage (most focus on producibility). This is a call to action for ship designers, and especially shipyards, to adapt their way of designing commercial vessels.

## **CONCLUSIONS**

Responding effectively to the maritime industry's decarbonization challenge is necessitated by the urgent need to reduce GHG emissions and meet global climate targets, such as the Paris Agreement and the IMO's revised GHG strategy aiming for net-zero emissions by 2050. The maritime industry, traditionally slow to change, must undergo a substantial shift in approach due to the proliferation of alternative fuels and technological options, as well as evolving regulatory, geopolitical, and market conditions.

Figure 3 provides a summary of the maritime decarbonization cause-and-effect chain that can be used to describe the overall challenge and the knock-on effects of maritime decarbonization on ship design. Industry stakeholders, including ship designers and owners, can enhance their methods and decision-making support for ship design and operation, incorporating considerations for a change in emphasis and new focus areas, including design for efficient operation, reduced emissions per unit of energy, and carbon pricing. EETs, alternative energies and fuels, and emission reduction technologies are available or are being developed to help achieve maritime decarbonization; however, they come with emerging economic and technical considerations.

These considerations include increased ship costs and complexity, the need to rethink safety, risk assessments, and reliability, increased uncertainty, the need for a lifecycle approach, and a fleet-level perspective. The significance of emerging economic and technical considerations for shipping segments such as container ships, bulk carriers, and tankers is creating a gap that needs to be filled; a gap that academic research already has the tools to support from experience with more complex ship design activities and decision-making under uncertainty.

**Figure 3: Maritime decarbonization ship design cause-and-effect chain**

To tackle the complexities and uncertainties involved, researchers and industry practitioners must strengthen their collaboration, with each having the ability to provide valuable contributions. Researchers are called upon to ensure applications are addressing the right challenges and utilizing relevant use cases to maximize impact. Practitioners are advised to integrate advanced ship design methods and decision-making processes into their standard operations to manage uncertainties effectively.

Ultimately, there is an imperative for immediate action, suggesting that a combination of regulatory compliance, technical progress, and innovative commercial strategies is essential to decarbonize the maritime industry. Decision-making under uncertainty is an important aspect that requires new strategies, tools, and a holistic approach that includes design, operation, and fleet-level perspectives.

Considering the complexity and dynamic nature of the decarbonization challenge, the maritime industry should employ a blend of strategic approaches to manage uncertainties. It is necessary to continue research in specific areas related to decision-making under uncertainty to better support the industry in reaching its ambitious decarbonization goals.

## **Part 2:**

# **DESIGN METHODOLOGY**

# SATISFACTION OF PASSENGERS – PROCESS COMPARISON BETWEEN TWO CRUISE SHIP CLASSES

Sabina Akter<sup>1,\*</sup> and Jani Romanoff<sup>2</sup>

## ABSTRACT

*In cruise ship design, a ship designer often focuses on the ship's function, while a cruise operator's focus is on the creation of a comfortable and enjoyable cruise experience for passengers. Today, these two viewpoints are strongly connected, and thus, the way the inside of a ship is designed can impact how satisfied passengers are on their cruise journey. Thus, we need to figure out the best way to design a passenger ship from the perspective of the passengers themselves. In this paper, we analyse the differences in the combination passenger ship environmental elements and overall consumer satisfaction in two different cruise ship classes from the same ship operator, but from different eras. First, we present a theoretical framework and model for the cruise ship environment that consist of ambient, layout/design, social, product/service and onboard enjoyment factors. Then, by using data collected from the public domain, we compare two types of cruise ships using open-source data (N=755). This allows us to identify the factors contributing to the discrepancy in expectations across cruise guests. Based on this limited data, we create several linear regression models which indicates a favourable and statistically significant link between environmental elements and passengers' conduct while on board. Information processed this manner can be utilised to make informed decisions on cruise ship layout and amenities. In addition, the developed innovative KPI proved instrumental in influencing decision-making processes related to cruise ship designs and operations. Therefore, the findings from our research show a positive link between the onboard environment and the overall happiness of passengers.*

## KEY WORDS

Cruise class comparison; Process comparison; Onboard environmental factors; Customer Satisfaction; Cruise experience.

## INTRODUCTION

Ships design is determined by their intended purpose or mission. Levander (2004) says that we start making a passenger ship by first understanding the customer's needs or the ship mission. When putting together a ship, different people might focus on different aspects. For instance, a naval architect might concentrate on the cost and how the ship works, while an interior designer might want to make the inside of the ship as pleasant as possible. Thus, we need to fully understand how best to design a passenger ship from a passenger's viewpoint.

Cruise ships are complex and their performance is not measured only by technical key-performance indicators (KPI), but also by cruise travellers' experience. The technical KPIs for cruise ships are well-documented; for example, in the chapter by Levander (2004) in the Ship Design and Construction. These include factors like GT/pax and crew/pax, which directly indicate the quality in terms of volume of the ship per passenger and service per passenger. However, this information is often

too general to provide a descriptive understanding of cruise experience itself and the effect of ship and cruise designs on the overall satisfaction of the passengers.

In recent tourism studies, tourist satisfaction has become the core concept of tourist behavioural studies (Huang et al., 2015). Therefore, cruise passengers, who are a pivotal group in the cruise industry, play a crucial role in the cruise purchasing cycle and thus their behaviour must be better understood. They make purchasing decisions periodically, but from the cruise industry's perspective, it is challenging to track and understand these decision-making processes and identify which aspects no longer satisfy the passengers' needs and expectations. On the other hand, building and maintaining clear lines of communication and transparency within the organization is pivotal to spotting and solving potential problems before they escalate. Routine reporting is advocated to promptly identify and correct performance issues, increasing visibility and accountability throughout project management. Collaboration between experts and customers is crucial for enhancing project outcomes. Ongoing customer feedback is instrumental in refining product quality and meeting customer expectations.

Individuals responsible for decision-making often tend to favour certain evaluative criteria over others. This bias is generally represented through the differential weighting assigned to each criterion. Upon deriving an initial ranking of decisions, these individuals might find it necessary to re-evaluate and adjust their original preferences. The discipline of multiple-criteria decision-making primarily deals with identifying and selecting the best possible choices (Gou et al., 2016). Businesses employ data mining, regression analysis and KPI techniques to discern consumer purchasing behaviours, enabling them to tailor their sales strategies and provide personalised customer services. Data-driven clustering methods are used to truly understand customer behaviour or tendencies. A significant obstacle in this area is the obfuscation of critical information due to its dispersal across the Internet and elsewhere. The exhaustive search for pertinent data is not only time-intensive and resource-consuming but is also frequently unsuccessful due to the vast amounts of irrelevant information. In many advanced organisations, the current strategic focus is on enabling dynamic decision-making. This requires consideration of several key aspects: acquiring and analysing real-time data, understanding the interconnectedness of data sets, and engaging users with data-driven strategic approaches. Analysing consumer behaviour is critical for generating system-driven recommendations in consumer-centric decisions.

Executives must quickly interpret this data, as timely and updated insights are crucial for adapting organizational strategies to meet market demands. Multi-attribute decision-making (MADM) involves selecting the most satisfying option from a range of alternatives, each characterised by specific attributes, a process inherent in human activities (Xu & Zhang, 2013). Therefore, ineffective data communication can lead to an organization's inability to fulfil customer expectations. Sustaining an organization in the contemporary market requires continual evolution and adaptation aimed at customer satisfaction, which necessitates a thorough assessment of organizational processes for effectiveness and efficiency. The present process is highlighted due to its complexity and propensity for errors. Simplifying and streamlining these processes is essential so all stakeholders understand the required actions clearly. An optimised process is anticipated to enhance efficiency, reduce customer complaints, and increase satisfaction for both customers and executives.

The cruise industry requires a systematic approach for continuous improvement, especially concerning passenger decision-making processes and the onboard environment including layout, ambience, service, and social features (see Akter et al. 2021 a and b), see Figure 1. In Figure 1, the entire circle represents overall satisfaction, which is essentially the overall rating of the cruise. The individual segments of the circle represent different aspects of the onboard experience, including ambient conditions, layout and design, social interactions, quality of products and services, and the overall enjoyment. These factors are regarded as independent variables that can influence overall satisfaction, which is considered the dependent variable in this context. Furthermore, it's important to note that the independent variables may vary in their impact based on different scenarios and circumstances (Tsotsou, R. H., & Wirtz, J. 2015; Akter et al., 2021 a).

Currently, the cruise industry heavily relies on the knowledge and skills of senior coordinators of ship design and building, and cruise operations, who process the information, make decisions, and pass on information and expertise to less experienced staff. The cruise experience environmental performance metrics are neither measured nor communicated between the stakeholders and real-time monitoring systems for establishing necessary Key Performance Indicators (KPIs) are not in place. Customer feedback, irregular and potentially biased, serves as the sole source of performance data, offering a view that may be disproportionately positive, neutral, or negative. Identifying customer issues is essential for continuous improvement of the cruise ships. Thus, this study introduces the cruise environment model proposed by Akter et al. (2021 a and b), which encompasses critical components such as ambient, layout/design, social engagement, product/service quality, and onboard enjoyment factors. This paper specifically emphasises the explanation of various environmental elements and the correlation between onboard environmental factors and an evolved Key Performance Indicator (KPI) is determined based on the absolute net score of the customer feedback measured with Likert scale. The computation of the KPI is automated using a standard procedure that processes customer reviews.

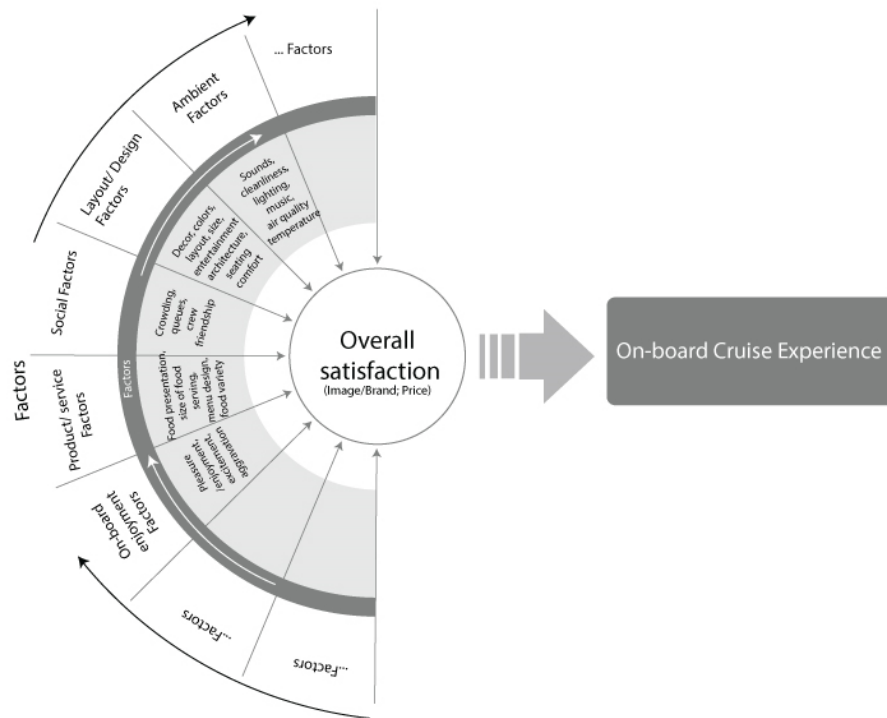

Figure 1: approach to describe onboard environmental factors affecting the onboard experience of cruise passengers' (Akter et al., 2021 a)

## THEORETICAL BACKGROUND

### Process and Key Performance Indicators (KPIs)

**Key Performance Indicators (KPIs)** are set to track and measure the performance of any advanced system. Establishing robust communication and transparency within the organization addresses the challenge of poor information flow, facilitating early problem detection. It is advisable to utilise daily reports to identify and address performance discrepancies quickly. This practice enhances visibility and accountability throughout project implementation. Establishing solid collaboration between experts and customers is crucial. In an organization such as the cruise industry, it is practical for supervisors to regularly update or auto-update projects. A steady flow of customer updates can improve production quality and meet customer demands effectively. Employing Key Performance Indicators (KPIs) is essential for tracking performance metrics. The challenge in cruise ship application is that the performance in service can be changed during and between the cruises, while issues related to the layout can be only significantly changed during ship conversions or dockings. Thus, the KPI developed must account for this bias in implementing corrective measures.

Services should be viewed as processes rather than mere outputs. The three-stage service usage model suggests that customers experience three key phases when using services: pre-purchase, service encounter, and post-encounter (Lovelock and Wirtz 2011; Tsiotsou and Wirtz 2012; Tsiotsou and Wirtz, 2015). Studies have explored each stage to understand their key factors, influences (both direct and indirect), processes, and results (Tsiotsou and Wirtz, 2015).

**The pre-purchase stage:** The pre-purchase phase in service decision-making is notably more intricate than that for products due to a broader range of factors and actions (Fisk 1981; Tsiotsou and Wirtz, 2015). Consumers are active participants in creating the service, so their decision-making process is longer and more complex. Consumer expertise, knowledge, and perceived risk are significant during this initial phase (Tsiotsou and Wirtz, 2015). Services, characterised by their experiential and credence attributes, are typically more challenging for consumers to evaluate before purchase (Mattila and Wirtz 2002; Zeithaml 1981; Tsiotsou and Wirtz, 2015).

**The service encounter stage:** Customers interact with the service provider during the service encounter stage. At this point, customers are not just buyers but active participants, helping to shape their own experiences and the final service delivered while assessing the service quality (Tsiotsou and Wirtz, 2015). Consumer engagement involves actions that show support or criticism of a service, such as giving positive feedback, recommending services to others, assisting fellow customers, blogging, posting reviews, or even taking legal actions (van Doorn et al. 2010). Recent studies highlight that consumer engagement is multifaceted, involving thinking (like being fully absorbed), feeling (such as commitment), and doing (such as energetic participation and interactions) (Brodie et al. 2011; Tsiotsou and Wirtz, 2015). Service encounters offer opportunities

for customers to develop and either positively or negatively enhance their engagement with a service provider (Tsotsou and Wirtz, 2015). These encounters are intricate, involving customer interactions and the setting influencing consumer expectations, contentment, loyalty, intentions to repurchase, and the likelihood of recommending the service to others (Tsotsou and Wirtz, 2015).

**The post-encounter stage:** The final phase of service consumption is the post-encounter stage, which encompasses consumers' behavioural and attitudinal reactions to the service experience. Research in this stage has predominantly focused on consumer satisfaction and perceived service quality due to their significant impact on business performance (Brady and Robertson 2001; Tsotsou and Wirtz, 2015). However, satisfied consumers with high perceptions of service quality may only sometimes become repeat customers or continue using the same service provider (Keiningham and Vavra 2001; Tsotsou and Wirtz, 2015). Therefore, recent consumer research has shifted its focus to other crucial post-purchase outcomes, including perceived service value, consumer delight, how consumers respond to service failures (e.g., complaints and switching behaviour), and how they react to service recovery efforts. This perspective is supported by Tsotsou and Wirtz (2015).

## **Onboard Environment Factors**

The servicescape of a cruise company encompasses a range of physical and social factors. As Bitner (1992) identified, the physical dimensions include ambient conditions, spatial layout, and functionalities, all enriched by various signs, symbols, and artistic elements. Beyond the tangible aspects, the social environment and the sense of enjoyment on board, generated by the interactions of those present on the ship, also play a vital role. Akter et al. (2021 a and b) proposed a categorization that expands this concept to include ambiance, layout/design, social dynamics, product/service quality, onboard enjoyment factors, and the overall satisfaction. These aspects are detailed in Table 1. The ambient conditions, highlighted by Jeon and Jeong (2009), consist of sensory elements such as temperature, colour, lighting, noise, music, and scent. These elements shape customers' perceptions of the cruise service environment.

Functional components such as architectural design, spatial layout, and functionality are essential in-service environments. They dictate the placement and interrelation of items like furniture, equipment, and service areas crucial for exhibitors to deliver services effectively. Such arrangements directly impact customer comfort and their emotional reactions. The physical environment's design, including ambiance, layout, and functionality, significantly influences consumer behaviour toward a service or business. Functionality specifically pertains to the enhancement of the service process and customer experience. Creating a user-friendly setting is crucial for customer satisfaction, as detailed by Rosenbaum and Massiah (2011).

In addition to the physical environment, a customer's decision-making process is also swayed by social elements and the service or product quality (Andersson, 2013). The servicescape model posits that the collective emotions within a service setting are mirrored by the interactions among employees, customers, and the venue's social density (Dad et al., 2016). It has been observed that several product and service dimensions, namely the culinary experience, presentation of dishes, size of servings, menu creativity, diversity of cuisine, and calibre of service, are critical to customer satisfaction (Akter et al., 2021a and b). The factors contributing to pleasure while onboard are linked to emotional states such as happiness, joy, excitement, and overall engagement. It has been further noted that a customer's comprehensive satisfaction correlates with aspects including the nation of service, the establishment's brand image, pricing, symbolic elements, artefacts, and the experience of value for money (Akter et al., 2021a and b), see Table 1.

**Table 1: Attributes of onboard environmental factors and overall satisfaction (extended from Akter et al., 2021a and b)**

<b>Ambient Factors</b>		
	<b>Dimensions</b>	<b>Attributes</b>
	sounds	music /sound effects; audio (music, noise); favourite sounds; auditory cues /elements. (e.g. music, noise; non-musical sound; music/sound effects; background music; both a quiet and loud disco, piano music acoustics, noise/ noise (level, pitch)
	cleanliness	cleanliness (scent, air quality, fragrance); cleanliness: coins, ashtrays, ceiling, machine screens, employees appearance, overall cleanliness; aesthetic cleanliness
	lighting/ light	visual aesthetic (lighting)
	air quality	air quality e.g. temperature, humidity, circulation /ventilation; ambient (temperature)
	odour	aroma/scents; olfactory cues (scent, air quality, fragrance)
	taste/smells	sensory component: seeing, hearing, smelling, touching, tasting; textures
	comfort and discomfort	seating comfort, seating comfort: seat back, elbow room, distance from table, overall comfortableness, easy in and out, comfortable furniture uncomfortable chairs, comfortable workspace
	color	colors used; color schemes; visual aesthetic
	atmosphere	atmosphere refers specifically to relaxing, having fun, home- and country-specific
	visual attractiveness	quality photos, animation effects, virtual tour; visual (e.g. lighting, colors, brightness, shapes visual aesthetic (shapes); materials sensory elements e.g. color, light, texture; variety, uniqueness, quality
<b>Layout/design factors</b>		
	<b>Dimensions</b>	<b>Attributes</b>
	style of décor	interior décor; design; interior design e.g. layout/ store layout/layout accessibility/overall structure/layout; design characteristics e.g. form, size, texture, animation; décor e.g., furniture, fixtures, artifact; the design of the outdoor areas, and a calm experience; separate design area for all age groups; classical and stylish restaurants; interior (design, equipment, furniture, layout); design factors: floor and carpet, aisle width, wall composition, paint and wallpaper, ceiling composition, merchandise, layout, drink placement, bar placement, cash register placement, waiting areas, waiting rooms, dance floor locations, traffic flow, queues, furniture, point of purchase displays, signs and cards, wall decoration, license and certificates, artwork, product displays, price displays, entrances; furniture; arrangement of furniture equipment; interior décor: background colors, electric signs design, wall treatment design, floor treatment design, overall design attractiveness; the design of the outdoor areas, and a calm experience; exterior factors: exterior signs, display windows, surrounding stores, address and location, architectural style, surrounding area, parking, exterior walls; luxuriously styled areas such as large windows provide a unique and beautiful panoramic view of the sea; ocean-view balconies; perceived services cape for exterior (external) variables e.g. entrance, parking, architecture, design, exterior design, surrounding area location and so on; landscape, architecture, parking; design and arrangement of buildings
	colours/ style of décor (incl. colour)	architecture, color; aesthetic e.g. color, style; aesthetic e.g.materials décor
	scale/size	shape, room/cabin size, spacious, modern and comfortable cabins; aesthetic e.g. scale shape: spacious, modern and comfortable cabins; space/function; shapes, symbols; signs, symbols and artefacts e.g. signage/ directional signage; informational signage, interpretational signage; personal artifacts
	architectural entertainment	product/service: room, restaurant, ball room, fitness center, kids center, uniqueness/hotel, resort, boutiques, and galleries; bathroom: bath, shower; basic amenities; considerations: non-smoking, swimming pool, high speed internet, fitness center, pet

		allowance, promenade and comfort; object-based authenticity: architecture impression, peculiarities of interior design, attractive historical town, heritage information; architecture; aesthetic e.g. architecture
	comfort or arrangement of seating	uncomfortable chairs, comfortable workspace
	space/function/layout and quality	layout e.g. easy to move, convenience; overall structure; traffic flow; way finding; quality of product: form, quality of performance, durability, design; assortment e.g. variety, uniqueness, quality; more single seating, more group seating, separate design area for all age groups; aesthetic e.g. texture, pattern; product display; overall structure/layout, navigation, way finding, the nine-story atrium, direct access to the spa, ocean-view balconies; use of space, space/function; need enough workspace; alternative space solutions; space/function consists of layout, equipment and furnishing; accessories-functional e.g., layout, comfort, signage, accessories
	product/furniture/displays	product display; furnishings; product assortment; amenities (tools, IT, equipment); equipment/ electric equipment and display/dining equipment; equipment, space/function: lounge (socializing), kitchen, toilet/shower, equipment (XX); furnishings, spatial crowding
<b>Social factors</b>		
	<b>Dimensions</b>	<b>Attributes</b>
	crowding	the level of crowd, the type of crowd; lack of privacy
	queues	front desk/check in
	friendliness of the crew	staff: attitude, enthusiasm, politeness, courteous, commitment, friendliness, staff quality; staff behaviour: customer orientation credibility; suitable behaviour; friendly staff, helpful staff, personalized, always there employee response: enjoy working and helping guests, feel happy; the nature of interactions; personal service; crew members' language skills and communication
	embarkation experience (employee-customer support, customer-to-customer interaction)	crew members' communication; friendly, helpful, happy, always look happy, cozy and welcoming atmosphere, homelike, security; privacy; personal service; crew members' language skills and communication; customer: being friendly with other guests; number, type and behaviour of customers and employees; customers: customer types, number, appearance; employees: service, personal, number, appearance, uniforms; customers' image, employees' image; social interactions between and among customers and employees; employees, customers, social density, displayed emotions of others; verbal interaction; interaction with others; reference groups, reviews; seeing others as motivation, others as distraction; social scape: social relationship; displayed emotions of others (emotional contagion); service relationship; in between salespeople relationship quality, salespeople store manager relationship quality; surroundings: couple-friendly, children-friendly; maintenance standard; employees' good/bad lookin; employees: service, personal, number, appearance, uniforms, physical appearance, both casual and formal attire with some preferring more casual dress; staff image: competence physical attractiveness, in addition, personal service: both casual and formal attire with some preferring more casual dress
<b>Product/service factors</b>		
	<b>Dimensions</b>	<b>Attributes</b>
	food quality	food and service experience refer specifically to food quality: delicious food and beverages
	food variety	food variety: in culinary terms such as offering many choices, cuisine offering almost all tastes, offering a '50s-style diner, American fast food, serving a variety of coffees, offering Italian food with five different restaurants, 12-13 bars with a wide variety of beverages
	food presentation	food presentation: providing different possibilities for enjoying food, providing the panoramic views through the meter-high glass; the size of food servings, menu design, the variety of food, food experience, variety, uniqueness,
	service experience	offers personal, friendly, professional and 24-hour free cabin service, etc.; service interface: service person (customer room service), technological support, call center, service guarantee, facility, security; service experience of expenses on-board refer specifically to the cost of a bottle of wine around 22 USD and above; passengers need to pay 11 and 12 USD as a service charge per day; additional charge for a table reservation, private experience, and private chef facilities; a service charge added to the

		drink prices ; whereas no additional charge for a pizzeria or sea view café ; an extra charge for breakfast in the cabin, and so on ; product/product characteristics: convenience vs. specialty, durable vs. nondurable; mattress, pillow comfort; complementary product, material; price (expensive, discounted, or affordable); additional charge; Environment -approval, others e.g. customer service, window display
	serviceability factor	convenience in layout, privacy, communication, w/staff wayfinding, cleanliness.
	Service encounter	service encounter- product quality e.g. variety /choice; value for money
	perceived serviceability	way finding, privacy protection, comfortable furniture, conduciveness to communication with staff, convenient layout
<b>On-board enjoyment factors</b>		
	<b>Dimensions</b>	<b>Attributes</b>
	pleasure or enjoyment; entertainment/emotional experience	entertainment experience activity includes a surf simulator; a romp in the aqua park; bathing in two whirlpools that hang XX metres above the sea; a sky pad virtual reality experience; a glow-in-the-dark laser tag facility; the “perfect storm” waterslide trio for all water lovers aboard; wall climbing; swimming pool; long water slide; sauna; mini-golf; enjoying fascinating shows; a 4d cinema; escape room; musical evenings; musical evenings; big casino; a disco; many bars; art auctions and has around XX paintings and sculptures; classic bingo games and lectures; various shops to avoid boredom, and so on; excitement, aggravation; consumer attitudes: innovativeness; variety, uniqueness, quality
	sports, fitness, and wellness	entertainment experience activity includes sports, fitness, and wellness refer specifically to sports and leisure activities for people of all age groups, or mostly focuses on younger groups of people; inside and outside the sports court; fitness gyms; a spa offering many different treatments for fees; a spacious fitness area with a splendid ocean view; a pool with a relaxation area; fitness centre and courses, XX square metres of facilities for wellness and relaxation; a large samsara spa and treatments, and so on
<b>Overall satisfaction</b>		
	<b>Dimensions</b>	<b>Attributes</b>
	country image or brand	cruise brands (an American or an Italian or other); includes a brand with an incredible history; the image of the country of its builders (Finland, German, Italy, other etc.); preferably focusing on all age groups or a mostly younger group of people; family-friendly ships; largest cruise ship; utility: market value brand, term and conditions, location convenience, price range, reputation, overall quality, risk management, trust, security
	price/ cost experience	price: discount, price conformity to product quality; cost experience; such as a good return on value for money, ticket price; choice: comparison, star-ratings, pictures, sorting facility, reviews, offers; in details, price e.g. loyalty program, member card, events program, advertisement; in details, promotion e.g. advertisement, sales promotion, personal selling, public relation; customer relationship: loyalty program, previous usage experience; consumer attitudes (e.g., price sensitivity, involvement, innovativeness)
	sign, symbol and artefacts	such as a slow cruise, a real adventure; often feeling as if the passengers are on board a floating city; physical clues; maps and painting; search aids & slogans: keywords, meta-tag, slogans
	approach/avoidance	switching behaviour, switching intent; customers e.g. individual response - approach e.g. affiliation, exploration, stay longer, commitment, carry out plan avoid

## MODEL AND RESEARCH METHODOLOGY

To examine the environmental factors affecting the onboard customer experience, Akter et al., (2021a and b) have identified following key factors: ambient, layout/design, social, product/service, and onboard enjoyment factors that result in overall satisfaction. To connect the passenger overall satisfaction to these elements of design, we have sorted the questions of one openly available website CruiseCritic according to these dimensions. The questions used on the website are about cabin quality, public rooms, family, embarkation, dining, service, value for money, entertainment, fitness and recreation and overall satisfaction. The questionnaire is divided into six sections. The questions of the first factor are related to *ambient factors* such as sounds, cleanliness, lighting, music, temperature, air quality, odour, etc., which impact the question related to, for instance, the cabin and public rooms. On the other hand, the *layout/design* factors of the cruise consisted of interior design, entertainment architecture, etc., which in turn impact questions about cabin, public rooms, family. Moreover, the *social factors* of the cruise consist of crowding, queues, crew friendship, embarkation experience, etc., influence questions about embarkation procedures and family interactions. *Product/service* factors of the cruise involve food experience, service experience, etc., which refer to questions regarding dining, service, and value for money. *Onboard enjoyment* factors of the cruise lie in pleasure or enjoyment, excitement, aggravation, entertainment experience, etc., referring to the questions regarding entertainment and fitness and recreation. In addition, factors contributing to *overall customer* satisfaction include the country image or brand and price, etc., impacting questions regarding questions about overall satisfaction and value for money. Respondents were requested to provide their agreement level of each item on a five-point Likert scale, where 1 is considered "strongly disagree," and 5 is "strongly agree. The answers were weighted as arithmetic means of the scores of the sub questions." The overall passengers' satisfaction is modelled with a regression model:

$$Y_s = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \beta_5 X_5 + e \quad [1]$$

where  $Y_s$  = tourists' overall level of satisfaction,  $\beta_0$  = constant (coefficient of intercept),  $X_1$  = ambient;  $X_2$  = layout/design;  $X_3$  = social;  $X_4$  = product/service and  $X_5$  = onboard enjoyment factors;  $\beta_1, \dots, \beta_5$  = regression coefficients and  $e$  = error term. We use the data from two ship classes from Royal Caribbean Cruise Lines: Freedom (3 ships, built 2006-2008) and Radiance class ships (4 ships, built 2001-2004). The ships present different eras of design and sizes, see for technical details and KPI's (crew to passenger, GT to passenger and stateroom to passenger -ratio) Table 3.

**Table 2: Onboard environmental factors for cruise- Freedom and Radiance class effects on the onboard cruise experience**

Factors	Dimensions	Case company's elements	Questions number
Ambient Factors	Sounds, cleanliness, lighting, music, temperature, air quality, odour, and so on	cabin, public rooms	1A, 1B
Layout/design Factors	Style of décor, colours, size, architectural entertainment, the comfort or the arrangement of seating	cabin, public rooms, family	2A, 2B, 2C
Social Factors	Crowding, queues, the friendliness of the crew, embarkation experience	embarkation, family	3A, 3B
Product/service Factors	Food presentation, the size of food servings, menu design, food variety, food experience and food quality; service, service experience provided by companies	dining, service, value for money	4A, 4B, 4C
Onboard enjoyment Factors	Pleasure or enjoyment, excitement, aggravation, emotional response, emotional experience, entertainment experience	entertainment, fitness and recreation	5A, 5B
Overall satisfaction	Country image or brand, sign, symbol and artefacts; price, cost experience	overall, value for money	6A, 6B

## DATA ANALYSIS AND DISCUSSION

Freedom class had 385 respondents (Freedom of the Seas 105, Liberty of the Seas 127, Independence of the Seas 153), and Radiance class, 370 respondents (Radiance of the Seas 62, Brilliance of the Seas 72, Serenade of the Seas 115, Jewel of the Seas 121), from the Cruisecritic website covering the period from January 1st 2019 to October 26th 2022 (total 773 respondents). The cruise company pays close attention to various aspects of the onboard cruise experience, such as cabin quality, public rooms, family, embarkation, dining, service, value for money, entertainment, fitness and recreation, and overall satisfaction. While some of questions may be related and interconnected, they are crucial for evaluating different aspects of the cruise experience and the overall process satisfaction. The post-travel experience per onboard environmental factors is summarised in Appendix and Figure 2. The regression model parameters are summarised in see Table 4.

**Figure 2: summary the post-cruise experience data observed in the two case ships' classes**

In the category of "**ambient factors**," it is apparent that the, older and in terms of size smaller, Radiance class ships received slightly lower customer satisfaction scores than those of the Freedom class at the scale of between 5 and 4. Notably, Submitted: 5 February 2024, Revised: 17 April 2024, Accepted: 1 May 2024, Published: 24 May 2024  
©2024 published by TU Delft OPEN Publishing on behalf of the authors. This work is licensed under CC-BY-4.0.  
Conference paper, DOI: <https://doi.org/10.59490/imdc.2024.892> e-ISSN: 3050-486

the number of passengers rating their satisfaction at the higher end of the scale (5) increased for both the Freedom and Radiance classes, with a larger concentration of Radiance class customers assigning a rating of 3 compared to Freedom class. Conversely, both ship classes recorded a substantial tally of lower-end scores, between 1 and 2, signalling customer dissatisfaction.

The newer Freedom class ships outperformed, with a notable 41% of respondents rating their satisfaction with **“layout/design”** at level 4. The Radiance class, while also receiving a significant positive response, peaked at 39% respondents giving a score of 4. However, the Freedom class ships were marked by a larger proportion, 10%, of responses at the lower satisfaction level 2, signifying a measure of discontent. Across both classes, there was a pronounced trend of passenger opinions favouring the higher end of the satisfaction scale (5).

From the gathered data, it is evident that **“social aspects”** were highly rated, with the Radiance class receiving a peak of 56% responses at the highest satisfaction level 5, followed by the Freedom-class with 27% respondents also giving a score of 5. Moreover, the distribution of responses shows a noticeable number of low-end ratings, suggesting some passengers experienced dissatisfaction. Notably, when considering the mid-range satisfaction level 3, passengers in the Freedom class exhibited a marginally higher contentment than those in the Radiance class.

Regarding **“product/service”** factors, the scores are more equal, with 40% and 39% passengers rating their experience at the satisfaction level 4 and equal scores of 23% at the highest level of 5. This indicates that the crew operations are almost equal and thus the age and size of the ship seems not to correlate with the ratings. Despite this, the Freedom class ships observed a larger share of lower ratings, specifically level 1, suggesting higher dissatisfaction among its passengers than those on the Radiance class ships.

In terms of **“onboard enjoyment”** factors, analysis reveals that the Freedom class ships receive, as a newer ship, many positive responses, with 39% of guests rating their satisfaction at level 4 and 22% on the level 5. The Radiance class also attained a robust satisfaction score, with 33% of guests granting a level 4 rating. Additionally, the Freedom class ships recorded fewer low-end ratings, between 1 and 2, indicating a generally satisfactory experience among its passengers.

Finally, the element of **“overall satisfaction”**: Regarding "overall satisfaction," the figures reveal that the Radiance class notched up 36% high-level satisfaction responses (scores of 4), while the Freedom class had a corresponding value of 35%. Both classes recorded a notable cluster of responses at the satisfactory level of 5, which amounted 24%. Comparatively, the Radiance class had fewer low-end ratings, indicative of a more satisfying passenger experience than the Freedom class, which displayed greater dissatisfaction overall (see Appendix).

**Table 4: Implementation of the Equations**

<i>Freedom class,</i> Model: Overall satisfaction = -1.114 + 0.42 Layout/design factors +0.59 product/service factors +0.21 onboard enjoyment factors +error.	Shares of Contributing Environmental Factors +59%, in product/service factors (e.g., dining, service) +42% layout/design factors (e.g., cabin, public rooms) +21%, onboard enjoyment factors (e.g., entertainment)
<i>Radiance class,</i> Model: Overall satisfaction = -0.758 + 0.32 Layout/design factors +0.68 product/service factors +0.16 onboard enjoyment factors +error.	+68%, in product/service factors (e.g., dining, service) +32% layout/design factors (e.g., cabin, public rooms) +16%, onboard enjoyment factors (e.g., entertainment)
<i>Freedom and Radiance class together,</i> Model: Overall satisfaction = -1,005 + 0.35 Layout/design factors + 0.06 social factors + 0.61product/service factors + 0.19 onboard enjoyment factors +error.	+61%, in product/service factors (e.g., dining, service) +35% layout/design factors (e.g., cabin, public rooms) +19%, onboard enjoyment factors (e.g., entertainment) +6%, social factors (e.g., embarkation, family)

**Figure 3:** A proposed model of user motion to describe factors affecting the onboard experience in “Freedom and Radiance class”.

As Table 4 indicates, the proposed environmental framework, and resulting regression model can be used to describe the ratio of ambient, layout/design, social, product/service, and onboard enjoyment factors on the overall satisfaction, see Figure 3 for Freedom and Radiance class separately and together. In Freedom class, 59% is the factor for the product/service factors, 42% for the layout/design factors, and 21% for the onboard enjoyment factors respectively; neglecting the effects of ambience and social factors completely. On the other hand, in Radiance class 68% is the factor for the product/service factors, 32% for the layout/design factors, and 16% for the onboard enjoyment factors; again neglecting the effects of ambience and social factors. In contrast, when the two ship classes, Freedom and Radiance are considered together, the resulting factors are 61% in product/service factors, 35% in layout/design factors, 19% in onboard enjoyment factors, and 6% in social factors respectively; this time only ambience neglected in the regression model. When using the model, comparing performance before and after making improvements and conversion in the layout, service etc is essential to evaluate how effective these improvements are in practice. Thus, the regression model proposed needs updates and new data after improvements. Here, Key Performance Indicators (KPIs) Tables 1 and 2 are set up for the purpose of continuous enhancement and commitment to quality. Employing KPIs is crucial for tracking performance, increasing productivity, and ensuring that operations align with the organization's larger goals. Based on these critical success factors' affected ratio, decision-makers can focus on further development and acquiring more information, continuing this analysis to determine areas for improvement.

## CONCLUSIONS

There has been a growing need for data mining and knowledge management (KPI) techniques to uncover and utilise the insights hidden within large volumes of stored data. This study investigated how different onboard environmental factors, including the ambient, layout/design, social elements, products/services, and entertainment, relate to overall passenger satisfaction after the cruise. The Key Performance Indicators (KPIs) were derived based on these elements. Based on the data from a public website, a simple regression model was derived for two cruise ship classes from the same operator. The resulting regression models were found to be different when ship classes were treated separately or together. In the newer ship class, the layout/design and onboard enjoyment factors dominated the overall satisfaction, while in the older ship class, product/service factors dominated. This indicates that the operators should change their strategy in securing customers' overall satisfaction as new ship classes enter their fleet. In both cases, the ambient and social factors were less significant contributors to overall satisfaction; in the

case where the ship classes were combined social factors became somewhat important. When the data changes, this conclusion can naturally change.

To discover customer behaviour or tendencies, data-driven regression methods should be exposed to large data sets from public and company databases. However, the data set used in this paper shows the potential of the proposed model in helping the decision-makers plan their actions related to the ship design, conversions/maintenance, and operations. Implementing the proposed model to larger data sets is left for future work, which should be done in the industry rather than academia due to sensitive source information.

# An Overview of Digital Engineering Methods for Platform Integration of Power and Energy Systems

Robert M. Ames<sup>1</sup>, Dr. Norbert H. Doerry<sup>1</sup>, Madeleine M. Koerner<sup>1</sup> and Dr. Mark A. Parsons<sup>2,\*</sup>

## ABSTRACT

*US Navy ships, and combatant ships in particular, have requirements for integrated systems that are designed and configured for operational efficiency, redundancy, and survivability. Mission systems today and in the future will not always come with their own energy and many may, at times, require extreme pulse power loads. In addition, the migration away from fossil fuels to hybrid systems with energy storage, or the requirements for autonomous platforms, is challenging our ability to design platforms for these systems. Understanding the interdependencies between components, the systems they support, and the energy domains they are member of is a critical ontological design requirement. This paper will address how we applied digital engineering principles and computer science to the design of ontologies that allow for the modeling of complex operational systems riding on the same shipboard energy network. This system network must support varying levels of detail needed during design while at the same time understanding the impacts of that design on ship system operations and their energy loads over time.*

## KEY WORDS

Design, Power, Energy, Ontology, System

## DEFINITIONS

**Capability** - The ability to achieve a desired effect under specified performance standards and conditions through combinations of ways and means [activities and resources] to perform a set of activities. Capabilities are only described in the abstract and does not specify how a capability is to be implemented. A Capability is structured as a hierarchy of Capabilities, with the most general at the root and most specific at the leaves. At the leaf-level, Capabilities may have a measure specified, along with an environmental condition for the measure.

**Component** – A Component class represents objects that can be thought of as parts of a Concept. They may be connected in ways that provide function and capability. Components can be thought of as any part of a ship that represents something physical and as discrete as a radar or engine, or as abstract as proxy for something temporal or needing further refinement. A Component is in many ways just a small Concept, but it is modeled as something a Concept owns. A Component does not have their own Systems, but Components do have most of everything a Concept does.

**Concept** - A class that defines the attributes, the Systems, the Components and the views of geometry that represents a product in design or under study. It is generic to all things engineered, but is used here to define platforms such as a ship, submarine, aircraft, or other engineered product.

**Connection** - The Connection class provides information on how the contained Component, System, Node, and Connection objects are connected (i). Connections are logical relationship between connection members (Component, System, Node, and other Connections).

**Diagram** - The Diagram class provides the schematic information that defines a connected graph or network. Diagrams can define a connected network between Components, within a Component, and a Connection between Components and Concept structure.

**Domain Network**– A Domain Network is a domain specific subset of the total Energy Network. Domain Networks facilitate the distribution of energy specific to its domain type. Domain types include, but are not limited to, electric, fluid, thermal, chemical, magnetic, structural, and mechanical. Each Domain Network is capable of energy transfer (work) within the Energy Network. Components may participate in zero or more Domain Networks. A Component can be both a Domain Source and a Domain Sink (e.g. battery). The Domain Network does not formalize energy flow, it only defines its possible boundaries.

---

<sup>1</sup> Naval Architecture and Engineering, Naval Surface Warfare Center Carderock, Bethesda, MD, USA

<sup>2</sup> Surface Ship Design and Systems Engineering, Naval Sea Systems Command, Washington DC, USA

**Domain Sink** – A Domain Sink is defined as a domain terminus. The Domain Sink is the last Component specific to a domain that is exclusive of any energy process outside of the sink Component. If the domain is electric, then a radar, light, or motor could be examples of Domain Sinks.

**Domain Source** – A Domain Source is defined as the source of energy specific to a particular domain. The Domain Source is the first Component specific to that domain that is exclusive of any energy transfer process outside of the Component. For example, if the domain is electric then a generator, solar panel, or fuel cell may be the Domain Source.

**Energy Network** – A Diagram defining an interconnected network of Components and Energy Resources that facilitate the distribution of energy throughout the Concept. Energy Networks are bounded by Primary Energy Resources at one end and the Natural Environment on the other. Within the network, energy is transferred from sources (Primary Energy Network) to sinks (Operational Energy Sink). Energy Networks are defined as Connections between Concept and Component via their respective Connections.

**Energy Resource** – An Energy Resource is something that can produce electricity, move objects, generate heat, and power and sustain life. Most shipboard energy today is matter stored energy from the Natural Environment. Forms of Energy Resources include, but are not limited to, fossil fuel, nuclear (fusion or solar, fission), energy stored in chemical bonds used in Components like fuel cells, and biomass.

**Manmade Energy Resource** – Manmade Energy Resources are Components that exist by design as sources of energy. They are not natural. Examples include, but are not limited to, batteries, capacitors, and flywheels. Manmade Energy Resources can be either primary or secondary resources depending on their configuration in the Energy Network and their intended use.

**Natural Energy Resource** – Natural Energy Resources are resources used in the conversion of energy and are extracted from the environment. They may be stored on the platform (e.g. fuel) or extracted from the environment during operation (e.g. solar). They include, but are not limited to, fossil fuels, wind, solar, natural gas, oxygen, uranium, and hydrogen.

**Natural Energy Resource Storage** - Some Natural Energy Resources are stored and consumed by the Concept (e.g. fuel, natural gas, uranium, hydrogen). This does not include Natural Energy Resources that are available through the environment (e.g. oxygen, wind, solar). In some cases, this storage exists within a Component and other cases it is stored in a compartment of space of a vessel.

**Natural Environment** – The Natural Environment is everything that is not owned by the Concept and is not an engineered physical thing. In contrast to the Natural Environment is the build environment. For a vessel operating in the real world, the Natural Environment includes everything that is in nature. This includes people. All elements of the Natural Environment are temporal. They can pass through and around Systems and Components within a Concept (e.g. crew, water, air, light, etc.) and can be stored, consumed, and replenished (e.g. potable water, fossil fuel, etc.) Note: Chemical and biological engineering cross the boundary between natural and man-made. Fossil fuel is a good example. Within this ontology, chemically engineered products like fuel or the generation of potable water from seawater are considered part of the Natural Environment.

**Node** - The Node class represents a location in space either relative to the Concept or relative to a Component. Nodes can be defined in Cartesian space, or they can be defined as a location in relative space (meaning, a Node can be defined as a location on a surface or curve of another object). The surface or curve can be owned by a Concept or a Component.

**Non-Operational Energy Sink** – A Non-Operational Energy Sink is like an Operational Energy Sink but it does not provide an Operational Capability. Non-Operational Energy Sinks include, but are not limited to, Components that reject significant amounts of energy like waste heat to the environment. An exhaust uptake is a good example. Since most Components transfer heat into the environment, Non-Operational Energy Sinks are differentiated by the need to network certain Components to the Energy Network for design reasons and simulate the transfer of energy to the environment through these Components. They are significant to the ship design and are therefore significant to the definition of the Energy Network. In theory, all Components store or transmit energy in some capacity and can participate as passive energy emitters into the Natural Environment (e.g. a Component's thermal energy emitted to a compartment). For purposes in modeling efficiency, not all non-operational energy emitters need to be designated as a Non-Operational Energy Sink. Only the ones that have significant impact at that stage of design.

**Operational Capability** - An Operational Capability is a Capability of a System to perform a mission, operation, or function in the intended environment. An Operational Capability is a specific type of Capability.

**Operational Energy Sink** – An Operational Energy Sink is a Component that transforms energy for the purpose of providing one or more Operational Capabilities. One or more Operational Sink Components can have direct or indirect relationships with Operational Capabilities through System Function Actions. An Operational Sink can be as complex as a weapon or sensor, or as simple as a light fixture. For example, a radar is an Operational Energy Sink that provides detection through the conversion of electrical and thermal energy into heat and radio waves. This energy is transmitted off the platform and is therefore considered an energy sink. A multi-function radar can also provide communications and Electronic Warfare (EW) functions. Because this Component is multi-functional, it has multiple System Function Actions which provide multiple Operational Capabilities. It is the System Function Action that provides the functions and properties that describe and define how the Operational Energy Sink(s) behave as needed to provide an Operational Capability.

**Primary Energy Resources** – Primary Energy Resources are the sole originating source of energy for the platform. Primary Energy Resources may be a Natural Energy Resource or a Manmade Energy Resource.

**Secondary Energy Resources** - Secondary Energy Resources are Manmade Energy Resources that provide energy to the Energy Network but are replenished from some Primary Energy Resource. Examples include, but are not limited to, an electric battery, flywheel, or capacitor Components.

**System** – A collection of connected Components and Energy Resources that support one or more Operational Capabilities. Systems are defined as the aggregation of all Components that are involved in providing energy to Operational Energy Sinks. Systems are bounded at one end by Operational and Non-Operational Energy Sink Components and all Primary Energy Resources necessary for the System to function at the other end. Systems interact and operate along Energy Networks and may involve one or more Energy Domains.

**System Domain:** A System Domain is defined as all the Components of a System in a Domain Network for a particular System. It is a subset of the Energy Domain specific to a System. The electric Energy Domain of a propulsion System is an example. The mechanical Energy Domain for the same System is another.

**System Information Networks:** A System Information Network communicates data for the purpose of System monitoring and control. This network may be a subset of a larger network that serves additional capabilities outside of System control. An Information Network includes all the Components necessary to generate information and move that information from the information sources to the information sinks. In many cases, information sources and information sinks could be associated with the same component – (an HMI, engine order telegraph, telephone for example); or they could only be an information source (a sensor) or an information sink (an actuator or display). The System Information Network influences how the Components of the Energy Network operate, and thus should be modeled to some degree. In some cases, the System Information Network includes properties of the energy – voltage level at the bus for reactive power sharing .... Frequency for real power sharing, I2t for circuit protection coordination, etc.) Connections within System Information Networks are logical and from a modeling perspective do not include the transfer of energy; the law of energy conservation does not apply.

**System Function Action** - A System Function Action defines the action of an Operational Energy Sink needed to support an Operational Capability.

## **INTRODUCTION**

Electric cars, renewable energy, autonomous vehicles, and consumer electronics are evidence that a new power and energy future is emerging in the civilian and military worlds. In the naval world, recent developments in weapon systems have delivered the next-generation in defense capability, and these systems are challenging existing ship design practices, theory, and engineering tools. Like hybrid or all-electric cars, Navy ships are moving to a new paradigm where electric power and energy supply are directly related to ship performance (Ames, R., 2016). In non-military applications, Yara Birkeland, developed by Yara International, is an autonomous, fully electric-powered container ship. She has a 7MWh battery, charged by Norwegian hydropower. In today's environment, everyone wants high-power density, energy-efficient systems, speed, control, survivability, and upgradeability—all at an affordable price in a functional package. For naval applications, the promise of these new systems is so compelling that it will set the stage for warships for the next 50 years and push naval design toward a future centered around high levels of power and energy that can be directed wherever it is needed, whenever it is required.

This new future will require power architectures that include energy storage, thermal management, and specialized power converters. For any future ship design activity, engineers, and the tools they use to design these Energy Networks, must understand the boundaries of what defines a system, how systems use energy, and how that energy is transferred and transformed (Ames, R. et al., 2018).

Ontologies are crucial for software applications as they provide a common vocabulary and relational structure to ensure a shared understanding of information structures. In the case of naval ships, it becomes even more critical to understand the interdependencies between ship Components, the Systems they support, and the Energy Domains they belong to. This understanding is necessary due to the complexity and diversity of the missions naval ships must support. Precise and sophisticated design and analysis are required at an early stage of design to ensure that ship designs meet their naval requirements.

To support these analyses, a comprehensive data model is needed to understand each ship System, its functionality, capabilities, and dependency within the full ship Energy Network. This necessitates an understanding of energy within a Component, between Components, and within a Energy Network of connected Components. Controlling this energy is vital to providing Operational Capabilities and meeting survivability requirements.

This paper will address how we applied digital engineering principles and computer science to designing ontologies that allow for the modeling of complex operational systems riding on the same shipboard Energy Network. This Energy Network must support varying levels of detail needed during design while at the same time giving insight into the impacts of that design on ship system operations and their energy loads over time.

An ontology precisely describes how Concepts can be decomposed into Systems and Components and how those Systems and Components are connected as part of networks. Well-defined ontologies are important to enable multiple design tools to unambiguously have a common understanding of a share Concept data model. See Noy and McGuinness 2001 for a complete description of ontologies and the ontology development process. The ontology described in this paper is being implemented through evolving the class structures of the Leading Edge Architecture for Prototyping Systems (LEAPS) in support of FOCUS. FOCUS is the US Navy-managed ship-specific ontology shared among multiple ship design tools. It is also an acronym for Formal Object Classification for Understanding Ships.

The bulk of the work in ontology building is to make sure that the definitions are sound. In some ways, the true output of this paper is the definitions. It is suggested that the reader refer to the definitions section often as they progress through the paper. Capitalized words in this document indicate that they are being used according to their respective definitions.

## **SYSTEMS AND ENERGY NETWORKS**

The relationship between Capabilities, Energy Networks, and operational Systems forms the foundation of the developed ontology. Wikipedia defines a System as; "... a group of interacting or interrelated elements that act according to a set of rules to form a unified whole. A System, surrounded and influenced by its environment, is described by its boundaries, structure, and purpose and is expressed in its functioning." In our ontology, a ship System represents a collection of interconnected Components and subsystems that work together to perform a specific function or set of functions that provide Operational Capabilities. We define a Capability as the ability to achieve a desired effect under specified performance standards and conditions through combinations of ways and means [activities and resources] to perform a set of activities. The boundaries of a ship System are expressed by the System's Capabilities to the operator at one end, and the energy source needed to function on the other. A System uses an Energy Network.

Illustrated in Figures 1 through 4 are simple schematic representations of an IPS propulsion System that spans three Energy Domains: electrical, mechanical, and fluid. We define a System, such as this propulsion System, as a collection of Components and Energy Resources that support one or more Operational Capabilities. An Operational Capability is the Capability of a System to perform a mission, operation, or function in the intended environment. In the case of our propulsion system below, the Capability supported is mobility – power is provided to the propellers and forward pod such that the ship can move from point A to point B.

Systems are bounded at one end by Operational Energy Sinks and on the other end by the Energy Resources necessary for the System to function. Energy sinks are Components that transfer energy into the Natural Environment. Operational Energy Sinks transform energy to provide one or more Operational Capabilities. Non-Operational Energy Sinks transfer significant amounts of energy to the Natural Environment but do not provide an Operational Capability. The seawater cooling outlets in Figure 4 are examples of Non-Operational Energy Sinks; they reject energy as waste heat into the environment. The propellers and the pod in Figure 2 are Operational Energy Sinks. The generator sets in Figure 1 are Electrical Domain Energy Sources. A Domain Source is the energy source specific to a particular Energy Domain. The Domain Source is the first Component specific to that domain that is exclusive of any energy transfer process outside the Component. A Domain Sink is defined as a domain terminus. The Domain Sink is the last Component specific to a domain exclusive to any energy process outside of the sink Component. Each propeller in Figure 2 is an example of a mechanical Domain Sink.

The Primary Energy Resource for the System is the fuel in the tank (Figure 3). An Energy Resource can produce electricity, move objects, generate heat, and power and sustain life. Most shipboard energy today is in the form of Natural Energy Resources. Natural Energy Resources are resources used to convert energy and are extracted from the

Natural Environment. They may be stored on the platform (e.g., fuel) or extracted from the environment during operation (e.g., solar). They include, but are not limited to, fossil fuels, wind, solar, natural gas, oxygen, uranium, and hydrogen. Manmade Energy Resources are Components that exist by design as sources of energy. Energy resources can also be categorized as either primary or secondary. Primary Energy Resources are the sole originating source of energy for the platform and may be natural or manmade. Secondary Energy Resources are Manmade Energy Resources that provide energy to the Energy Network but are replenished from some Primary Energy Resource. Examples include, but are not limited to, an electric battery, flywheel, or capacitor Components.

Each System is part of a larger Energy Network that defines the network of Components and Energy Resources that facilitate the distribution of energy throughout the Concept. Energy Networks are bounded by Primary Energy Resources at one end and the Natural Environment on the other. Within the Energy Network, energy is transferred from source to sink. Energy Networks consist of all of the Connections between concept and Components, between Components, and within Components.

A Domain Network is a domain specific subset of the total Energy Network. Domain Networks facilitate the distribution of energy specific to its domain type. Domain types include, but are not limited to, electric, fluid, thermal, chemical, magnetic, structural, and mechanical. A System Domain is defined as all the Components and Connections of a System in a Domain Network for a particular System. Figure 1 depicts the electrical System Domain for the propulsion System. Figure 2 shows the mechanical System Domain. Figure 3 and Figure 4 show the system in the fluid Domain.

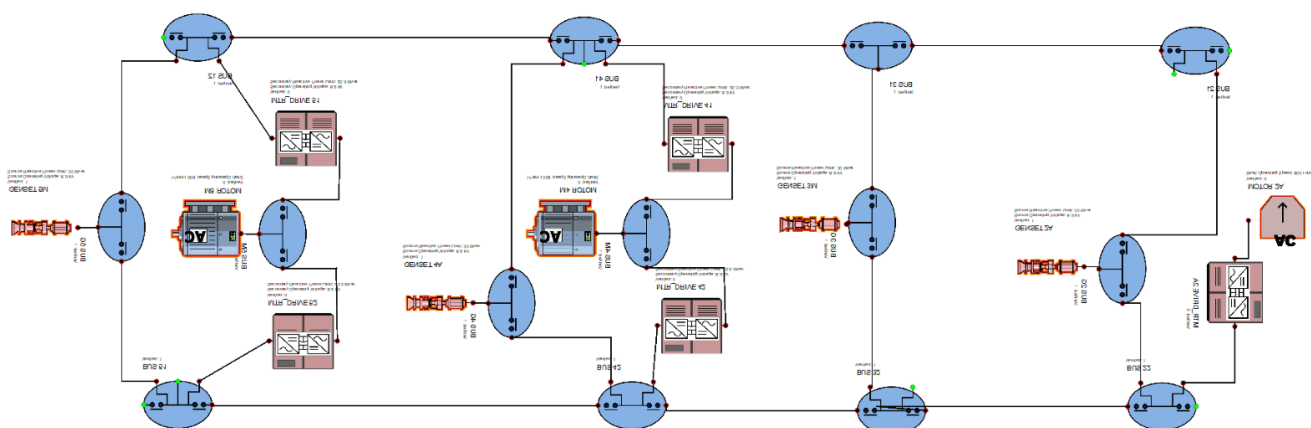

Figure 1- Example IPS propulsion System, electrical domain view

Figure 2- Example IPS propulsion system, mechanical domain view

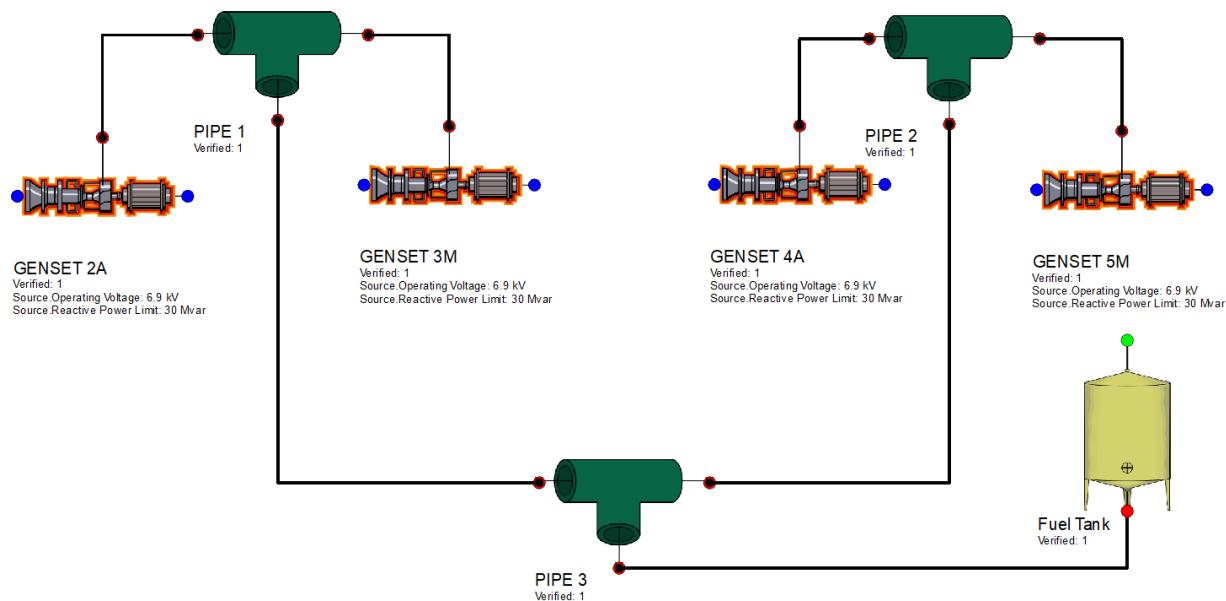

Figure 3- Example IPS propulsion System, fuel proxy, fluid domain

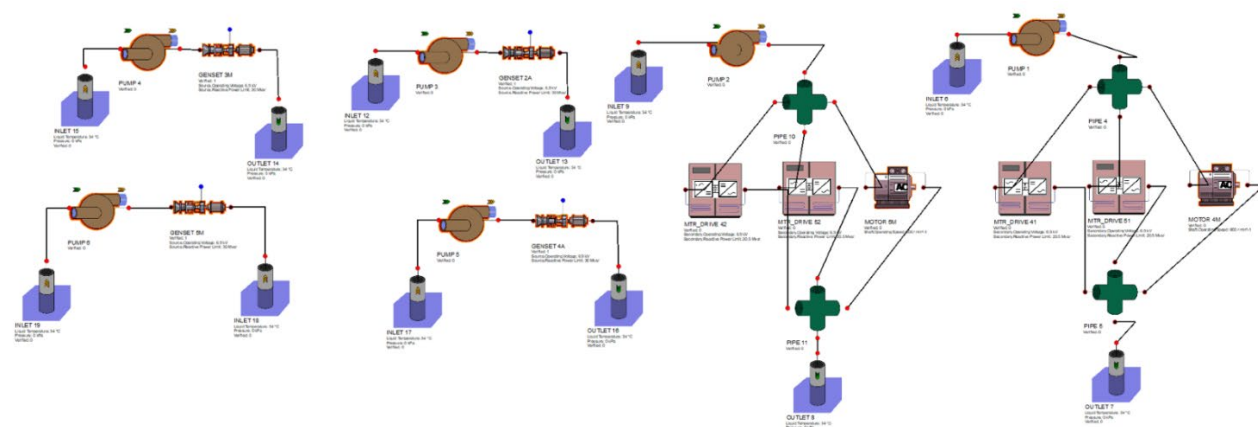

Figure 4- Example IPS propulsion System, seawater cooling, fluid domain

We should not design and engineer Systems independently, but rather we should design and engineer Energy Networks that provide and transport energy through these Systems. The differentiation between Systems and Energy Networks is foundational to any modeling requirement used during the design process. For example, the sizing of generators, chillers, and load centers, and the design of zonal architectures are done to support multiple ship Systems. In this way, a ship design objective is to engineer an Energy Network that supports the operational requirements of all ship Systems; and to discover the interdependence between these Systems and the Components that they share. The challenge becomes designing an Energy Network while at the same time meeting System requirements.

Designing Energy Networks and analyzing System performance cannot be properly executed without appropriate tools. These tools must be able to model and analyze the design; the design analyzed should be based on a commonly understood definition of the Concept's design. This requires a data model or ontology that can capture the complexity of the network/system relationship while dealing with the various levels of knowledge about the design as it matures along an acquisition process.

An Energy Network can be thought of as a graph defining how Components and Energy Resources are connected to distribute energy throughout the ship. Within the Energy Network, energy moves from one or more primary Energy Resources, like oxygen and fuel, through connected Components and terminates at Operational Energy Sinks where the energy provides an action necessary for an Operational Capability to exist. The actions of these terminus Components transfer that energy to the natural environment. Once the understanding of energy flow and conversion is gained, building an ontology model that represents this Energy Network and the Systems riding on it becomes the challenge.

The modeling philosophy that was applied makes the following assumptions.

1. Through the law of energy conservation, energy is a conserved quantity that cannot be created or destroyed but is instead converted in form.
2. Energy resources are part of the Energy Network. For example, if a ship runs out of stored fuel, or the batteries of a fully electric ship are depleted, and the ship is dead in the water, then energy was converted, is now in the environment, and is no longer onboard and available for use.
3. Energy is distributed, controlled, and converted along one or more distinct Energy Networks to support required Operational Capabilities.
4. Energy Networks have multiple Energy Domains. These include but are not limited to electrical, mechanical, and fluid (gas and liquid).
5. Humans are not part of the Energy Network. They are operators and are part of the Natural Environment.

Most engineers will logically think of Energy Networks in the context of a network of connected Components. Engineers model these Components and networks within modeling and simulation tools/applications appropriate to answer specific questions. The ontology used by these modeling and simulation applications must provide the mechanism to define and simulate these Components and networks unambiguously; the definitions must be understood the same way among multiple applications.

Figure 5- Connected Components

In Figure 5 we have three connected Components, but we know nothing about A, B, and C individually; we know only that they are connected. Concerning their Connections, we may have information about the Ports on each Component, the Energy Domains, properties, and possibly even the physical interface of each Port. We can formalize the Connection object, which can have properties. But at this level of modeling, we do not know what happens inside each Component or how it behaves in relation to its connected neighbors. For all Components of an Energy Network to simulate, applications would need to know specific details about each Component's behavior and its ports. Each Component needs to be defined, formalized, unique, and have associated code modeling its behavior.

A simplistic example of these Energy Networks might include an engine connected to a generator by way of a shaft (Figure 6). A cable is connected to a generator that powers some electrical device, like a radar, through a switchboard and/or load center.

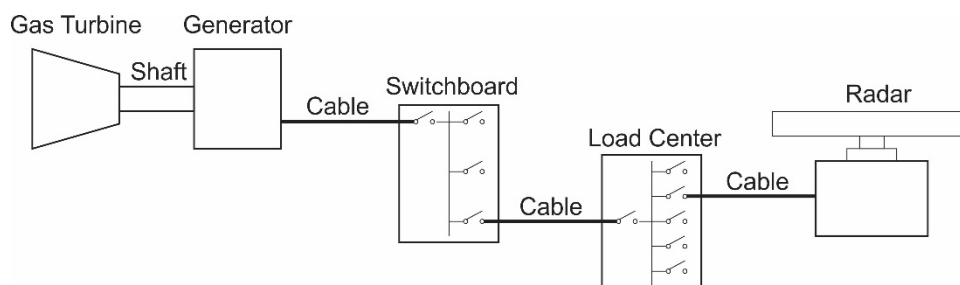

Figure 6-Simple Engine and Electric Load

In the model shown in Figure 6, the network is incomplete as an energy model. It is incapable of being simulated without additional modeling assumptions. It could exist as a pattern or subnetwork for reuse, but it is incapable of an end-to-end energy simulation as no energy can be generated for use in one or more Systems; there is no energy source or resource. The model also does not include dependent Components like chilled water that are required for it to function. This increased level of detail is depicted in Figure 7. Like the generic model depicted in Figure 5, to perform an end-to-

The diagram illustrates a multi-domain system with three main components: A (orange hexagon), B (blue square), and C (green hexagon). Component A has an 'Internal Port' and a 'Control Port', both labeled as 'electrical'. Component B is labeled as 'fluid'. Component C has an 'electrical' port. Connections are shown between A and B, and B and C, labeled as 'connection'. Fluid paths are shown as blue lines, and electrical/control paths are shown as brown lines.

Figure 7 - Components with Internal Connectivity

If we consider again the model in Figure 6 as a use case, we can see how this Energy Network meets the requirements of a single System supporting a single radar and its Operational Capabilities. We also know that many of these Components will serve more than this single System function within the larger context of the ship design. This simple example can quickly get complicated when the fuel necessary to power the engine is stored in a compartment in the ship, and we add additional Components needed to support additional capabilities like ship propulsion (Figure 8).

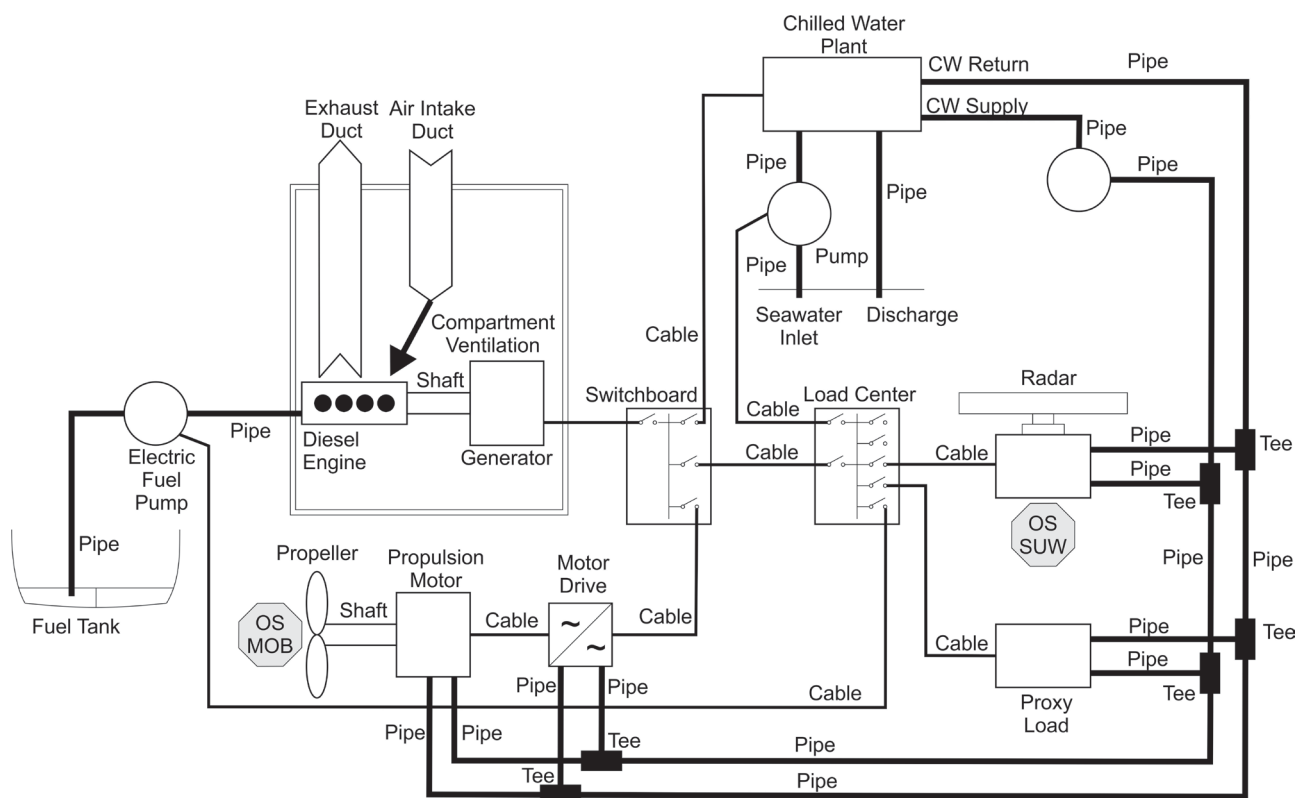

Figure 8- Simplified Notional Energy Network

Now, there are two ship functions that share some, but not all, of the Energy Network Components. Both are dependent on fuel and oxygen to provide energy to the network and, therefore, to each system. The ontological relationships between Energy Network Components are critical. Note that the capacity of the tank is directly related to the design of the ship and space available for fuel storage and, therefore, defines the operational limits of ship Systems. Two Components of Figure 8, the radar and the propeller are the Operational Sinks for two Operational Capabilities; these two Operational Capabilities are implemented through two interconnected Energy Sinks Networks. During their operation, these two Energy Networks consume Energy Resources and act as an energy sink to transfer energy off the Energy Network through some action. This relationship breaks down into well-defined model objects that ultimately define each of the two Systems (the propulsion system and the air radar sensing system.)

In the example shown in Figure 8, the air in this naturally aspirated combustion engine comes from air within a compartment. The compartment air is serviced by an air intake duct via a ventilation System that terminates at a Domain Source. This Source Port has a Connection to a Natural Energy Resource which is oxygen from outside air. Likewise, the engine is cooled by seawater; without cooling, the engine will fail. This figure also illustrates the multiple domains of the Energy Network: electrical, mechanical, and fluid.

Figure 9 shows a 3D view of the Compartment/air relationship. The HVAC duct serves to both cool the Compartment and to ensure that air is provided to the engines. Since the Compartment doors can be closed, a dedicated external air source is required. In the event the HVAC fans fail, or the intake air is blocked, the Compartment doors can offer a redundant air source. An Energy Network should be able to model this relationship. While not shown in the figure, a System Information Network could be used to sense whether the HVAC fan fails and to cause the Compartment door to be opened, either manually or automatically. In this example, the exhaust duct would be an example of a Non-Operational Energy Sink.

Figure 9 - Notional Machinery Room

## DEVELOPMENT OF NETWORK ONTOLOGY

The requirements and use cases that drive the modeling of an Energy Network should be identified prior to ontology development. The objective is to enable Component and platform sizing, technology fusion, and operational measures of performance during early stages of design. However, the strategy of ontology design and development follows a philosophy of supporting all stakeholders of data at all stages of design. The ontology model must be rich in information related to connectivity, properties, and operational state. The energy flow model must be able to understand this ontology, analyze energy flow, and be able to change the state of Components. The ontology model must be able to characterize behaviors between Components, within Components, and between Components and Concept space (e.g. arrangements).

In ship design it is easy to ignore the complexity of some standard ship Components simply because there are so many of them, and modeling everything at all levels of detail is not possible or desirable. To the engineer worried about the performance of some of those Components, however, these details matter. Ontology development should not care what you choose to model, or how much detail you provide or require, only that you can provide the data necessary to model the problem. This leaves the detail of details to the application generating or using the data.

The following are some of the decisions that were made about ontology development given the requirements we established.

From a data modeling standpoint,

1. Capabilities correspond to a hierarchy of required Operational Capabilities. Capabilities are only described in the abstract and does not specify how a capability is to be implemented. A Capability is structured as a hierarchy of Capabilities, with the most general at the root and most specific at the leaves. At the leaf-level, Capabilities may have a measure specified, along with an environmental condition for the measure.
2. An Operational Capability is the last Capability in the hierarchy related to a System Function Action.
3. A System Function Action defines the action of an Operational Energy Sink needed to support an Operational Capability. An Operational Sink is the Component, or Components, providing the System Function Action that transfers the energy off platform.
4. Operational Sinks define the function of a System and are the terminus of the System boundary.
5. Systems are defined as all connected Components of the Energy Network required to provide energy to the System Function Action that enables the Operational Capability of the System. This includes Components required to maintain operational integrity that do not necessarily provide energy to the System. (e.g. cooling).

Table 1 provides examples of Operational Capabilities and how they are implemented through Systems, Operational Sinks, and System Function Action.

**Table 1: Example of linkages among Capability, Systems, Operational Sinks, and System Function Actions.**

<b>Mission</b>	<b>Capability</b>	<b>Operational Capability</b>	<b>System</b>	<b>Operational Sink</b>	<b>System Function Action</b>
MOB	MOB 1.7-Transit at high speed.	Move	Propulsion Prime Mover System	propeller(s)	generate thrust
MOB	MOB 7.3- Get Underway/Moor	Hoist	Mooring System	windlass (s)	rotate
AW	AW 6.7- Detect, classify, track	track	Surface Surveillance Radar System	radar antenna(s)	Transmit-Receive-Rotate
AW	AW 6.7- Detect, classify, track	track	Surface Surveillance Radar System	display monitor (s)	emit

## LEAPS, FOCUS, and UML

The system ontology developed is generic in its approach and was modeled using the Unified Modeling Language (UML). The UML model was built as part of the Leading Edge Architecture for Prototyping Systems (LEAPS) software development framework. Two software products, the Rapid Ship Design Environment (RSDE) and the Smart Ship Systems Design (S3D) tool (Rigterink, et al, 2016) are both leveraging this ontology model as part of design tool integration. RSDE is a 3D ship design tool that is having its Machinery Module modified to support Energy Networks and System analysis, and S3D will be a plugin within RSDE that will provide for multi-domain Energy Network modeling, energy flow, and System discovery. Once completed, these tools and others will be able to support the integration of operational requirements, Energy Network design, System discovery, and operational analysis like Electric Plant Load Analysis (EPLA). As described by Snyder et al. (2019), LEAPS and FOCUS are also being used to integrate other ship design tools.

The LEAPS MetaModel is part of the LEAPS framework. The LEAPS MetaModel is a class structure - a set of classes and the relationships between them. It is designed to be flexible enough to represent any engineered system or structure. The current version, LEAPS 6, was upgraded to facilitate the work described in this paper. A few key classes are introduced below.

**Concept class** - A class that defines the attributes, the Systems, the Components and the views of geometry that represents a product in design or under study. It is generic to all things engineered, but is used here to define platforms such as a ship, submarine, aircraft, or other engineered product.

**Component class** – represents physical objects that can be thought of as parts of a Concept. They may be connected in ways that provide function and capability. Components can be thought of as any part of a ship that represents something as discrete as a radar or engine, but also includes parts like stiffeners, plates, foundations, and mounts. A Component in many ways acts as a small Concept, but it is modeled as something a Concept owns. Components do not have their own Systems, but Components do have most of everything a Concept does.

be simulated. The gas turbine in Figure 11 supports an explanation of Energy Network Diagrams as they relate to the behavior of a Component.

Figure 11-External Ports for Gas Turbine Diagram

In this example, the gas turbine has internal Component energy transformation as well as external Port Connections to Energy Domains like fluid-HVAC via intake and uptake ducts. Energy Domains within Components may have interacting behaviors. Consider a Component fluid domain designed to cool the electrical domain or mechanical domain – these domains will have a direct dependency on each other's behavior. It is the responsibility of the Component to capture the dependency/behavior relationship between Energy Domains interacting with each other within a Component. In the gas turbine example, when connected into the Energy Network, the HVAC ducting Components will impact the gas turbine's performance based on losses from their routing or the ambient intake air temperature. Figure 12 illustrates this relationship. In this case, pressure losses for the design of the intake duct (fluid domain Port) and the exhaust duct (fluid domain Port) are affecting rated output power at the shaft (mechanical domain Port).

Figure 12- Port and Component Dependency

This use case requirement for Components to have internal network Diagrams demonstrates that Components can model a complexity level usually associated with Concepts, and that they have their own operational states, performance, and controls, just as a Concept does.

Ultimately the Energy Network is a graph composed of both Concept and Component networked objects. Components can have varying levels of configuration in addition to varying levels of modeling detail. Configurable Components add significant complexity when differentiating one from another. A computer Component is a perfect example. Because

Concepts and Components can have any number of Diagrams having any number of Ports (Nodes) and Port Connections, the ability to formalize something like a computer at the instance level is possible. Both the tablet and the blade server can be modeled. The challenge is in the building of specific computer instances that represent an actual Component. What will differentiate one from the other will be the Component's Diagrams. Defining these internal Energy Networks will take time and effort. As such, the need for a library of available Components with their respective Diagrams is essential.

## Logical and Physical Views

The ontology follows a data centric approach. This means that the data model is designed to represent reality rather than the data requirements of any software application. In a data centric strategy, all tools see the same data even if the application is limited and specific in its use of that data. If we look at 2D schematic flow solvers like S3D, we recognize that these tools perform analysis on a logical view of the Energy Network. Applications like RSDE are more 3D driven, requiring accurate weight and volume analysis that the logical tools do not need or use. Both S3D and RSDE need to model the same Energy Network and understand the Systems represented in the design. Logical and physical views of a single data representation are possible and desirable in a data centric model, but the data must be synchronized as each application makes changes to the shared data. Consider the arrangement of Components within a Concept in the example shown in Figure 13. The purpose of the example is not to demonstrate a realistic Energy Network, but rather to show the logical and physical relationship between a cable and two connected and arranged Components. In a data centric model, there is only one cable, one laser, and one energy storage device. A very plausible use case may suggest that the logical data like Ports and Connections of the three Components may exist first. It is very likely that these logical designs will exist as patterns or collections of sub-networks persisted for reuse by tools like RSDE or S3D across different designs.

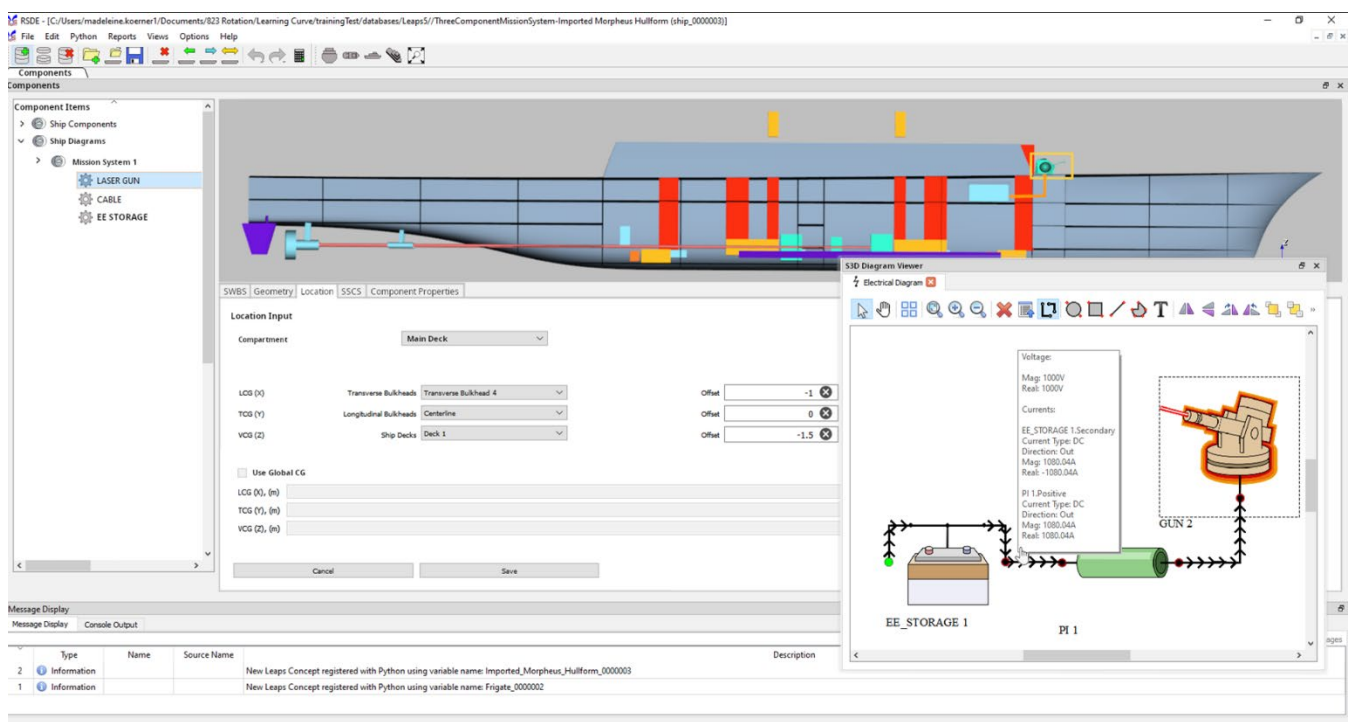

Figure 13- RSDE (physical) and S3D (logical) views of the same data

RSDE may need to add this pattern and rearrange either the battery Component or the laser Component. Within RSDE the cable would need to be routed and the resultant cable length updated in the database. The logical connectivity between the three Components remains unchanged.

The relationship between the electricCable Component and the electricalCableLength Property in the UML model is depicted in Figure 14. The cable owns this length property, but it is the responsibility of the applications to ensure that as a cable changes, its data is updated.

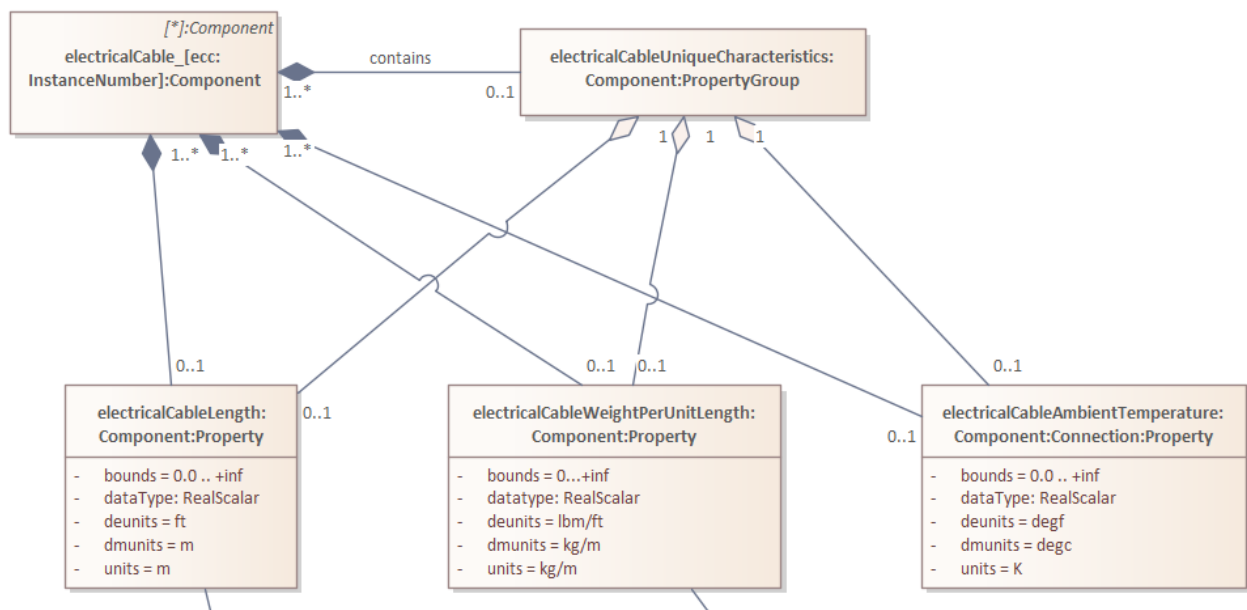

Figure 14- Electrical Cable properties

The electrical resistance of the cable provides another example of the interdependency between the Concept and the Component. This property will change based on the temperature of the compartments that the cable is routed through. The powerflow simulation is therefore affected by the Concept even if the simulation is unaware the Concept exists. Ship design software like RSDE define and update Component Property data, such as cable length, during arrangements. Analysis software such as S3D use these Component property data to analyze and simulate the Concept.

## Proxy Components

During early stages of the design process, not every Component will necessarily be modeled. Compartment lighting is a good example. It is not feasible during concept design to model every light and electrical cable and switch on the ship so estimates of the lighting load are used. These estimates are captured in Proxy Components.

Currently tools like RSDE estimate the lighting load based off of the arrangeable area of compartment spaces in the ship. A Proxy Component should have both a knowledge of the Concept it belongs to and a method to solve for its load independent of the power flow simulation. For the lighting example, the proxy lighting Component (or an external application) would get the space volume data from the Concept and would include the equation that relates the volume to the properties, such as requestedElectricalPower, necessary for the power flow simulation. Proxy Components can also be used to simulate a portion, or sub-network, of an overall Energy Network by providing substitute sources and loads. As depicted in Figure 15, the proxy Components provide or sink the energy at the boundary interfaces of the sub-network under study; they establish the sub-network boundary conditions.

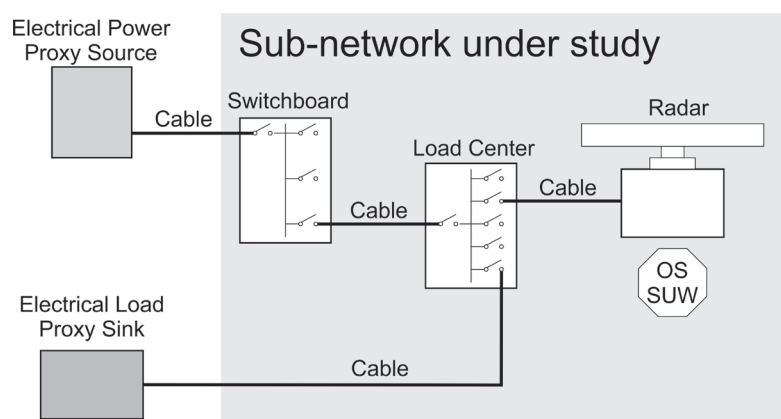

Figure 15-Proxy Source and Sink Components

## Ports

As depicted in Figure 16, Component Ports can be of multiple Port types:

Figure 16- Port examples

### Component External Ports

External Ports are Ports that allow for input and output into and out of a Component, and provide Connection to other Components via their external ports. For example, the gas turbine from Figure 11 will have multiple external ports. There will be input external ports for fuel and air, there will be output external ports such as power out and exhaust out. These ports have attributes such as Connection type, ratings for inputs such as flowrate for fluids and power ratings for electrical ports. External ports can also be bi-directional.

### Component Internal Ports

Internal ports are used to define any changes within a Component that provide necessary information for a simulation. An example of an internal Port is a T-Pipe. Unlike a straight pipe, a T-Pipe will have a single input and two outputs (or vice versa.) At the intersection point of the T, an internal Port will be used to inform the fluid flow simulation that the flow is splitting at this location and to calculate the necessary flowrates for all inputs and outputs.

### Component Control Ports

Component Control Ports are ports on a Component that describe controllable attributes or measured quantities for simulations. A simple example of a control Port could be a ball valve actuator handle. See Figure 17. The Port would not have an effect on the physical representation of the Component but would contain the information needed for analysis in simulation tools.

Figure 17: Component Control Port example

### Source Ports

A Source Port will be the entry point of an Energy Network where an Energy Resource (Natural or Manmade) enters the network from the concept or the environment. An example of this type of Port is the inlet to a fuel line or an air intake to a gas turbine. See Figure 18. A space in the ship used to store fuel is not a Component, but the fuel contained there is a

natural Energy Resource. The external Port of an inlet pipe should connect with and understand that it is connected to a fuel tank if the Energy Network is to connect sources to sinks. It may need to understand the tank's capacity.

Figure 18- Source Port Example

### ***Sink Ports***

A Sink Port is the last point of an Energy Network where energy is discharged to the Natural Environment. The propellers of a ship would have Sink Ports (Figure 18) where the energy from Fuel and Air for Combustion Sources is finally discharged to the environment to “Move” the ship. (A lot of the energy is also discharged through the exhaust pipes – but not all of the energy discharged through the exhaust pipes is attributable to a given Energy Network)

Figure 18: Sink Port Example

### ***Concept Ports***

Concept ports are the subset of Component Ports that connect to the environment at the boundaries of the Concept but are neither Source Ports nor Sink Ports. In LEAPS, openings can have properties that define them as doorways, hatches, ducts, and other open boundaries in the ship's geometry where the knowledge of that opening is important. Knowing a compartment has an opening with a door associated with it allows for the opening to have a state (open, closed). Concept Ports also provide for energy transfer between Components that are not physically connected.

## **ONGOING WORK**

This paper has described the ontological work completed to date. We are currently exploring the incorporation of Elements, Patterns, and Templates into the ontology.

An Element (Figure 19) is a type of Interface that provides for a specific and possibly formalized function. Elements are composed of other Interfaces that provide logical Connections to proxy Components, Component Blocks, Patterns, or other Elements. Elements can be owned by either the Concept, Component, or Catalog Component Item.

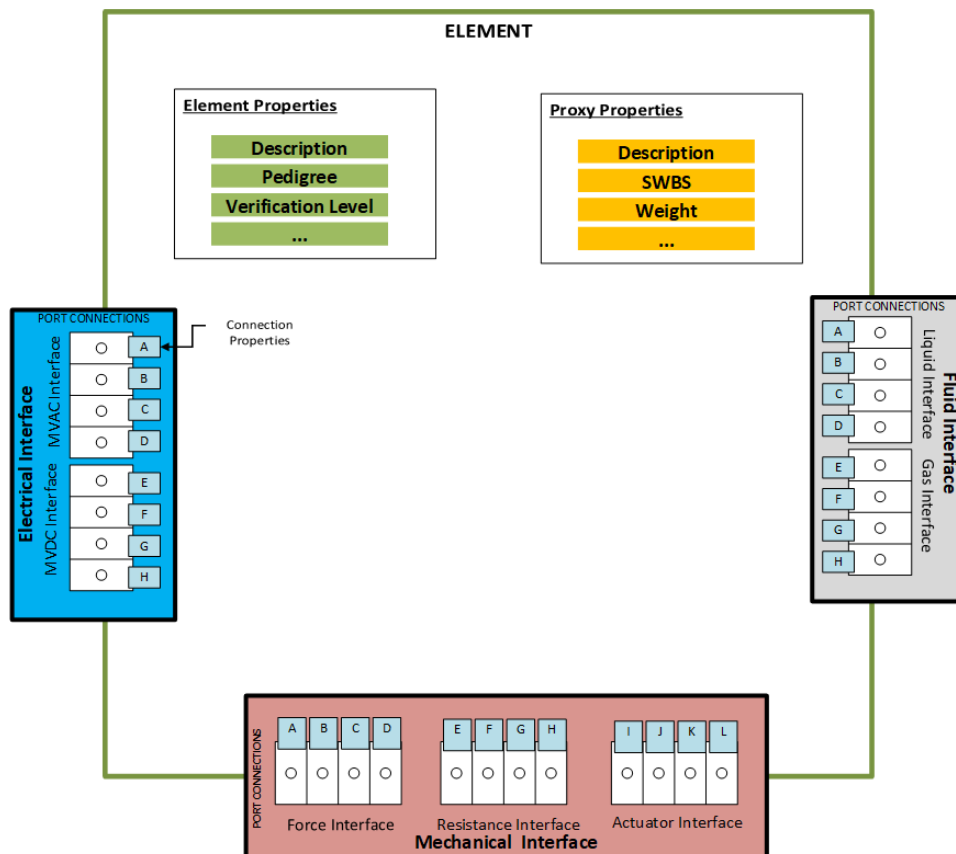

Figure 19: Element example

Elements can have many applications. The initial application of interest is the ability to represent a single interface from which multiple Components, Component Blocks, and Patterns can be substituted during design and analysis. As a design matures, the Element remains as an architectural feature of the network, but the model structure connecting its interfaces can become more detailed as required. Figure 20 depicts an Element where the contained Component evolves from a proxy Component to a diagram of Components. Ongoing work is determining how to represent elements within the ontology.

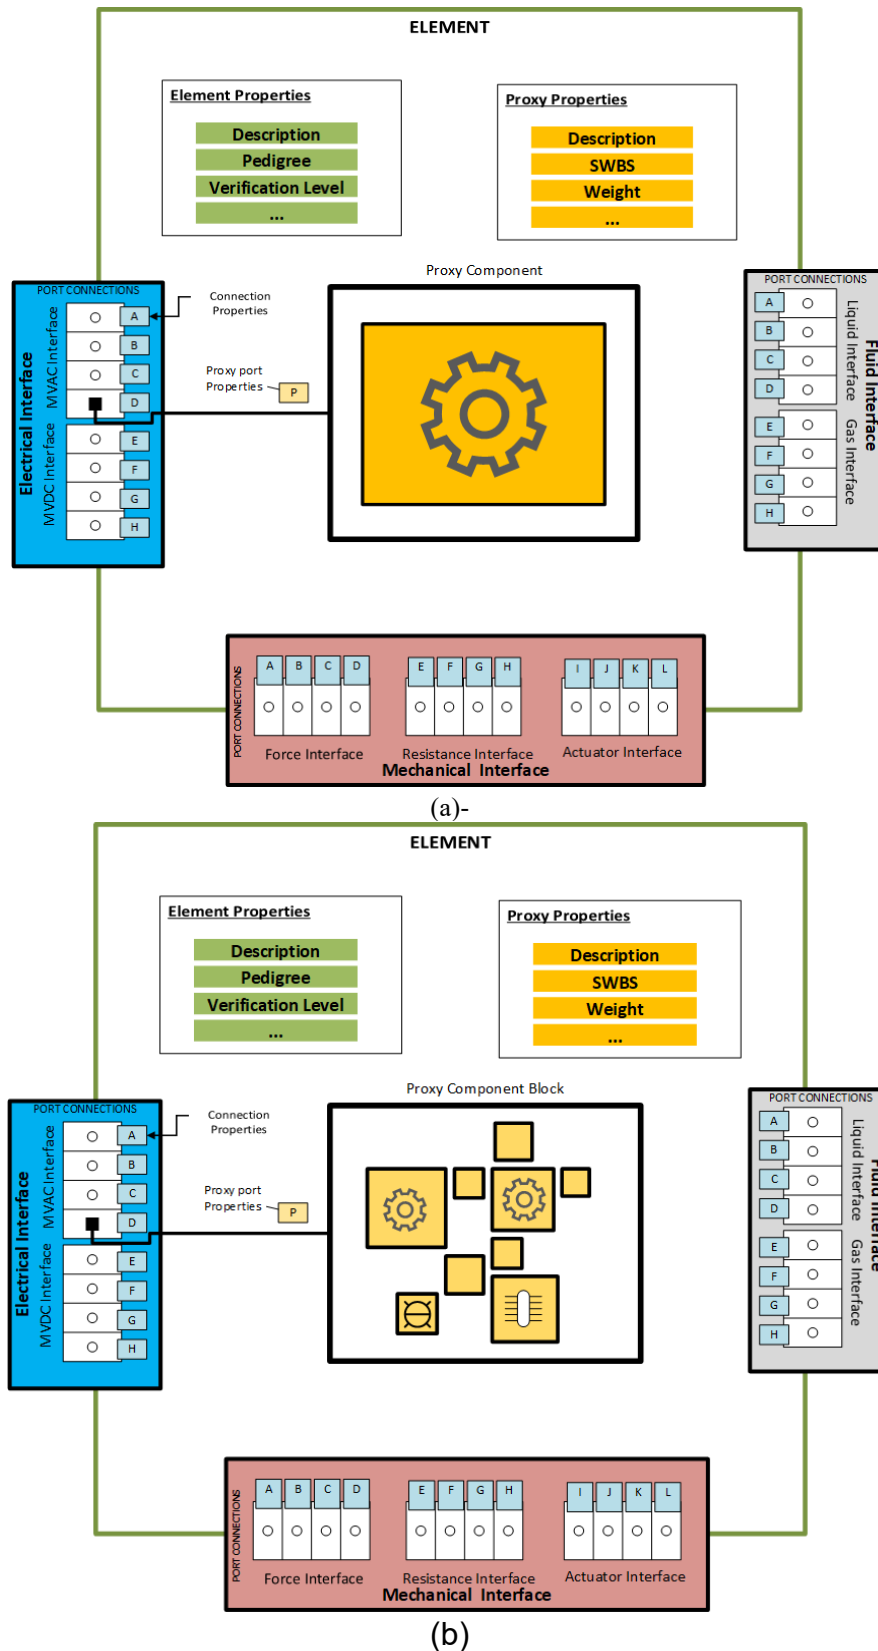

Figure 20: Element evolution (a) early stages of design (b) later stages of design

As described by Righerink et al. 2016, Chalfant and C. Chrysostomidis 2017, and Chalfant et al. 2019, patterns are diagrams of sub-networks or networks where the Component properties are set at default values. Patterns enable reuse of architectures across multiple designs; the Components serve as functional entities. A template is a pattern where the Component properties have been defined to represent a specific concept and sufficient sources and sinks (perhaps proxy sources and sinks) are incorporated to conduct a simulation to answer a specific question. Ongoing work is identifying how to represent patterns and templates within the ontology.

## CONCLUSION

A well-defined and extendable ontology is a key enabler for integrating multiple ship design and analysis tools. This paper focuses on describing ongoing efforts to define such an ontology to support ship design and the analysis of Energy Networks. This ontology is being implemented in LEAPS and FOCUS to enable interoperability of RSDE and S3D in the near term. More tools are anticipated to be integrated in the future.

# Hydrodynamics of an Underwater Vehicle Near the Sea Surface

Mavrakos S. Anargyros<sup>1,2</sup>, Konispoliatis N. Dimitrios<sup>2\*</sup>, Rossides George<sup>3</sup>, Mavrakos A. Spyridon<sup>2</sup>

## ABSTRACT

*The primary goal of this study is to evaluate the hydrodynamic characteristics and the wave exciting forces on a shallowly submerged vehicle. A thin, rigid plate, which is completely submerged beneath the free surface in waters of finite depth is considered herein. The examined body is similar to an unmanned vehicle which is developed in Cyprus Marine and Maritime Institute for ocean science applications. From the present analysis the phenomenon of negative added mass and rapid variations of the added mass and damping coefficients is verified due to the free surface effect which is explained in terms of near-resonant standing waves above the submerged body.*

## KEY WORDS

Hydrodynamics; Exciting Forces; Added Mass; Damping Coefficient; Submerged Structure.

## 1. INTRODUCTION

Studying the hydrodynamic characteristics of bodies submerged near to the sea surface is especially crucial for specific scenarios in ocean engineering. Specifically, the maneuverability and control of unmanned underwater vessels when they interact with the sea surface become critical for safe operations, requiring accurate prediction of hydrodynamic loading and vessel motion characteristics. However, motion maneuvering analysis is traditionally focused on surface vessels and submerged bodies floating far away from the free surface. On the other hand, little analysis is available on the case where a vessel is floating near the free surface.

As early as 1960s [Ogilvie \(1963\)](#) presented a two-dimensional analysis concerning horizontal cylindrical bodies with circular or square cross sections submerged near the free water surface, concluding to a negative hydrodynamic (added) mass occurrence. In addition, [Chung \(1977\)](#) conducted experiments on a two-dimensional submerged circular or square cross section which was forced to oscillate in sway and heave directions for several submergences below free water surface. He illustrated negative added mass values for a square section when the submergence was on quarter of the semi-width. [Newman et al. \(1984\)](#) explained the occurrence of negative added mass values, along with rapid variations in the damping and added mass coefficients for certain frequency ranges, based on the resonant free surface motion observed in the fluid region above a submerged body. Similar physical argumentation was applied by [Mavrakos \(1993\)](#) in order to explain the negative added mass and sharp peaks of the force coefficients and the hydrodynamic characteristics of groups of interacting axisymmetric submerged bodies near the free surface or the seabed. Recently, a self-regulating fuzzy depth control method was developed by [Shao et al. \(2012\)](#) in order to maintain a cylindrical submerged structure at a specific depth below the free water surface, under free surface disturbances.

Fully submerged objects moving near the free surface deform the water surface and create propagating waves that carry away energy. This dissipation of energy leads to a resisting force known as wave drag force. The problem was theoretically treated by [Michell \(1898\)](#) and [Havelock \(1917, 1931\)](#) for spheres and spheroids, whereas [Chepelianskii et al. \(2010\)](#) addressed the

influence of an immersed cylinder on wave propagation based on the analysis on submerged spheres. Also, [Benusiglio et al. \(2015\)](#) used fully submerged spheres to study the effect of the wave drag near the free surface. It was emphasized that the wave drag was comparable in magnitude to the hydrodynamic drag when the top of the sphere was at less than one sphere radius from the surface.

Although little analysis is available on submerged axisymmetric cylindrical/spherical bodies near the free surface, the movement of submarines in a near-surface water environment has been the subject of many studies in the literature. Submarines descend to periscope or snorkeling depth for target exploration or battery recharging. In such scenarios environmental loads like waves, currents, resistance and suction forces are imposed on the submerged structure ([Arentzen and Mandel, 1960](#); [Burcher and Rydill, 1995](#)). Several studies have been presented in the literature investigating the impact of the free water surface on an underwater vehicle through both numerical and experimental methods. Indicatives are [Jagadeesh et al., 2009](#); [Manssorzadeh and Javanmard, 2014](#); [Nematollahi et al., 2015](#); [Conway et al. 2018](#); [Amiri et al., 2018, 2019a, 2019b, 2020](#); [Lambert et al. 2020](#); [Sudharsun et al. 2022](#); [Ling et al. 2023](#). Furthermore, since the imposed forces on a submerged structure are different from those in large water depths, submarines are required to keep the necessary navigating pose (depth, roll angle and trim angle). Consequently, numerous research activities on depth control have been performed. Specifically, [Hao et al. \(2004\)](#) developed a two-step depth fuzzy controller to produce stern angle to counteract the second-order exciting wave forces on a submarine, whereas [Choi et al. \(2006, 2008\)](#) proposed a mathematical model for the evaluation of the wave exciting forces on a submerged structure and performed depth control simulations using the proportional-integral-derivative method. [Rezazadegan et al. \(2015\)](#) proposed a novel adaptive trajectory tracking control of an autonomous underwater vehicle in six-degree of freedom. In addition, [Park et al. \(2016\)](#) elaborated an adaptive control technique utilizing a neural network and a proportional-integral-derivative controller to regulate the depth of a submerged body in close proximity to free water surface. At the same time, the case of the water surface being covered with ice has also been considered. [Zemlyak et al. \(2021, 2023\)](#) studied theoretically and experimentally the motions of a submerged body near the free water surface when the latter was covered by ice. Here a sink-source model was applied, and the ice cover was simulated as a thin elastic plate floating on the water surface, whereas the experiments were performed in an ice tank. It was concluded that the variation of the relative submergence of a body moving at a shallow submergence attained non negligible values.

The main objective of this investigation is to evaluate the hydrodynamic characteristics and the wave exciting forces on a shallowly submerged vehicle. A thin, rigid plate, which is completely submerged beneath the free surface in waters of finite depth is considered herein. The examined body is similar to an unmanned vehicle which is developed in Cyprus Marine and Maritime Institute (CMMI) for ocean science applications. In the present analysis a semi-theoretical formulation is described by properly composing the solutions of the diffraction and the motion radiation problems around the floating structure within the framework of linear potential theory. This is done under the assumption of an incompressible and inviscid fluid and an irrotational flow. In addition, two numerical simulation tools, ANSYS Aqwa and HAQI software, are also implemented to compare the numerical results with the theoretical ones.

The rest of this paper is structured as follows. In Section 2 the geometric model of the underwater vehicle is introduced. Section 3 presents the developed theoretical formulation within the domain of linear potential theory, whereas focus is also given to the applied numerical models. Section 4 is dedicated to the presentation of the outcomes of the two applied formulations whereas conclusions of the work are drawn in Section 5.

## 2. DESCRIPTION OF THE CONSIDERED AUTONOMOUS UNDERWATER VEHICLE

Underwater gliders are autonomous vehicles that move through the water by changing their buoyancy and pitch ([Javaid et al., 2014](#)), which makes them more energy-efficient than other types of autonomous marine vehicles (AMVs) while minimizing their acoustic signature. This makes them ideal for many oceanic surveying applications, including long-term environmental monitoring, marine animal tracking and oceanographic surveying ([Javaid et al., 2014](#)). Additionally, gliders are relatively low-cost and can be deployed for extended periods.

The traditional torpedo-shaped underwater gliders are limited by their slow speed and restricted maneuverability, which can make them unsuitable for some applications ([Javaid et al., 2014](#)). To address some of these limitations, Disk-Type Underwater Gliders (DTUG) emerged ([Nakamura et al., 2007, 2008](#); [Yu et al., 2017](#); [Zhou et al., 2020](#)). Unlike torpedo-shaped gliders, DTUGs have omnidirectional motion capabilities, which make them more maneuverable and better suited for navigating complex underwater environments, such as near islands or inside narrow channels. An important example of such a marine environment is the Aegean Sea, where the existence and close proximity of large and small islands and rocky islets as well as the dense marine traffic (both for commercial and leisure purposes), require autonomous vehicles that operate in this region to have high-maneuvrability capabilities. The Cyprus Marine and Maritime Institute is exploring the DTUG trend through the design and implementation of its own DTUG prototype, which has diameter of 5.2m and overall height of 0.86m, as shown in Figure 1, specifically for use in the Aegean Sea and eastern Mediterranean regions.

**Figure 1: Schematic representation of the examined Disk-Type Underwater Glider**

The large size of the DTUG enables it to carry high-volume buoyancy engines, which in turn allow it to navigate while carrying large payloads of more than 200kg, including components of energy harvesting technologies that can enhance its overall power autonomy. Additionally, its flat and wide structure offers stealth capabilities when the DTUG lies on the ocean surface, since it can become nearly invisible to both underwater and above surface detection methods (e.g., underwater sonar and above-surface radar).

The existence of negative hydrodynamic (added) mass and excitation forces that can occur near the ocean surface can enable the DTUG to maintain its shallow depth without the need for additional consumption of energy. At the same time, to achieve full submersion away from the ocean surface, these hydrodynamic effects need to be overcome. The creation of a comprehensive autonomous controller that can properly utilize or overcome these hydrodynamic effects depending on the mission needs of the DTUG, requires the proper understanding of the magnitude and occurrence of these effects under different situations.

According to Fossen (2011), from a maneuvering theory perspective, the 6 DOF motion model of an underwater vehicle is given by:

$$\mathbf{M}\dot{\mathbf{v}} + \mathbf{C}(\mathbf{v})\mathbf{v} + \mathbf{D}(\mathbf{v})\mathbf{v} + \mathbf{g}(\mathbf{x}) = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{wave}}, \quad (1)$$

where  $\mathbf{v} = [u, v, w, p, q, r]$  is the glider's velocity vector in the body frame, as shown in Figure 1, while  $\mathbf{x} = [x, y, z, \varphi, \theta, \psi]$  is the glider's position and orientation vector in the inertial frame.  $\mathbf{M} = \mathbf{M}_{RB} + \mathbf{M}_A \in \mathbb{R}^{6 \times 6}$  is the system inertia matrix,  $\mathbf{C}(\mathbf{v}) \in \mathbb{R}^{6 \times 6}$  is a skew-symmetric matrix describing the Coriolis and centripetal effects due to the motion of the glider and  $\mathbf{D}(\mathbf{v}) = \mathbf{D}_p + \mathbf{D}_v + \mathbf{D}_n(\mathbf{v}) \in \mathbb{R}^{6 \times 6}$  is a positive-semidefinite symmetric matrix denoting the (potential, linear and quadratic) damping forces. It should be noted that quadratic damping forces (described by the  $\mathbf{D}_n(\mathbf{v})$  matrix) are largely excluded from the motion model of underwater gliders, due to the very low maximum speeds that they can reach. Additionally, forces occurring by Coriolis and centripetal effects (described by the  $\mathbf{C}(\mathbf{v})$  matrix) can be also assumed to be negligible due to the low maximum speeds of the vehicle. These simplification assumptions are further strengthened in the case of DTUGs, where their omnidirectional motion characteristics allow for small deviations between the actual motion of the DTUG and its modelled behaviour, caused by such forces, to be easily corrected as soon as they occur.

The vector  $\mathbf{g}(\mathbf{x}) \in \mathbb{R}^6$  describes the gravitational/buoyancy forces and moments acting on the underwater vehicle, while the vector  $\boldsymbol{\tau} \in \mathbb{R}^6$  describes its actuation forces and moments. In the case of underwater gliders, the actuation of the vehicle occurs through the manipulation of its gravitational/buoyancy forces and moments and thus the two terms can be merged. Lastly, the vector  $\boldsymbol{\tau}_{\text{wave}} \in \mathbb{R}^6$  describes the excitation forces acting on the glider when it operates at water depths close to the ocean surface, inside the wave-affected zone. Therefore, the simplified motion model of the DTUG takes the form:

$$[\mathbf{M}_{RB} + \mathbf{M}_A]\dot{\mathbf{v}} + [\mathbf{D}_p + \mathbf{D}_v]\mathbf{v} + \mathbf{g}(\mathbf{x}) = \boldsymbol{\tau}_{\text{wave}} \quad (2)$$

$\mathbf{M}_{RB}$  represents the rigid body mass and inertia and assuming that the centre of gravity (CG) of the vehicle is at the origin of its body frame, it is given by:

$$\mathbf{M}_{RB} = \begin{bmatrix} m & 0 & 0 & & & \\ 0 & m & 0 & & & \\ 0 & 0 & m & & & \\ & & & I_x & -I_{xy} & -I_{xz} \\ & & & -I_{yx} & I_y & -I_{yz} \\ & & & -I_{zx} & -I_{zy} & I_z \end{bmatrix} \quad (3)$$

$\mathbf{M}_A$  is the hydrodynamic (added) mass matrix which can be approximated using the potential coefficients  $\mathbf{A}(\omega)$  by:

$$\mathbf{M}_A \approx \begin{bmatrix} A_{11}(0) & 0 & & & 0 \\ 0 & A_{22}(0) & & & A_{26}(0) \\ & & A_{33}(\omega_{heave}) & 0 & 0 \\ & : & 0 & A_{44}(\omega_{roll}) & 0 \\ & & 0 & 0 & A_{55}(\omega_{pitch}) \\ 0 & A_{62}(0) & & \dots & A_{66}(0) \end{bmatrix} \quad (4)$$

where the natural frequencies  $\omega_{heave}$ ,  $\omega_{roll}$  and  $\omega_{pitch}$  depend on the hydrostatic characteristics of the vehicle in the centre of flotation (CF) (Fossen, 2011). Due to the actuation characteristics of underwater gliders, their CF may be continuously varying throughout their operation. Describing the internal configuration of the actuation elements of the studied DTUG is beyond the scope of this paper and therefore, further analysis on how the aforementioned natural frequencies can be obtained will not be presented.

Like  $\mathbf{M}_A$ , the potential damping matrix  $\mathbf{D}_P$  can be approximated using the potential coefficients  $\mathbf{B}(\omega)$  by:

$$\mathbf{D}_P \approx \begin{bmatrix} 0 & 0 & & & 0 \\ 0 & 0 & & & 0 \\ & & B_{33}(\omega_{heave}) & 0 & 0 \\ : & & 0 & B_{44}(\omega_{roll}) & 0 \\ & & 0 & 0 & B_{55}(\omega_{pitch}) \\ 0 & 0 & & \dots & 0 \end{bmatrix} \quad (5)$$

On the other hand, the linear viscous damping matrix  $\mathbf{D}_V$  is usually approximated by a diagonal matrix:

$$\mathbf{D}_V \approx \text{diag}\{B_{11v}, B_{22v}, B_{33v}, B_{44v}, B_{55v}, B_{66v}\} \quad (6)$$

where the elements  $B_{iiv}$  ( $i = 1, \dots, 6$ ) depend on the potential coefficients  $\mathbf{A}(\omega)$  and can be computed from the time constants and natural periods of the vehicle (Fossen, 2011). Once again, further elaboration on the methods used to obtain the time constants and natural periods of the vehicle, requires a description of its internal actuation elements, which lies beyond the scope of this paper.

The presented manoeuvring theory applies to vehicles operating at water depths below the wave-affected zone and it results in reduced model complexity to enable real-time motion prediction and control. To achieve this reduced complexity, the theory assumes no coupling between the surge, heave-roll-pitch and the sway-yaw subsystems, which in turn excludes the use of the potential coefficients  $A_{15}, A_{51}, A_{24}, A_{42}, B_{15}, B_{51}, B_{24}$  and  $B_{42}$  from Equations (4) and (5).

Conversely, motion control near the sea surface is limited due to the way of actuation of DTUGs and it primarily involves motion along their heave-roll-pitch degrees of freedom (i.e., using the potential coefficients  $A_{33}, A_{44}, A_{55}, B_{33}, B_{44}, B_{55}$ ) while also considering possible wave-excitation forces. That said, the calculation of other significant potential coefficients ( $A_{15}, A_{51}, A_{24}, A_{42}, B_{15}, B_{51}, B_{24}$  and  $B_{42}$ ) can enable further DTUG functionalities to be developed in the future. More specifically, using advanced parameter-estimation algorithms along with a more detailed motion model, it is expected that the vehicle will be able to accurately estimate the current sea-state, based on its past motion, both for oceanographic surveying applications and in order to be able to submerge itself in unfavourable weather conditions. To this end, the rest of this paper will focus on the study of all significant potential coefficients  $\mathbf{A}(\omega)$  and  $\mathbf{B}(\omega)$  for the studied DTUG.

### 3. FORMULATION OF THE PROBLEM

#### 3.1 Theoretical Formulation

We consider a cylindrical submerged disk with vertical axis of symmetry, similar to the above DTUG, which is exposed to the action of regular waves propagating in water depth  $d$  with frequency  $\omega$ . A cylindrical co-ordinate system  $(r, \theta, z)$  is defined with origin on the sea bottom and its vertical axis Oz directed upwards (Figure 2). Let the linear translation and rotational

vector of the body's motion be denoted by  $\xi = (\xi_1, \xi_2, \xi_3)$  and  $\theta = (\xi_4, \xi_5, \xi_6)$ , respectively. Their components correspond to the surge ( $j = 1$ ), sway ( $j = 2$ ), heave ( $j = 3$ ), roll ( $j = 4$ ), pitch ( $j = 5$ ) and yaw ( $j = 6$ ) modes of motion. Under the assumption of a symmetrical mass distribution, a vertical cylindrical body undergoes three-degree of freedom motion in the wave propagation plane under the influence of a regular wave train, i.e. two translations (surge,  $\xi_1$ ; heave,  $\xi_3$ ) and one rotation (pitch,  $\xi_5$ ).

Assuming further that the viscous effects are negligible, the fluid is incompressible, and the displacements of the body and the wave height are small, classical linearized water wave theory can be employed. The fluid flow can be delineated by the potential function:

$$\Phi(r, \theta, z; t) = \text{Re}[\varphi(r, \theta, z). e^{-i\omega t}] \quad (7)$$

where the complex potential function  $\varphi(r, \theta, z)$  can be expressed, on the basis of linear modelling, as a superposition of the incident,  $\varphi_0$ , scattered,  $\varphi_7$ , and radiated wave fields due to the motion of the body, i.e.

$$\varphi = \varphi_0 + \varphi_7 + \sum_{j=1,3,5} \dot{\xi}_{j0} \varphi_j = \varphi_D + \sum_{j=1,3,5} \dot{\xi}_{j0} \varphi_j \quad (8)$$

**Figure 2: Submerged disk. Definitions and discretization of the flow field around the body.**

Here,  $\varphi_j$  denotes the potential of the wave field due to the forced oscillation of the body in the  $j$ th mode of motion with unit velocity amplitude  $\dot{\xi}_{j0}$ . Moreover, all contributions to the total potential  $\varphi$  must be solutions of the Laplace's equation in the entire fluid domain and must meet the following boundary conditions:

$$\omega^2 \varphi_D - g \frac{\partial \varphi_D}{\partial z} = \omega^2 \varphi_j - g \frac{\partial \varphi_j}{\partial z} = 0, \quad z = d, \quad j = 1, 3, 5 \quad (9)$$

$$\frac{\partial \varphi_D}{\partial z} = \frac{\partial \varphi_j}{\partial z} = 0, \quad z = 0, \quad j = 1, 3, 5 \quad (10)$$

$$\frac{\partial \varphi_D}{\partial n} = 0, \quad \text{on } S \quad (11)$$

$$\frac{\partial \varphi_j}{\partial n} = n_j, \quad \text{on } S, \quad j = 1, 3, 5 \quad (12)$$

Where  $\partial(\ )/\partial n$  stands for the derivative in the direction of the outward unit normal vector  $\mathbf{n}$  to the mean wetted surface  $S$  of the body and  $n_j$  are its generalized normal components specified by:

$$\mathbf{n} = (n_1, n_2, n_3), \quad \mathbf{r} \times \mathbf{n} = (n_4, n_5, n_6) \quad (13)$$

$\mathbf{r}$  is the position vector of a point on  $S$  with respect to the body's reference point of motion expressed in the co-ordinate system  $(r, \theta, z)$ . Finally, a radiation condition must be enforced stipulating that propagating disturbances must be outgoing.

The velocity potential of the undisturbed incident wave system,  $\varphi_0$  propagating along the positive  $x$  – axis can be described in the cylindrical co-ordinate system  $(r, \theta, z)$  as follows:

$$\varphi_0(r, \theta, z) = -i\omega A \frac{Z_0(z)}{Z_0'(d)} \sum_{m=0}^{\infty} \varepsilon_m i^m J_m(kr) \cos(m\theta) \quad (14)$$

In Equation (14),  $A$  denotes the wave amplitude,  $\varepsilon_m$  is the Neumann's symbol (i.e.,  $\varepsilon_0 = 1$ ;  $\varepsilon_m = 2$  for  $m > 0$ ),  $J_m$  is the  $m$ th order Bessel function of first kind,  $Z_0$  equals to:

$$Z_0(z) = N_0^{-1/2} \cosh(kz) = \left[ \frac{1}{2} \left[ 1 + \frac{\sinh(2kd)}{2kd} \right] \right]^{-\frac{1}{2}} \cosh(kz) \quad (15)$$

and  $Z_0'(d)$  denotes  $Z_0$  derivative at  $z = d$ . The wave number  $k$  is associated with the wave frequency  $\omega$  by the dispersion equation:  $\omega^2 = kg \tanh(kd)$ .

For solving the diffraction and radiation problems, the method of matched axisymmetric eigenfunction expansions will be utilized. As per the method, the flow around the submerged cylinder is subdivided into cylinder - shaped fluid regions, denoted by *I, II, III* (see Figure 2), where appropriate series representations of the fluid's velocity potential in cylindrical co-ordinates will be established.

In accordance with the series representation of the undisturbed incident wave potential, eq. (14), the diffraction potential at each fluid region  $\ell = I, II, III$  is anticipated to:

$$\varphi_D^l(r, \theta, z) = -i\omega A \sum_{m=0}^{\infty} \varepsilon_m i^m \Psi_{Dm}^{\ell}(r, z) \cos(m\theta) \quad (16)$$

while for the radiation velocity potential  $\varphi_j^p$  at each fluid domain,  $\ell$ , yields:

$$\varphi_j^l(r, \theta, z) = \sum_{m=0}^{\infty} \Psi_{jm}^{\ell}(r, z) \cos(m\theta), \quad j = 1, 3, 5 \quad (17)$$

In the unknown functions  $\Psi_{jm}^{\ell}$  (see Equations (16) and (17)), the first subscript  $j = D, 1, 3, 5$  signifies the representative boundary value problem being considered, while the second subscript the  $m$  values that need to be taken into account. It is worth noting that the fluid flow resulting from the forced oscillation of the cylinder in still water, is symmetric about  $\theta = 0$  - plane and antisymmetric about  $\theta = \frac{\pi}{2}$  - plane for surge ( $j = 1$ ) and pitch ( $j = 5$ ) mode of motions, whereas it is symmetric with respect to both these planes for heave mode, ( $j = 3$ ). Hence, Equation (17) can be rewritten as:

$$\varphi_j^l(r, \theta, z) = \Psi_{j1}^{\ell}(r, z) \cos(\theta), \quad j = 1, 5 \quad (18)$$

$$\varphi_3^l(r, \theta, z) = \Psi_{30}^{\ell}(r, z), \quad j = 3 \quad (19)$$

To evaluate the unknown functions  $\Psi_{jm}^{\ell}$  the method of separation of variables for the Laplace differential equation is employed. Consequently, suitable series representations of the functions  $\Psi_{jm}^{\ell}, j = D, 1, 3, 5; \ell = I, II, III$  in each fluid domain around the submerged disk can be established (Kokkinowrachos, et al, 1986; Mavrakos, 1985, 1988, 2004)

(a) Outer fluid domain *I* ( $r \geq a, 0 \leq z \leq d$ )

$$\frac{1}{\delta_j} \Psi_{jm}^l(r, z) = g_{jm}^l(r, z) + \sum_{n=0}^{\infty} F_{jmn}^l \frac{K_m(a_n r)}{K_m(a_n a)} Z_n(z) \quad \text{for } j=D, 1, 3, 5; \quad (20)$$

where:

$$g_{Dm}^l(r, z) = \left\{ J_m(kr) - \frac{J_m(ka)}{H_m(ka)} H_m(kr) \right\} \frac{Z_0(z)}{d Z_0'(d)}; \quad g_{11}^l(r, z) = g_{30}^l(r, z) = g_{51}^l(r, z) = 0 \quad (21)$$

and  $\delta_D = \delta_1 = \delta_2 = \delta_3 = d$ ,  $\delta_4 = \delta_5 = d^2$ ;  $H_m, K_m$  are the  $m$ -th order Hankel function of first kind and the modified Bessel function of second kind, respectively. Also,  $F_{jmn}^l$  are the unknown Fourier coefficients to be established by the solution process. Moreover,

$$Z_n(z) = \left[ \frac{1}{2} \left[ 1 + \frac{\sin(2a_n d)}{2a_n d} \right] \right]^{-1/2} \cos(a_n z), n \geq 1 \quad (22)$$

The eigenvalues  $a_n$  are roots of the transcendental equation:  $\omega^2 + g a_n \tan(a_n d) = 0$ , which possesses one imaginary,  $a_0 = -ik, k > 0$  and infinite number of real roots.

(b) For the fluid domain of type *II* ( $0 \leq r \leq a, h_2 + h \leq z \leq d$ )

$$\frac{1}{\delta_j} \psi_{jm}^{II}(r, z) = g_{jm}^{II}(r, z) + \sum_{q=0}^{\infty} F_{jmq}^{II} \frac{I_m(a_q r)}{I_m(a_q a)} Z_q(z) \quad \text{for } j = D, 1, 3, 5 \quad (23)$$

where:

$$g_{Dm}^{II}(r, z) = g_{11}^{II}(r, z) = 0; \quad g_{30}^{II}(r, z) = \frac{z}{d} - 1 + \frac{g}{d\omega^2}; \quad g_{51}^{II}(r, z) = -\frac{r}{d^2} \left[ (z - d) + \frac{g}{\omega^2} \right] \quad (24)$$

and  $\delta_D = \delta_1 = \delta_2 = \delta_3 = d, \delta_4 = \delta_5 = d^2; I_m$ , the  $m$ -th order modified Bessel function of first kind. Here  $F_{jmq}^{II}$  denote the unknown Fourier coefficients to be determined by the solution process. Additionally,

$$Z_q(z) = \left[ \frac{1}{2} \left[ 1 + \frac{\sin(2a_q(d - (h + h_2)))}{2a_q(d - (h + h_2))} \right] \right]^{-1/2} \cos[a_q(z - (h + h_2))], q \geq 1 \quad (25)$$

The eigenvalues  $a_q$  are roots of the transcendental equation:  $\omega^2 + g a_q \tan[a_q(z - (h + h_2))] = 0$ , which possesses one imaginary,  $a_0 = -ik_{II}, k_{II} > 0$  and infinite number of real roots.

(c) For the fluid domain of type *III*

$$\frac{1}{\delta_j} \psi_{jm}^{III}(r, z) = g_{jm}^{III}(r, z) + \sum_{p=0}^{\infty} \varepsilon_p F_{jmp}^{III} \frac{I_m\left(\frac{p\pi r}{h_2}\right)}{I_m\left(\frac{p\pi a}{h_2}\right)} \cos\left(\frac{p\pi z}{h_2}\right) \quad (26)$$

where:

$$g_{Dm}^{III}(r, z) = g_{11}^{III}(r, z) = 0; \quad g_{30}^{III}(r, z) = \frac{z^2 - (\frac{1}{2})r^2}{2h_2 d}; \quad g_{51}^{III}(r, z) = -\frac{r[z^2 - (\frac{1}{4})r^2]}{2h_2 d^2} \quad (27)$$

$\delta_j, j = D, 1, 3, 5$ , is defined above and  $\varepsilon_p$  is the Newmann's symbol, see eq. (8);  $F_{jmp}^{III}$  are the unknown Fourier coefficients to be determined through the solution process. In Equations (20), (23) and (26),  $g_{jm}^l(r, z), l = I, II, III$  and  $j = 1, 3, 5$  represent particular solutions for the different mode of motions, which satisfy the respective kinematic conditions on the horizontal boundaries of the fluid domains of types *I, II* and *III*. The same is valid for the homogeneous parts of the series expansions of the velocity potential representations, see Equations (20), (23) and (26), which are properly selected so that the kinematic boundary conditions on the horizontal walls of the cylindrical body, the linearized dynamic condition on the free surface, see Equation (9), and the kinematic one on the seabed, see Equation (10), are satisfied beforehand. Employing Galerkin's method the potential solutions are aligned by ensuring continuity of hydrodynamic pressure and radial velocity at the vertical boundaries of adjacent fluid regions. Additionally, kinematic conditions on the bodies' wetted surfaces are satisfied. The methodology has been thoroughly detailed in prior publications for both the diffraction and the radiation problems (Kokkinowrachos, et al, 1986; Mavrakos, 1985, 1988, 2004) and thus, it will be no further elaborated in the present study.

Considering the extreme positions of the cylindrical disk near the free surface, i.e.  $h_1 \rightarrow 0$ , special attention has to be paid as the respective arguments of the Bessel functions involved in the series representation (23) become too large. To circumvent the difficulty, asymptotic expressions for the Bessel functions for large arguments are introduced (Abramowitz and Stegun, 1970) and the corresponding expression for the velocity potential representation in the second fluid domain, i.e.  $j = II$ , is recast as follows:

$$\frac{1}{\delta_j} \psi_{jm}^{II}(r, z) = g_{jm}^{II}(r, z) + \sum_{q=0}^{\infty} F_{jmq}^{II} \sqrt{\frac{a}{r}} \frac{e^{a_q r} f_1(a_q r)}{e^{a_q a} f_1(a_q a)} Z_q(z) \quad \text{for } j = D, 1, 3, 5 \quad (28)$$

with

$$f_1(z) = 1 - \frac{\mu-1}{8z} + \frac{(\mu-1)(\mu-9)}{2!(8z)^2} - \frac{(\mu-1)(\mu-9)(\mu-25)}{3!(8z)^3} + \dots \quad (29)$$

where  $\mu = 4m^2$ ; the rest of the symbols and functions involved in Equation (28) have been defined previously.

### 3.2 Numerical Formulation

Concerning the numerical formulations, two simulation tools, ANSYS Aqwa and HAQi software, are implemented. ANSYS AQWA is part of ANSYS Mechanical Enterprise suite which performs diffraction and radiation analysis based on potential theory ([ANSYS AQWA theory manual, 2015](#)). The physics of AQWA are applicable for finite depth waters and are solved under the frequency domain framework. The version that is used in the present work is the 2021R1. The central processing unit (CPU) time required to achieve the numerical simulation using 17208 wetted elements is about a quarter of a minute for each wave frequency. Figure 3 depicts the element discretization of the examined submerged body.

**Figure 3: Mesh overview of the examined submerged body for ANSYS AQWA.**

HAQi is an in-house developed numerical panel code ([Bardis and Mavrakos, 1988](#)) using the sink source technique. Specifically, the velocity potential at every point in the field is derived as the superposition of potentials arising from pulsating singularities (sources) distributed across the wetted surface of the body. Consequently, the fluid potential  $\Phi_j, j = 1, \dots, 6, 7$ , around the submerged structure, can be expressed as:

$$\Phi_j(x, y, z) = \frac{1}{4\pi} \iint_{S_0} Q_j(\xi, \eta, \zeta) G(x, y, z, \xi, \eta, \zeta) dS, j = 1, 2, \dots, 6, 7 \quad (30)$$

Here  $Q_j(\xi, \eta, \zeta)$  is the strength (i.e. density) of the singularity at  $(\xi, \eta, \zeta)$ ; the  $G(x, y, z, \xi, \eta, \zeta)$  is the Green function for finite water depth as given in [Wehausen and Laitone \(1960\)](#);  $x, y, z, \xi, \eta, \zeta$  are rectangular coordinates, and  $S_0$  is the submerged body's mean wetted surface.

The Laplace differential and the proper boundary conditions are automatically satisfied (see Section 3.1). Hence, the following integral equation can be derived for the diffraction ( $j = 7$ ) and the radiation problems ( $j = 1, 2, \dots, 6$ ), respectively:

$$\frac{1}{2} Q_j(x, y, z) + \frac{1}{4\pi} \iint_{S_0} Q_j(\xi, \eta, \zeta) \frac{\partial G(x, y, z, \xi, \eta, \zeta)}{\partial n} dS = \begin{cases} -\frac{\partial \varphi_0}{\partial n} & \text{for } j = 7 \\ n_i & \text{for } j = 1, 2, \dots, 6 \end{cases} \quad (31)$$

Here  $n_i$  denote the generalized normal components.

Equation (31) is addressed by subdividing  $S_0$  into plane quadrilateral or triangular elements with singularities positioned at the geometrical center of each element. The integral in Equation (31) is approximated by a finite series of  $P$  terms, where  $P$  represents the number of plane elements. Consequently, a linear system of  $P$  equations is formulated, which is then solved with respect to the source's strengths  $Q_j(\xi, \eta, \zeta), j = 1, 2, \dots, 6$ . Once  $Q_j(\xi, \eta, \zeta)$  has been computed for each element the flow potential can be readily determined from Equation (30). The theoretical framework of this three-dimensional method is extensively described in [Wehausen and Laitone \(1960\)](#); [Garrison \(1974, 1975\)](#); [Mavrakos and Bardis \(1984\)](#), thus it is no further elaborated herein.

The computational workload of the sink-sources formulation can be decreased for bodies with a symmetry plane. Specifically, in the examined case one half of the immersed surface is subdivided. Hence, a total of 266 elements have been considered for the discretization of the half body's wetted surface as can be seen in Figure 4, whereas the CPU time required is about less than a min for each wave frequency.

Figure 4: Panel discretization of the examined submerged body for HAQi.

#### 4. NUMERICAL RESULTS

This section compares and discusses the outcomes of the three presented formulations on the hydrodynamics of the submerged unmanned vehicle. The precision of the theoretical modelling is influenced by the evaluation procedure of the Fourier coefficients within each fluid domain surrounding the body. In the present calculations 80 terms are utilized for the series expansions of the velocity potential in the outer *I*, and upper *II*, fluid domain, whereas 150 terms are retained for the velocity representation in the lower type *III*. The theoretical results are acquired using an in-house computer software (Mavrakos, 1995) in FORTRAN programming language. The CPU time is set to less than a second for each analyzed wave frequency.

The geometric characteristics of the considered submerged body are: height of the body  $h$ , radius of the body  $a = 3.023h$ , whereas the water depth  $d = 290.7h$ . These dimensions have been properly selected based on the geometry of the underwater vehicle developed by the CMMI (see Section 2). Initially, the body is assumed to be floating at  $0.116h$  below the free water surface. In Figure 5 the Response Amplitude Operator (RAO) of the exciting wave forces and moments on the submerged vehicle are presented. The depicted results are evaluated by the theoretical formulation and the numerical software.

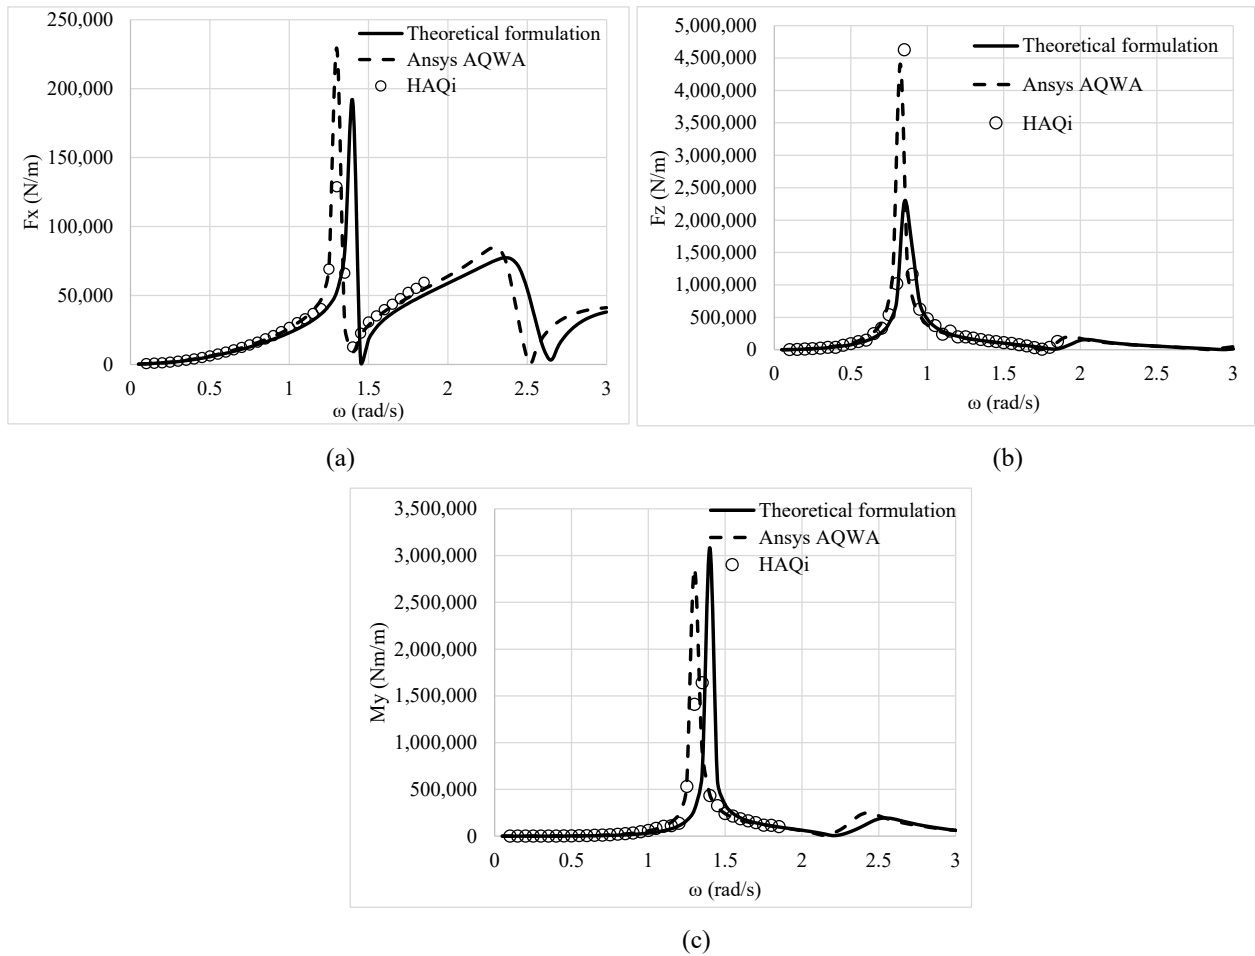

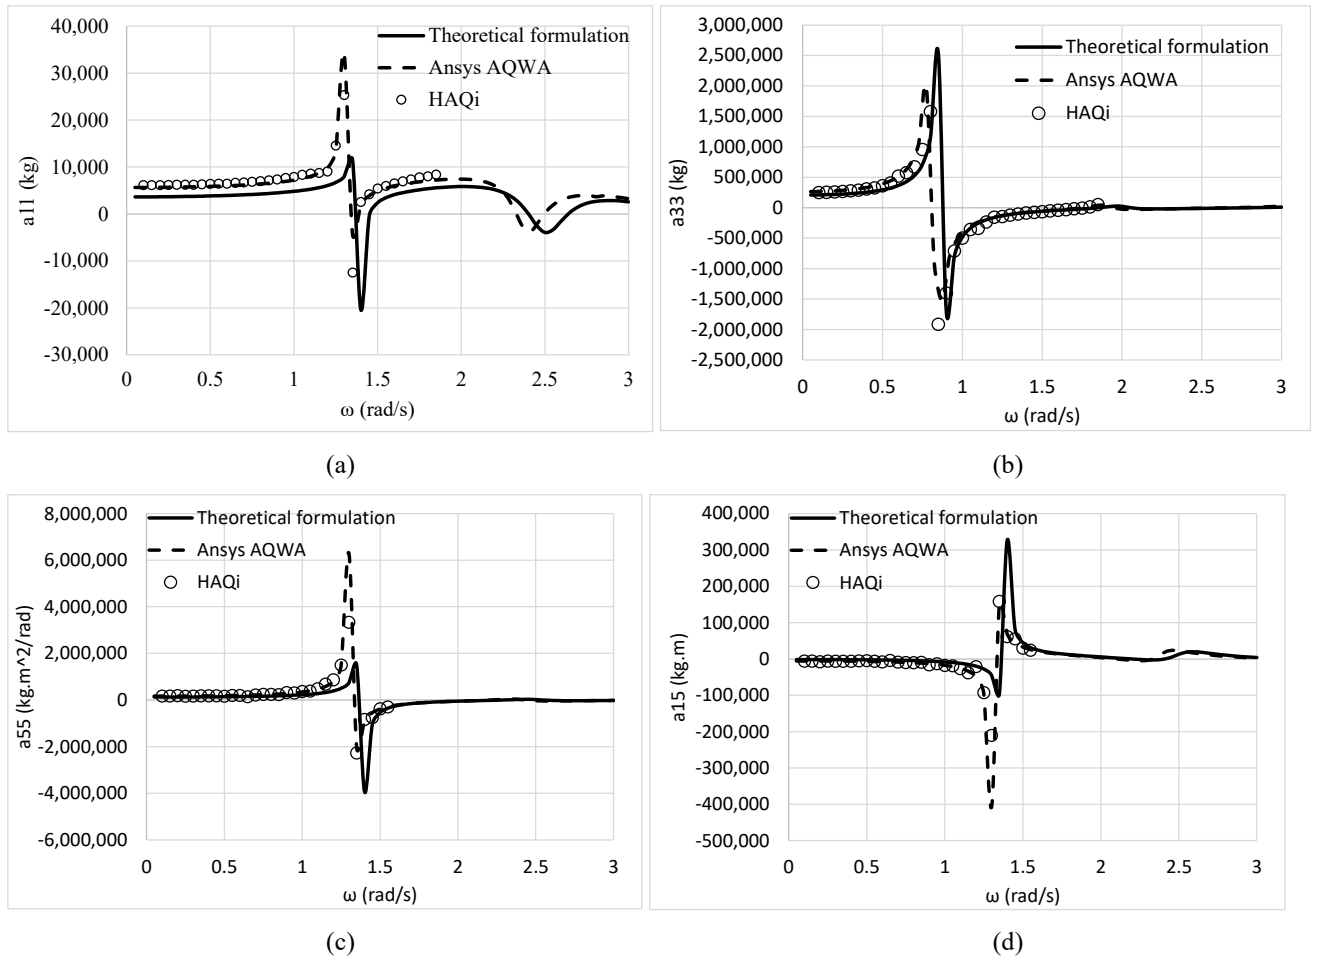

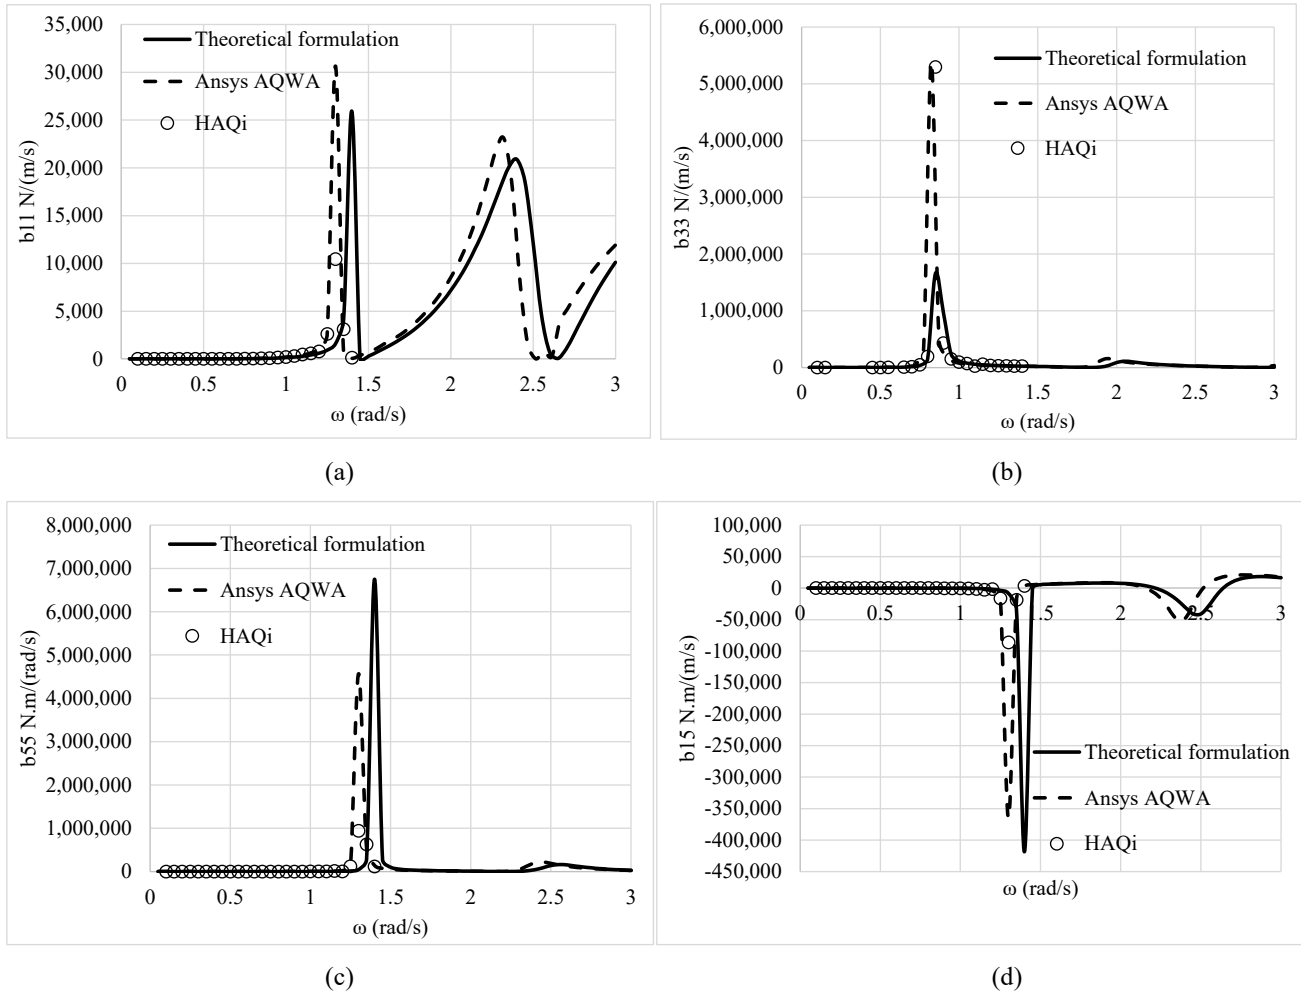

Figure 5: RAO of the exciting forces and moments on the submerged body: (a) horizontal forces; (b) vertical forces; (c) horizontal moments

It is evident from Figure 5a that the horizontal exciting forces show an oscillatory behavior. Specifically in the vicinity of  $\omega = 1.3\text{rad/s}$  the forces depict a quite rapid increase, while a rapid decrease follows leading to a local minimum at  $\omega = 1.4\text{rad/s}$ . The values of  $F_x$  exhibit a similar pattern of variation also in the vicinity of  $\omega = 2.3\text{ rad/s}$  and  $\omega = 2.4\text{ rad/s}$ , with a smoother, however, increase and decrease, respectively. It can be also seen from Figure 5c that similar to the surge exciting forces, the sharp peaks observed in horizontal moments are presented at the same wave frequencies. Regarding, the heave exciting forces (see Figure 5b) a smooth variation pattern is depicted with a peak at the neighborhood of  $\omega = 0.85\text{rad/s}$ . As far as the comparisons of the applied methodologies are concerned it can be seen that the results from the numerical software HAQi correlate excellently to the outcomes of AQWA. It is worth noting that certain differences between the results of the theoretical and numerical methods, particularly at wave numbers where the exciting forces reach peaks, can be deemed negligible. This is because the theoretical results are perfectly aligned with the variation pattern observed in the outcomes derived from the numerical formulation.

Figure 6 illustrates the comparison of the added mass coefficients,  $A_{11}, A_{33}, A_{55}, A_{15}$  between the theoretical and the numerical models. A strong frequency dependence on the hydrodynamic mass is depicted. The latter is accompanied by sharp peaks at certain frequency ranges. It should be noted that the variation of  $A_{11}$  is marked by the occurrence of distinct peaks at the same wave frequencies in which  $F_x$  attains maximum and minimum values (see Figure 6a). The same applies to the concerned wave frequency range, where resonance phenomena occur in  $A_{33}$  (see Figure 6b). Specifically,  $A_{33}$  shows an oscillatory variation pattern at the neighborhood of  $\omega = 0.85\text{rad/s}$ , where the heave exciting forces also attain a peak. Additionally, it is important to note that negative values of the added mass coefficients  $A_{11}, A_{33}$ , are depicted near the resonant frequencies. Ogilvie (1963) also observed a similar phenomenon. Regarding the comparisons between the applied methodologies, it can be obtained that the two numerical approaches attain similar results. However, discrepancies between the results of the numerical and the theoretical methods are notable, especially at the vicinity of the resonant frequencies.

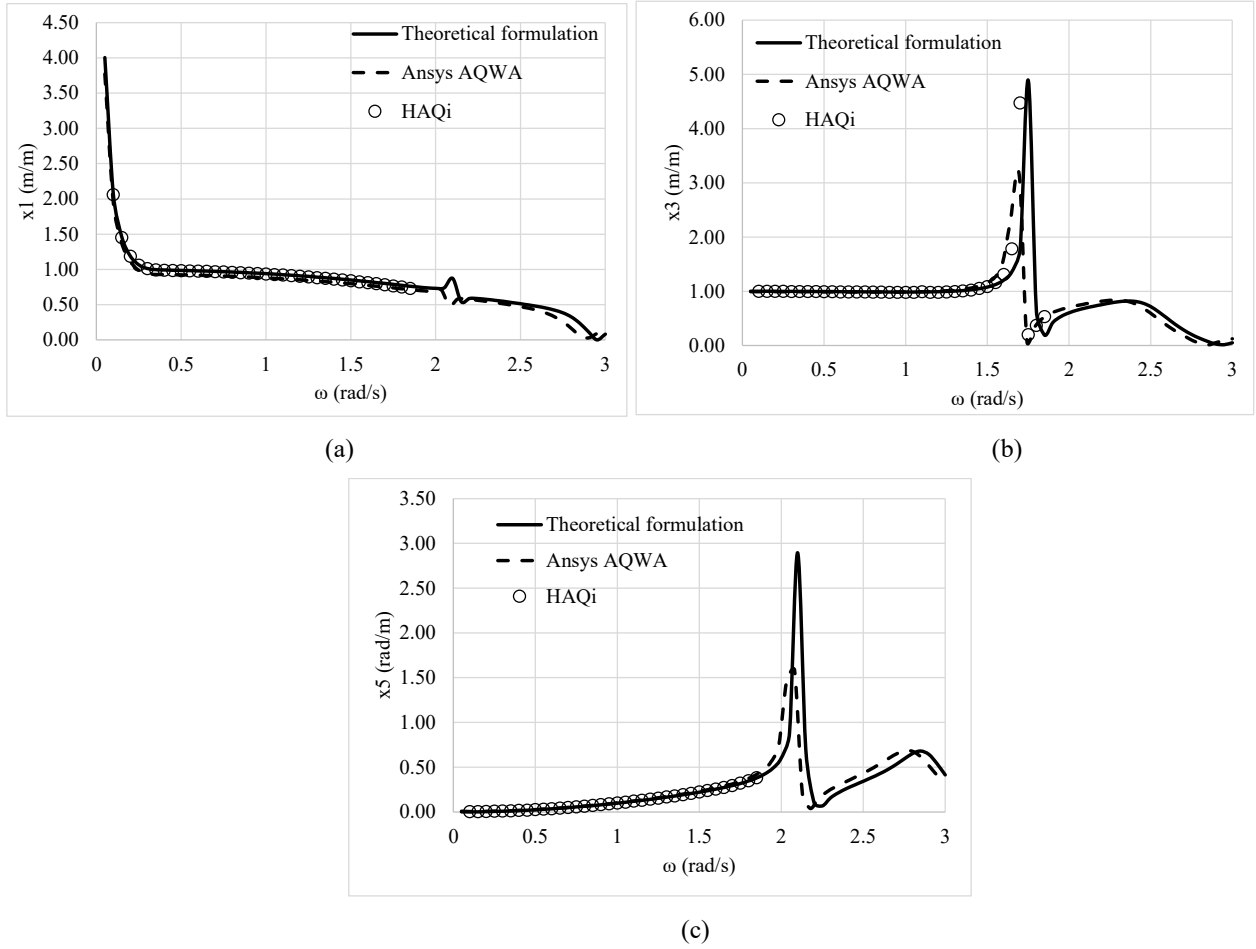

**Figure 6: Hydrodynamic mass of the submerged body: (a) at the surge direction due to its forced oscillation in surge; (b) at the heave direction due to its forced oscillation in heave; (c) at the pitch direction due to its forced rotation in pitch; (d) at the surge direction due to its forced rotation in pitch**

**Figure 7: Damping coefficient of the submerged body: (a) at the surge direction due to its forced oscillation in surge; (b) at the heave direction due to its forced oscillation in heave; (c) at the pitch direction due to its forced rotation in pitch; (d) at the surge direction due to its forced rotation in pitch**

Figure 7 illustrates the comparison of the damping coefficients  $B_{11}$ ,  $B_{33}$ ,  $B_{55}$ ,  $B_{15}$  among the three considered formulations. It is evident that  $B_{11}$ ,  $B_{33}$  follow, in general, the variation pattern of the surge and heave exciting forces, characterized by peaks occurring in the neighborhood of  $\omega = 1.3 \text{ rad/s}$  and  $\omega = 0.85 \text{ rad/s}$ , respectively. It is worthwhile to note that the damping coefficients express positive values in the examined wave frequency range. Concerning the comparison between theoretical and numerical methods, it can be concluded that both numerical methods achieve comparable outcomes, whereas the theoretical analysis predicts the resonant locations at slightly higher values of wave frequencies. Nevertheless, these discrepancies are limited only near the resonant frequencies, whilst the theoretical formulation can describe accurately the hydrodynamic characteristics in the remain wave frequencies.

In Figure 8 the horizontal and vertical motions, as well as the horizontal rotations of the submerged vehicle are plotted. It can be seen that the values of  $x_1$  decrease as the wave frequencies increase. On the other hand,  $x_3$  begins its variation from a baseline value of one (at  $\omega = 0.05 \text{ rad/s}$ ), and it increases up to  $\omega = 1.7 \text{ rad/s}$ , where a local maximum of  $x_3$  is attained. A smooth decrease follows leading to a local minimum of  $x_3$  at  $\omega = 1.8 \text{ rad/s}$ . Regarding  $x_5$  a sharp increase is depicted in the neighborhood of  $\omega = 2 \text{ rad/s}$ , which is followed by a prompt decrease at  $\omega = 2.2 \text{ rad/s}$ . Furthermore, it should be noted that both the numerical models and the theoretical formulation attain similar results for the body's motions and rotations.

**Figure 8: Motions and rotations of the submerged body: (a) horizontal motion  $x_1/(H/2)$ ; (b) vertical motion  $x_3/(H/2)$ ; (c) horizontal rotation  $x_5/(kH/2)$**

Subsequently, several submergences below free water surface are examined. Specifically, the submerged vehicle is assumed to be floating at  $1h, 2h, 3h, 4h$ , below the free water surface, whereas the geometrical characteristics of the body and the water depth are remained constant. Here the outcomes are derived by the theoretical formulation, whereas the AQWA software is applied for comparative purposes for a submergence of  $0h$ , i.e., there exists no gap between the body's upper surface and the free water surface.

Figure 9 depicts the exciting forces and moments on the body for the various considered submergences. It can be seen that the oscillatory behavior of  $F_x, F_z, M_y$  for the  $0.116h$  case is not present for higher submergences and for the scenario where the body is floating at the free surface. Furthermore, it is depicted that the exciting forces and moments decrease as the submergence increases.

Figure 10 displays the hydrodynamic coefficients of the submerged body for different levels of submergence considered. The figure illustrates that the closer to the free surface the submerged body is, the stronger the frequency dependence of the hydrodynamic parameters is. The latter is described by the decrease of sharp peaks at certain frequency ranges as the submergences increase. This also holds true for the body floating on the free surface in which no sharp peaks are presented. Therefore, it can be concluded that the hydrodynamic characteristics of the submerged cylinder undergo considerable influence by the position which is closest to the free surface. Based on McIver and Evans (1984) this can be attributed to near-standing waves which are occurred at certain wave frequencies above the submerged body at small submergence distances compared to the body's diameter.

## 5. CONCLUSIONS

In this paper, the effect of submergence on the hydrodynamics of an unmanned cylindrical vehicle floating below the free water surface is investigated. Three different methodologies, one theoretical and two numerical, are described and compared for various submergence distances between the body and the sea surface. The main conclusions of this study are as follows:

- the hydrodynamics of the submerged cylinder are significantly affected by the submergence of the body below the free water surface. Specifically, for small distances between the body and the free water surface sharp peaks are attained on the vehicle's hydrodynamics,
- the added mass coefficients express negative values at specific wave frequencies are noted for small submergence, which are eliminated as the body-free surface distances increase. Nevertheless, the damping coefficients express positive values in the examined wave frequency range, regardless the submergence values,
- regarding the applied methodologies, the in-house numerical software HAQi attains similar outcomes with the commercial AQWA software. Furthermore, the results from the developed theoretical formulation are perfectly aligned with the variation pattern of the outcomes from the numerical methods. However, deviations do exist at wave frequencies in which the body's hydrodynamics attain peaks.
- The findings of this analysis suggest that in near-surface operations (i.e., for a submergence depth lower than the radius of the submerged body), wave motion primarily consists of a standing wave, leading to swift alterations in both added mass and damping coefficients. Therefore, when designing submerged bodies, it's crucial to carefully consider the geometric attributes in relation to the wave characteristics since unexpected forces on the hull may be introduced increasing the inertia of the body and affecting its acceleration.

This inquiry could be expanded to explore the effect of the distance between a submerged body and the seabed on the body's hydrodynamics. Furthermore, the analysis could be further developed on the effect of various submergence distances between the free water surface and a random shaped body on the latter hydrodynamics.

# The Importance of Ontological Commitment and Linguistics in Relation to the Elucidation of Design Requirements

Connor W. Arrigan<sup>1,\*</sup>, Morgan C. Parker<sup>1</sup>, and David J. Singer<sup>1</sup>

## ABSTRACT

*One of the design process's earliest and most critical stages is establishing and determining requirements. Design requirements are often expressed through language, whether in written documents, diagrams, or verbal discussions in terms of the client's "wants" and "needs" or balancing what they can "afford." Designers use of quotes around "wants," "needs," and "afford" signals ambiguity or doubt in the meaning of the terms. The language used during early discourse is crucial for expressing and translating these ambiguous terms into specific unambiguous design requirements, which significantly shape and constrain possible solutions. In philosophy, this concept is known as ontological commitment. Embedded language in requirements documents, expressed through constraints, objectives, and functions, establish the ontological commitment to a specific solution space. Prior marine design research has focused on the wicked problem of requirements elucidation, with the goal visualizing potential solutions derived from language, and a more direct link to ontological commitment was developed by Andrews in the concept of style Duchateau (2016) van Ores (2011) Andrews (2012). However, the role and impact of linguistics in translating and interpreting uncertain or ambiguous terms into specific design requirements has been largely overlooked. This paper presents modern direct examples of ontological commitment from requirements development for the Littoral Combat Ship.*

## KEY WORDS

Design Requirements, Ontological Commitment, Naval Vessel Design, Linguistics, Early-Stage Concept Design

## INTRODUCTION

The process of engineering design is a complex, highly entangled, and multifaceted endeavor, that commences with concept design and the establishment of design requirements. At this formative stage, the articulation of design needs, goals, and constraints are often conveyed through language, be it in written documents, visual diagrams, or verbal interactions. An intriguing phenomenon within this domain is the use of scare quotes by designers to underscore terms such as "wants," "needs," and "afford," signifying an element of doubt or ambiguity surrounding these crucial design aspects. Numerous examples of scare quotes can be found for in the design language for both military and commercial ships. A recent defense example can be seen through the development of the Landing Ship Medium. An article announced the "Draft Proposal for 'Affordable' Medium Landing Ship" Lagrone (2023). The scare quote around the word affordable signal the uncertainty with the cost of the vessel being designed. Further, some of the initial desired features for the ship state the want for

“a “modest” suite of C4I equipment” or “a “Tier 2+” plus level of survivability” O’Rourke (2023). In both of these cases there is a level of ambiguity in how one would define modest or the level of survivability. These scare quotes, which typically serve to express uncertainty, are emblematic of the intricate interplay between language and the design process. One commercial example from the cruise ship industry can be seen through the idea used by Royal Caribbean of “above and beyond compliance” Royal Caribbean Group (2020). Primarily, this scare quote is concerning safety and environmental concerns, although they weren’t initially specified requirements at the onset of the design process in terms of what “above” compliance means in relation to additional capability needed. Throughout the design process ideas evolved into innovative concepts such as the Safety Command Center Royal Caribbean Group (2024). Initially undefined, this concept emerged and matured during the design process, guided by the philosophy of surpassing mere compliance to embrace a higher standard of safety. Additionally, one can argue that there is a large amount of uncertainty with what “above” compliance really means.

Language, with its capacity to express the nuanced aspects of “wants” and “needs,” plays a pivotal role in translating abstract desires into precise, unambiguous design requirements. The manner in which these requirements are framed through embedded language significantly influences and constrains the realm of possible design concepts and solutions, a concept analogous to the philosophical notion of ontological commitment. In philosophy, ontological commitment explores the connection between statements of existence and specific entities or types of entities, and in the context of design, the language embedded in requirements documents as well as design approaches, methods, processes, and tools establishes an ontological commitment to a predicated solution space Jubien (1998). The purpose of this paper is to present ontological principles within the framework of marine design, elucidating their impact on and ability to clarify design results.

## **Philosophy in Marine Design**

Engineering, as a discipline, is often perceived as a realm of technical knowledge and practical applications. However, “overlying every technical or civil system is a social system that provides purpose, goals, and decision criteria” Miles and California Institute of Technology (1973). All engineering activities, including the language used in requirements or the logical reasoning behind decisions, are grounded in humanity based fields like cognitive psychology or philosophy. Looking back, Aristotle believed there were many reasons philosophy was practically important, “the analysis of foundational philosophical concepts cannot but influence science” Rovelli (2016) Andrews (2018b). Additionally, in his discussion on the philosophy of design, Galle argues that philosophy “serves the end of helping, guiding, suggesting how the [designer] comes to understand what he is doing, and not simply how he comes to do what he is doing.” This coming to understand what one is doing, rather than just understanding how to do it is an insight about design... [that] can only be pursued by philosophical means” Galle (2002) Andrews (2018b). Philosophy enhances conceptual clarity in engineering. It helps engineers define and refine abstract concepts, such as efficiency, sustainability, affordability, and risk, to ensure that they are well-understood and can be effectively implemented in the design and evaluation of engineering systems.

Andrews’ exploration of Style in many works largely aims to introduce philosophy into the domain of ship design and requirements elucidation Andrews (2018a). Andrews states that “the style to be adopted in a specific design option is seen to be the key design decision for that option and so is the first design decision...” Andrews (2018b). Additionally, Andrews argues that “style can make a substantial difference to the final outcome of a design, so their relative impact ought, in the case of a complex ship, to emerge from a proper dialogue between designer and client ...” Andrews (2018a). Keane and Tibbits similarly argue that “the way ahead for a successful ship design starts with establishing the initial design philosophy...” Keane and Tibbits (2013). A design philosophy sets the tone for an entire program, such as “Design/Build” for the U.S. Navy’s Virginia class attack submarine, which signaled major changes to organizations, contracts, and processes relative to past Navy programs.

The setting of a design philosophy or Style is an ontological commitment, in how ontological commitment directly establishes relations to a predicated solution space. A direct justification of the need for Style in design lies within the concepts of ontology. The intent of this paper is to introduce ontological concepts in the context of marine design, and how they can influence and explain design outcomes.

## IMPORTANT PHILOSOPHICAL AND ONTOLOGICAL CONCEPTS IN ENGINEERING DESIGN

The following section introduces and defines multiple philosophical and ontological concepts that are relevant to engineering design and in elucidating design requirements. The case study presented later in this manuscript largely utilizes and investigates the concepts of a universe of discourse, an ontological anchor, and ontological conflict (anguish). However, the other concepts introduced below are to help provide a more compressive understanding.

### The Notion of a Universe of Discourse

A universe of discourse establishes the scope or domain of a statement or argument, indicating what is relevant and applicable to the discussion at hand. A universe of discourse is implied or defined, clarifying the boundaries of the discussion and ensuring that statements or arguments are meaningful within the specified context. Certain types of objects or concepts will be included, while others will be excluded. The universe of discourse is particularly important in relation to the elucidation of design requirements as this is a key point in the design process when domains to be included in a design are set and ranges on design variables are specified. Returning to Style, selecting a certain Style directly influences the universe of discourse of a design. For example when designing a container ship one may consider the styles of robustness, commercial quality, operational serviceability, or producability, but would probably not include lethality. On the other hand if one were designing a naval vessel by nature one would need to include lethality, while excluding commercially unique concepts. In general terms, a universe of discourse is an inclusive class of entities that is implied or defined relative to a statement or theory.

### The Notion of Ontological Commitment

Ontological commitment is defined “to be a relation that holds between persons or existence assertions, on the one hand, and specific entities or kinds of entities, on the other” Jubien (1998). This implies that “assertions of the existence of specific entities or kinds of entities are the intuitive source of the notion of an ontological commitment” Jubien (1998). In more basic terms, the concept of ontological commitment represents the acknowledgment that one assigns value to something through inference of belief within an existing domain or context, and the ontological commitment is only valid when it is connected to some conception of past existence. There are many examples that exist of ontological commitments. For example, some of the ontological commitments of physics include atoms, quarks, and space-time. To further this example, physics theory is ontologically committed to the concept of electrons. This means that the truth of physics requires that electrons exist and behave in certain ways.

Another way to think about ontological commitment is through the idea that ontological commitment reveals the “demands imposed on the world” Rayo (2007). Explicit and implicit ontological commitment are two of the more recent concepts that have been introduced. The concepts are directly a byproduct from the modern efforts to try to quantify all entities involved in a commitment and were originally present by Peacock and Krämer and expanded upon by Österblom Peacock (2011) Krämer (2014) Österblom (2017). Explicit ontological commitments are defined by the entities that are claimed to exist that are directly stated in the statement of a theory or statement Peacock (2011) Österblom (2017). In other more simple terms “a theory is explicitly ontologically committed [to an entity] if it contains some sentence that means there are X” Krämer (2014) Österblom (2017). Explicit ontological commitment is a pretty clear notion and really covers any direct statement of existence. In common language, explicit commitment refer to relations, statements, or entities that are clearly stated and actually understood by individuals. To cover the commitments that are not directly stated or directly related to a theory or statement there is implicit ontological commitment. Implicit ontological commitment are defined by two criteria. The first of the criteria for determine implicit ontological commitments is “the theory could not be true unless X existed,” and the second is “the theory is committed to X and not explicitly committed to X” Peacock (2011) Österblom (2017). In more common language implicit commitments refer to relations, statements, or entities that either classify as believed to be understood or that fall into the category of unknown-unknowns. In relation to the case study presented later in this manuscript,

this work does not directly attempt to use ontological commitment from philosophy but is inspired and investigates commitments relative to design requirements and decisions.

## **The Notion of Ontological Cost**

Ontological cost was introduced by Peacock and furthered by Österblom and it is meant to look at the preconditions of an ontological commitment and reckon what cost is imposed by making that commitment Österblom (2017) Peacock (2011). The “ontological cost of a theory is to ask what is given that it must be true. It is to ask what entities or kinds of entities are needed or required for the truth of the theory” Österblom (2017). In other words this is essentially to ask what explicit and implicit commitments are needed to make a given ontological commitment. In relation to the case study presented later in this manuscript, ontological cost can be physically interpreted and measured by the cost implications of a specific design requirement, ontological commitment, or design change or decision.

## **The Notion of an Ontological Anchor**

A novel, critical concept to introduce that is directly related to the concept of ontological commitment is the concept of an ontological anchor. The term ontological anchor is not defined in the field of philosophy, but is rather inspired from philosophy. The term was coined in a conversation with a retired U.S. Navy Captain. The term ontological anchor refers to a stronger concept than ontological commitment. An ontological anchor refers to the fastening of one’s view of the universe of discourse or belief system to a specific assertion or assertions. While at first ontological commitment and ontological anchors may seem the same, there are some important subtle differences. An important note on ontological commitment is that in evaluating relations the universe of discourse and truth are static. There is also a dependence that the universe of discourse and truth statement need to be aligned in ontological commitment. In this context a truth statement is defined by a proposition or sentence that is considered to accurately represent reality. It is a statement that is true or perceived true, meaning it corresponds to the facts or the way things really are or how things are perceived. However, with an ontological anchor, truth is independent of the universe of discourse. Thus, the largest and most important difference between ontological commitment versus ontological anchors is truth versus untruth. Ontological anchors hold in situations with false truth statements as one either creates a universe of discourse to justify the incorrect truth statement or ignores the universe of discourse all together. Organizational bias can be seen as a strong example of an ontological anchor. Ontological anchors can also be supported from concepts from organizational theory. Two concepts from organizational theory that help support the concept of an ontological anchor are the anchoring effect and the concept of strategic misrepresentation. The idea of the anchoring effect is that “an individual’s judgements or decisions are influenced by a reference point or “anchor” which can be completely irrelevant” Wikipedia (2023). Strategic misrepresentation is the concept that “decisions are based solely on the optimism of benefits and projected accordingly to management or leadership” The Strategy Institute (2023). In both of these theories the root influence or reference represent an ontological anchor.

Cognitive dissonance theory suggests that individuals experience discomfort or tension when holding conflicting beliefs, attitudes, or values. When someone is presented with information that contradicts their existing beliefs, they may experience cognitive dissonance and attempt to resolve it by reinforcing their existing beliefs rather than changing them Festinger (1957). Thus, direct truth or facts cannot be used since the individual is anchored to a universe of discourse that justifies their views. In more common language the ontological anchor occurs when people or designers know what they are doing is bad or incorrect, but they proceed to do it anyway even though they know better.

To introduce an analogy as an example of an ontological anchor one can consider a game of Sudoku. In Sudoku a number of the squares depending on the difficulty are already filled in with numbers. These numbers can be considered one’s ontological anchors. When playing Sudoku one must account for the pre-filled in numbers in their solution and if the pre-filled in numbers are moved or changed, the predicated solution changes or may become infeasible. This same behavior can be seen with design and complex engineering problems.

Two interesting examples of ontological anchors during design are illustrated through the SR-71 Blackbird Program. With

the SR-71, the U.S. Air Force insisted on having its insignia painted on the wings and fuselage, “even though no one would ever see it at eighty-five thousand feet” Rich and Janos (1994). This anchor of needing insignia painted even on a spy aircraft caused for major ontological costs, actual costs, and development. They even had to use pink paint instead of white to try to limit detection Rich and Janos (1994). Another example of an ontological anchor during the program was how the U.S. Air Force also mandated the aircraft could pass a dust test for low altitude flight over the desert even though the aircraft would be flying at altitudes of over 16 miles Rich and Janos (1994). These can be seen as ontological anchors as they directly show the fastening of the U.S. Air Force’s view on the design of an aircraft.

## **The Notion of Ontological Conflict (Anguish)**

Ontological conflict (anguish) is an important concept to define prior to delving into the presented case study. Ontological conflict or anguish is not defined in the field of philosophy, but is rather inspired from philosophy. In philosophy the existential concept of anguish, as articulated by philosophers like Jean-Paul Sartre and Søren Kierkegaard, plays a significant role in the context of decision-making. This concept is rooted in the idea that human existence is characterized by a fundamental sense of anxiety and anguish, which arises from our freedom and responsibility to make choices. Existential anguish, also known as existential dread or anxiety, is considered a fundamental aspect of the human condition. It emerges from the realization that human beings are free to make choices, and with this freedom comes the burden of responsibility for those choices. The act of making choices in this context becomes a source of anguish. When individuals confront a decision, they experience existential anguish as they grapple with the uncertainty of outcomes and the weight of their choices. This anguish is not merely a psychological condition but an inherent part of the human experience. This can directly apply to the decision making one faces as a designer or an engineer. In relation to ontological commitment, when a design decision is made that causes for a misalignment of “truth,” universe of discourse, or another ontological commitment, there exists ontological conflict (anguish) associated with the decision. This will be shown later in the investigated case study. Practical examples of ontological anguish can be seen through computation fluid dynamics (CFD) replacing towing tanks or one’s struggle in developing new methods that disprove prior methods.

## **The Philosophical Concept of Discourse Ontology**

In philosophy, discourse ontology refers to the study or analysis of existence and reality as expressed through language and discourse. It involves examining how our understanding of being and the nature of reality is shaped, conveyed, and constructed through language and communication. Discourse ontology explores the relationship between language and our understanding of reality. It considers how language structures and influences our perception of being and existence. Tombras defines discourse ontology formally as “an ontology—in so far as it concerns being, i.e. the open space where a world can present itself as intelligible to the human being—with the designation “discourse” denoting the source of this intelligibility” Tombras (2019). One should note that by combining discourse ontologies one is able to form a universe of discourse. This process involves bringing together various discourses or ways of talking about existence to create a broader and more inclusive context for investigation and inquiry.

## **Introducing Philosophy to Engineering Design**

Navigating the intricate realm of design requires a nuanced understanding of its complexities and entanglements. Entanglement in this case refers to the concept that one cannot look at certain aspects or concepts in isolation but rather as a whole in terms of both macroscopic and microscopic impacts. As begins the elucidation process of defining requirements and initiating the design process, the philosophical and ontological concepts introduced above each wield a substantial influence on the process. Among these, the notions of universe of discourse, ontological commitment, ontological cost, ontological anchor, ontological anguish, and discourse ontology play a profound role in shaping the trajectory of design endeavors. By delving into real-world examples, one can unravel the intricate interplay of these ontological considerations and appreciate their substantial impact on engineering design. To underscore their significance, it is insightful to examine the challenges

encountered by naval vessel design programs, as they represent long duration design projects, and many have significant amounts of publicly available information. The following sections will look at public information from the Littoral Combat Ship (LCS) program to illustrate philosophical and ontological aspects in design and the elucidation of design requirements.

## **AN INTRODUCTION TO U.S. NAVY SURFACE SHIP DESIGN**

The design of U.S. Navy ships involves several key entities including the Office of the Chief of Naval Operations (OPNAV), Naval Sea Systems Command (NAVSEA), Program Executive Office Ships (PEO Ships), and shipbuilders. For ship design, OPNAV establishes strategic and operational requirements and is responsible for resource allocation. PEO Ships manages the design, construction, and delivery of ships, ensuring that ships meet operational, schedule, and budget requirements. PEO Ships is affiliated with NAVSEA, and NAVSEA engineering directorates are the principal authority for design and engineering. NAVSEA defines and manages technical requirements including adherence to safety, environmental, and performance standards. Shipbuilders and industry play a pivotal role in the actualization of naval ship designs, translating design specifications into detailed designs and ultimately construction and delivery. The process for the acquisition of a ship is complicated and bureaucratic, involving the development of binding design requirements, specifications, and contract documents.

## **THE LITTORAL COMBAT SHIP (LCS) AS A CASE STUDY**

One of the U.S. Navy's more recent ship design programs was the development of the Littoral Combat Ship (LCS). The design of LCS proves to be an insightful study as there is an atypically large volume of publicly available literature showing a change in perception of the design. Perception has ranged from being what the Navy needed as a "streetfighter" during concept development, to derision as "The Navy's Very Expensive Mistake" when several ships in the class were decommissioned early Barbaro and Lipton (2023). This case study looks to explain that change in perception through a philosophical and ontological analysis of the design challenges and requirements development.

It is the authors' premise that top level truth statement(s) for an organization must hold true for a design to be successful, acting as ontological anchors. These anchors can be considered a Style, or design philosophy. If the motives or narrative for a design or design decision are in line with the ontological anchors, the process can move ahead smoothly. However, if entities are working toward false anchors or the design becomes misaligned with the true ontological anchors, this will result in design churn or re-work until the design either aligns or fails. Recognizing and accounting for the discourses, ontological commitments, and ontological anchors is critical for a successful design program. In the case of LCS, the change in perception about the program may be explained using the premise that a global universe of discourse with shared ontological anchors did not exist. Once the true anchors became clear and were commonly held, the pull toward alignment came in the form of changes to the program.

Three aspects of the LCS program will be presented as two cases: changes in vessel rules during the bidding and design process, changes in the evaluation of survivability over the design process, and changes in vessel lethality over the design process and introduction to the fleet.

### **Case 1: The Ontological Anchors of a Commercial Parent, Commercial Rules, and Survivability**

The LCS program was originally conceived as part of a surface combatant family of ships. LCS was envisioned to be the small and low cost ship that could be built in larger numbers, in part relying on the broader force network for effectiveness and survivability Work (2014). Attempting to meet affordability targets meant designing LCS to a commercial parent, with reduced survivability, and to commercial standards. Each of these ontological anchors is examined in turn.

The first ontological anchor was to use a commercial parent hull form and industry partnered vessel rules. Based on the initial stipulations for LCS, industry designs were based on high speed ferries. “The philosophy of the two industry design teams was to leverage technical advances and risk-reducing lessons learned in these high-speed commercial ferry designs, while integrating features and design approaches that are unique to a U.S. Navy Combatant” Keane and Tibbits (2013). However, “the incorrect framing assumption was that these commercial vessels were appropriate parents upon which to base an appreciably different warship” Keane and Tibbits (2013). While at the time this may have seemed like a good idea, this represents a major ontological commitment. By using commercial ferry designs as a parent hull, the industry design teams greatly predicated, influenced, and committed the universe of discourse for the design and translation of requirements for LCS. During this process however, “grumbings from the surface warfare community, which was highly skeptical of warship based on commercially derived designs,” started to cause a shift in requirements Work (2014). This shift is an example of ontological conflict resulting from a false ontological anchor. In this case, the design started to be pulled away from the false ontological anchor (commercial parent) and begin aligning with the underlying true ontological anchor (warship).

The next ontological anchor is that industry partnered rules were sufficient for a warship. When initially setting out the bid for LCS, “the Navy initially asked for ship designs using American Bureau of Shipping (ABS) High Speed Naval Craft Rules, which were essentially commercial standards” Work (2014). In 2003, a partnership was developed between the U.S. Navy and ABS. The partnership was intended to help develop the Naval Vessel Rules (NVR), a set of rules meant to update military general specifications and develop rules in collaboration with industry. LCS was the first vessel where NVR would be implemented. It should be noted that the “implementation of new Naval Vessel Rules (design guidelines) further complicated the Navy’s concurrent design-build strategy for LCS. These rules required program officials to redesign major elements of each LCS design to meet enhanced survivability requirements, even after construction had begun on the first ship” United States Government Accountability Office (2007). The switch from ABS High Speed Naval Craft Rules to the NVR occurred after the contract for the vessel was awarded.

In testimony before Congress at the time, NAVSEA stated the partnership with ABS was “to write a new set of rules to take the best of the old and some of the good commercial practice from ABS and blend them together in a set of Naval Vessel Rules for the ship. A problem is that we did that throughout—concurrently throughout the time when the bidders were bidding on the ship and the ship that we bid and the ship that we costed out is not the same ship that we are buying today because of the parallel development of those rules” U.S. Government Printing Office (2007). The development of the rules in parallel with the design of the ship caused for numerous late stage design changes. This can directly be seen through how NAVSEA stated in the testimony that “the ship that was bid did not include many of the provisions of the Naval Vessel Rules because it was based on a commercial design and in getting the ship design from the commercial design to meet the rules that we need to keep our sailors safe” U.S. Government Printing Office (2007). The ontological anguish of this can also be seen on the shipbuilder side from the same hearing from testimony by the president of Lockheed Martin at the time, “we bid, as [NAVSEA] said, a commercial ship. ABS class ship was our bid. The Navy decided, for good reasons, to make this ship a surface combatant which would be very survivable, which it is. And that caused a lot of change” U.S. Government Printing Office (2007).

The final anchor, alluded to above, was the acceptability of a less survivable warship. At the outset, LCS was designed to a “Level 1+ survivability standard, which is greater than the Level I standard to which the Navy’s current patrol craft and mine warfare ships were designed, but less than the Level II standard to which the Navy’s current Oliver Hazard Perry (FFG-7) class frigates were designed” O’Rourke (2012). However, hitting this requirement with a commercial parent and commercial based standards proved a challenge, “...designers simply did not believe they could hit the LCS cost targets... Consequently, early program documents established “crew survivability” as the minimal design standard” Work (2014). Even then, this meant changes relative to commercial rules, including shock hardening of systems, additional water-tight compartmentalization, and redundant firefighting systems. The yards selected for the ship did not initially have the capability needed to build the ship to the increased level of survivability, and it had to be built up. Even with all of the design churn, the Director, Operational Test and Evaluation did not expect LCS “...to be survivable in a hostile combat environment. This assessment is based primarily on a review of LCS design requirements, which do not require the inclusion of the survivability features necessary to conduct sustained operations in its expected combat environment” O’Rourke (2012).

The public record and abundance of published opinions about LCS survivability are evidence the ontological anchor was

false Lagrone (2013) Hilger (2016). Remembering that an ontological anchor is the fastening of one's view of the universe of discourse to a specific assertion, the LCS survivability anchor was false because the assertion that Level 1+ survivability was sufficient was based on a false perception of the Navy's universe of discourse on survivability. The true universe of discourse was around traditional warship survivability. This is evidenced by the 2014 Secretary of Defense directive for the Navy to submit more frigate like survivable alternatives to LCS.

## **Case 2: The Ontological Anchor of Lethality**

The LCS was designed to be lethal against asymmetric near coastal threats, emphasizing prosecution of small boats, mine warfare, and littoral anti-submarine warfare, enabling other forces to focus on primary missions Defense Acquisition Management Information Retrieval (2004). This ontological anchor for lethality was fastened to a universe of discourse in the context of a "...a new security agenda that addresses contemporary threats such as the proliferation of nuclear, chemical and biological weapons, terrorism, and international crime" The White House (2000). Over the course of the program the universe of discourse shifted, "inter-state strategic competition, not terrorism, is now the primary concern in U.S. national security," but the original ontological anchor for lethality had already been actualized via design, construction, and delivery of ships and was still reflected in program reports U.S. Department of Defense (2018) Defense Acquisition Management Information Retrieval (2018). The ontological anchor for lethality was true for the original universe of discourse, but became a false anchor as the universe of discourse shifted. Attempts to align the two did occur. Efforts to change the ontological anchor to align with the shifting universe of discourse started in 2014 when the Secretary of Defense directed the Navy to "...submit alternative proposals to identify and procure a more lethal and survivable small surface combatant, with capabilities generally consistent with those of a frigate" U.S. Department of Defense (2014). Attempts to change the universe of discourse to better align with original anchor also occurred, "to compensate for any gaps in the ship's survivability and lethality capabilities, the Navy continues to redefine the concept of operations (CONOPS) for LCS" United States Government Accountability Office (2015) .

The misalignment over time between anchor (lethality) and universe of discourse (threat) has ultimately resulted in early decommissioning of several ships, and cancellation of key portions of the program, including the Anti-Submarine Warfare (ASW) mission package. The explanation was that "those requirements for that ASW package for LCS were developed back in 2008 against a diesel [submarine] threat in the littorals. And then our minds shifted to we'll be using these things in the deep blue ocean" Ong (2022). However, what is intuitive retrospectively (significant changes in requirements means rework and consequent cost and schedule impacts) can be difficult to see in the present. Ontological and philosophical concepts provide a more general, structured and rigorous way to identify and understand as a designer what one is doing, rather than just understanding how to do it.

## **DISCUSSION**

One of the most important concepts that can be gleaned from the presented case study is that requirements elucidation is really just working to resolve one's ontological anchor (true or perceived). Work to resolve the ontological anchor is supported by low fidelity engineering, for example, concept design activities. Once the ontological anchor or anchors are resolved, the process moves into the design phase where the anchors are considered to be set. To implement the anchor, one conducts design activities so that design knowledge can be generated over time. If an anchor changes, an anchor is found to be false, or a new anchor emerges, this causes for design rework or for the design to fail.

In regards to the LCS program, this can be clearly seen through how in the Work report it is stated that "perhaps the most serious objection to LCS is that the Navy charged into series production without having a clear idea of how the ship would be used" Work (2014). This sentiment is directly connected to the idea of not properly resolving one's ontological anchor.

One of the reasons for the larger amount of rework and failures seen with naval design is the time scale. The duration of Navy design programs are very long, some upwards of 20 years. Given the long time scale of naval design, the probability

of an ontological anchor or universe of discourse changing is very high. This means if the anchor changes the prior engineering work may no longer support the new anchor. The high probability of an ontological anchor changing can also be partially attributed to changes in personnel over the course of a design program or evolving threats.

The case on survivability hints that even if entities try to do things differently, an organization will be pulled toward its cultural anchors. Cultural and societal based ontological anchors can be enduring, whereas anchors based on an individual's vision are comparably unstable and short. Thus, in an organization with long-time scale projects and staff turnover, things are likely to revert to more enduring cultural or societal anchors. This could directly be seen with LCS in how the initial vision for a commercially based less survivable ship was pulled toward the more culturally accepted idea of a frigate. The pull away from anchors for commercial parents, standards, and reduced lethality and survivability toward more traditional anchors is not unique in warship design.

## CONCLUSIONS

In conclusion, the elucidation of requirements is foundational in the early stages of the engineering design process. In the realm of design, language serves as a crucial medium for articulating desires and necessities, which then transform into explicit and unambiguous design requirements. This transformation, facilitated by embedded language in various design documents and tools, contributes significantly to shaping and constraining potential solutions, encapsulated in the philosophical concept of ontological commitment.

However, the translation of uncertain or ambiguous language into concrete design requirements has been overlooked from a linguistic standpoint. The true implications of design requirements and their ontological commitments and anchors, often only become fully apparent later in the design process. The real-world examples presented from the Littoral Combat Ship program underscore the tangible impact of ontological and philosophical concepts in the requirements process. These examples serve as a modern lens through which to examine how language, through the articulation of requirements, shapes and guides the trajectory of design solutions. As the design process evolves, it becomes increasingly evident that the linguistic choices made in the early stages exert a profound influence on the ontological commitments and anchors that underpin the final design outcomes. While the presented case may seem specific the concepts and method introduced are largely and generally applicable to marine design and other design disciplines.

A few important concepts can be taken from the case study presented in this manuscript. One important realization is that universe of discourse and truth statements can be relative to an individual or group. This is akin to the idea that "beauty is in the eyes of the beholder." This concept does not work in naval design. Given this, in design it is important to try to find a universe of discourse that is generally global and robust. The other critical realization is that requirements elucidation is really just working to resolve and properly account for one's ontological anchor. This is critical to try to get right from the early stage of the design process to try to prevent design churn, re-work, or failure.

Looking to the future, concurrent engineering approaches may address the challenges facing current and future design programs, based on the presented theory. Concurrent engineering approaches, including close interaction between stakeholder organizations, may be able to avoid silo effects and better identify enduring ontological anchors and form a global universe of discourse. In any event, ontological anchors and commitments will need to be accounted for and properly resolved.

# Practical implementation of configuration management in the context of concept ship design – first lessons

S. Bedert<sup>1,\*</sup>, R. Hoogenboom<sup>2</sup>

## ABSTRACT

*The implementation of configuration management (CM) in support of concept design activities at the Products and Proposals department of Damen Naval has put forward a number of challenges that seem to be unique to the shipbuilding industry and the process of concept development therein, that traditional enterprise-level product lifecycle management software and processes are unable to tackle. Information fluidity, an uneven and fast evolving tooling landscape and limited team sizes have driven us to pursue dedicated software implementations in support of CM during concept design. From the first attempts of doing so, we have seen that a number of performance requirements for the software that were completely under the radar are now driving factors for further selection (mostly related to speed and agility of the tool), while some others even impact our way of working and organizational structure as a whole, requiring us to carry system responsibility per discipline, instead of only functional responsibility.*

## KEY WORDS

Configuration Management; concept design; contract design; database; shipbuilding; ship design;

## INTRODUCTION

This paper aims to describe the lessons learned derived from our initial attempts to introduce configuration management and the associated tooling in our concept design workflow at the Proposals department of Damen Naval. Given that the number of theoretical papers on the subject, and descriptions on cross-industry abstraction levels are widespread, the explicit premise of this report is to stay as practical and ‘down-to-earth’ as possible, noting and highlighting primarily the challenges faced within the context of our own department, and the naval shipbuilding industry by extension, as far as the processes and organizational structures applied are comparable with those of Damen Naval (which cannot be verified by the author).

The paper starts by defining configuration management (CM) as applied in the context in this paper and the reasons why this is deemed ‘special’ in the context of ship concept design. In a second part, the paper shortly touches the rules of play of configuration management (CM) as laid out at Damen Naval and describes two initiatives rolled out for the introduction of configuration management software.

In the final part, the actual lessons learned from these initiatives are described, with a possible outlook for further work.

## SCOPE DEFINITION

This chapter defines (and restricts) the scope of the term Configuration Management to that part relevant in the context of this paper and the concept design department of Damen Naval and describes why this is deemed to be a special case of implementation compared to more widespread descriptions, definitions and uses of the concept warranting custom implementation.

## Configuration Management

Since Configuration Management is a multifaceted concept, it is essential to establish precise boundaries for its application in the context of this paper.

The fundamental goal of the work done is/was to create a centralized repository for information related to the physical components and systems that constitute a ship, especially suitable for use during concept- and tender design phases in a ship's lifecycle. This information, especially the aspects which holds cross-disciplinary importance, such as size, weight, and electrical power requirements, will be managed by the relevant specialists. The objective is to maintain this information as a constantly available and up-to-date snapshot over time. In simpler terms, we are focusing on managing the ship's system configuration, rather than the concept design project configuration, which primarily involves document and requirement management and has not been considered in this context.

The overall aim is to allow the different systems in the ship to be developed in accordance with their own largely unaligned, albeit overlapping, timelines, without having to wait for a full design cycle on all systems before an updated snapshot is made available, as long as all the data available is the 'latest status available at that time' in any given snapshot.

Once the initial idea was proposed, we structured it into an internally peer-reviewed 'master' functional specification (the concept was dubbed Krypton at the time, a name which persists to this day within our company for anything related to the concept). With this functional specification in hand, we pursued the following implementation routes:

- a. We invited software vendors to offer solutions that align with the specification.
- b. We developed software in-house from scratch that matches the specification.
- c. We sought partnerships to explore and enhance an existing system based on this specification.

Over time, steps (a) through (c) have been carried out in overlapping cascade, with (a) now completed, (b) nearly finished/scrapped, and (c) in a start-up phase. As a result, this paper focuses on the lessons learned during steps (a) and (b), which are of course also being considered in the execution of step (c).

## Concept Development/Contract Design vs Engineering

It is to be noted that configuration management both in terms of document control and technical data management are well established within the (ship) engineering and building processes. In support of these, many well-established (Product Lifecycle Management; PLM) software suites are available, both on an enterprise and small business level.

So, what makes ship concept design activities so much different from production activities that we claim we need special software to do it? The reasons for that as we have identified them within our company are the following:

- **Data persistence rigidity:** Concept design is largely a matter of design space exploration and solution generation. Configuration items are generated, changed and deleted again on the fly on every level of detail throughout the process. In opposition, data is created in a PLM environment once, and is made there to stay, because the underlying hard- or software is being procured, built or created in real life. In essence, a concept design is all about defining a solution and all (building) budgets related to it, while a production phase is about realizing a (pre-)defined solution from definition to reality as quickly and efficiently as possible.
- **Interfacing to tools/availability of software functionality:** The PLM packages in use are targeted for interfacing with the existing engineering and building tool suites (CAD/CAM packages etc.). Just as the PLM package itself, however, the intrinsic overhead of that tool suite is in almost all cases too high for use in concept design, and much simpler alternatives are used.
- **Procedural overhead vs. project throughput times:** the speed at which tenders, and concept development projects are started, scrapped, and renewed is not compatible with the application management overhead of traditional PLM packages. Traditionally, it can take up to 4 to 8 weeks to setup a project in our PLM environments, involving at least three different departments at an average of two people per department.

## IMPLEMENTATION INITIATIVES

This chapter describes two implementation initiatives taken to introduce configuration management in our department, corresponding to cases (a) (implementation through external vendor software) and (b) (implementation through own software development) from the scope definition described above.

In each of these cases, the practical goal was to have:

- A collaborative piece of software that allowed multiple users to work simultaneously.
- Gather, per discipline, lists of equipment that contained sufficient data to support the three main ships balances (weight, electrical load and heat load) in a single database.
- Get all relevant data out of the database in a format that allowed updating of the balance sheets.

Although the goal seems quite simple, from a database point of view this proved to be quite the feat, as in practice, this implied the system had to be capable to manage a Product Breakdown Structure, a ship's space list with associated data and a ship's equipment list, and the allocation between those data concepts (e.g. a piece of equipment is always part of one or more parts in the PBS structure, and always allocated to a space).

Beyond that basic goal, ambitions were set even higher on a few functionalities. For example, we expected the data fields to be managed to be flexible (user-managed) and values to be flexible on unit of measurement. Furthermore, we wanted to be able to compare ship configurations (since it is applied during concept design), which meant we wanted to 'disable' part of the database temporarily in favor of an alternative (i.e. support for trade-off from within the tool analysis).

### External Software (Case (a))

For the first pilot attempt, we selected a closed but flexible platform from a software vendor that offered a 'configured to spec' version of their software. The software had a principally closed architecture, with interfacing created especially for us to be able to implement data I/O using an excel interface. At the time of delivery, the software implemented approx. 80% of the original Krypton functional specification.

After initial testing of the software using parts of a fictional ship concept and a limited dataset, the application was deployed for use in the most recent large contract design project ran by the Damen Naval Proposal department to keep track of ship (system) configuration. The software was used over the full period of the project (p/m two years) and served as configuration management tool for disciplines Propulsion, Electrical, Auxiliaries and Automation.

Success criteria for the pilot execution did not constitute numerical KPI's as such. The sole, practical pass criterion was that the tool would enable multiple engineers to input data of equipment in their disciplinary scope and in accordance with their discipline's applicable timelines, and that data could be exported again in support of a weight calculation and electrical load balance, which it did to successful extent.

However, after careful review, it was still decided to discontinue its use, primarily due to the lessons learned *Adaptability* and *software performance/scaling challenges* as described below (even if these were not part of the pilot's original success criteria). The web portal providing the user interface, for example, became unmanageably slow due to the server capacity reserved for the proof-of-concept once the pilot project contained its 'full' list of equipment, spaces and PBS elements. As a further example, we were unable to change the data views ourselves for the most basic use cases (for example, showing the space number to which a piece of equipment was allocated in the tabular equipment overview was impossible without outside consultancy).

### In-house Development (Case (b))

To implement the initial lessons learned concerning openness of interfaces to unlock data (refer to below), mostly instigated by server capacity limitations and a need for more customizability, we swung almost stereotypically to the opposite extreme of the spectrum and started building our own version of what Krypton should be, as opposed to an externally sourced, closed architecture software package. In that attempt, we built a rudimentary piece of software that implemented the core functionalities of the Krypton spec, using SQL (SQLite) databases and a Django framework with web front-end.

This software was never developed further than a proof-of-concept. It was never used in production, nor was it put through serious 'malicious' testing. Success criteria for this test were also not defined as numerical KPI's. The practical pass criterion here was to have a 'configurable' data model available (adaptable to different types of equipment and systems), in which we could define data and later extract it again, and in that goal, the software succeeded again without fail.

Although it could be considered a successful ‘start’, the work was never finished because we saw that the work involved would require us to venture too far off from our core competences, as described in the *Software Support* lesson learned described.

## LESSONS LEARNED

The lessons learned from using the third-party software (case (a)) and programming our own tool(s) (case (b)), roughly fall into the following categories:

1. Software functionality and performance
2. Modelling conventions
3. Organizational structure
4. Obvious/novice mistakes

Firstly, we are not above admitting that some very basic mistakes were made in all this (category 4). As we do not buy, create, or configure software every day, we obviously fell into pitfalls which may be marked as stereotypical. To get them out of the way, the most notable:

- We grossly overestimated the percentage-ready associated with a proof-of-concept at approx. 80% instead of the 30% it deserved. As you will see from all the lessons learned below, we still have a lot to figure out. This applies independently to both implementation case (a) and (b) as some of the main lessons learned relate directly to business rules, and not software implementation itself.
- We underestimated the effect of computational speed and performance on useability and user satisfaction in our on-premise implementation, lapsing too far from well-established 0.1/1/10 norms posed by (Miller, 1968).

It is worthwhile to notice that the second point is directly related to the concept design challenges described in the Scope Definition chapter before. Given that data values are more fluid in concept design, the software speed associated to data manipulation should be an order of magnitude faster than what we have seen in the past in traditional PLM packages (where our company has more experience and a more widespread frame of reference). So software speed is a unique aspect in which we will expect more instead of less when compared to traditional PLM packages.

### Software functionality and performance

#### *Batch editing*

In drafting the functional Krypton specification, the use of batch creation and editing was posed as a nice-to-have. However, in use of both Krypton implementations, this proved to be a more than essential feature. In hindsight, this is a perfectly logical conclusion provided that in reality, most of the data is created and/or updated in batches from parts of the design process (e.g. a space list is (re)generated from a CAD source in one go for all spaces in a ship; or an equipment list for a full system is defined by a specialist or generated by a subcontractor in one go). As such, the majority of interactions with users with the software will be batch related, and the functionalities provided thereto should be on-point.

#### *Adaptability*

Tooling in support of configuration management is not the only part of our working environment that is undergoing changes. With the launching of the Krypton concept, we also inspired a wave of initiatives that aim to disclose information between software tools, calculation sheets and 3D models regardless of what we come up with on the configuration management side (e.g. transporting the information from a 2D general arrangement to a 3D model for further evaluation).

With that, a whole new set of data and related data formats come into play that could also be relevant for plugging in to a CM database, signifying the importance of adaptability of the Krypton implementation, as the tools surrounding the CM platform will, with a high chance, evolve faster than the platform itself. This in turn poses a requirement for any Krypton platform to be highly adaptable, not only regarding input and output formats, but data visualization within the tool itself.

#### *Scaling challenges*

As the products we build are large in absolute scale by themselves, the number of elements within them that contribute significantly to their design balances is equally so. Consequently, the number of elements to be considered for CM is also large. Both of our implementation cases have shown that these numbers can cause problems in the tested software packages, which both rely on server-side processing for data integrity checks on each Create, Read, Update or Delete (CRUD) action on the data, when server-side processing capacity is not duly considered.

Apart from server-side computational power limitations, it has also been remarked that the lists and tabular data representations used on both our implementations started to become cumbersome to work with (with endless scrolling, and just-not-there-yet

filtering capabilities). Without knowing what to look for exactly for improvements in further experimentation, this is a point that deserves attention.

## **Modelling conventions**

In a conceptual design phase, team sizes are notably smaller compared to a production environment, where an extensive group of engineers and CM professionals collaborate on ship configuration maintenance. In a 'typical' conceptual design team, each discipline is represented a single individual or a handful of people. These team members primarily engage in primary design activities, next to ensuring that the configuration management effort remains commensurate with the phase of development.

To prevent CM activities to dominate design work, it is essential to tailor the level of abstraction in the information provided to the specific requirements of the design phase. Consider a main engine as an illustrative example. The scope of delivery for a main engine extends beyond the engine itself. It encompasses a long list of associated elements, each with dedicated specifications regarding weight, dimensions, etc. (e.g., a preheater, a local control panel, or external coolers). However, during the conceptual design phase, the primary interest often only lies in confirming the presence of a main engine installation rather than scrutinizing the particulars of its constituent parts. Yet, if inexperienced engineers receive the instruction to model solely the main engine, there is a risk that they may overlook the associated components, inadvertently underestimating the overall system's weight. Nevertheless, it is impractical to model and maintain each of these individual components separately. Doing so would introduce superfluous data into the configuration, resulting in excessive effort and the potential loss of 'belongs-to' relationships among these objects.

Hence, it is imperative to permit aggregation of a configuration to the appropriate level, alleviating the burden of model maintenance while retaining sufficient details to instill confidence in users and model auditors regarding completeness and the preservation of 'belongs-to' relationships. For instance, one approach may involve modeling large items with three distinct weight values: one for the primary hardware, one for associated hardware fluids, and one for all auxiliary components.

However, as you can image, the aggregation level that is acceptable is not uniform over all the different systems in a ship, nor, if you are truly honest, across projects. Inevitably so, finding the correct aggregation level is a matter of getting a 'feeling', or more extensive experience in using such models. In the end, it is not unimaginable for this experience to end up in some sort of data modelling guideline.

## **Development time**

Given the considerations mentioned, achieving proficiency in data aggregation, and identifying suitable data views requires substantial practice and experience. Given the rapid pace of concept design projects and their heavy workload, expecting rapid mastery is unrealistic.

It is important to leverage the flexibility inherent in any chosen tool and remain open to iterative adjustments. Nevertheless, crafting an effective working method will take considerable time, potentially spanning years. Therefore, exercising patience is crucial, particularly when encountering user complaints during the initial implementation phase.

However, it's essential to recognize that despite potential challenges, benefits from implementing configuration management in concept design can still be observed from the outset, even if perfection isn't immediately attainable.

## **Organisational Structure**

### ***Data Ownership***

The introduction of configuration management has brought to surface a fundamental aspect in the organizational structure of various disciplines within our department, that requires attention and improvement to fully realize the potential of this initiative.

At our department, knowledge, responsibilities, and people are organized in traditional shipbuilding-related disciplines (naval architects, structures, propulsion, electrical...). That division in disciplines is, as the pilots done in the context of this paper have clearly shown however, purely on functional level, meaning that a specialist is held responsible for defining what is necessary of an item to perform its primary function, but not directly for any secondary information that is a direct consequence of that decision. For example, a mechanical engineer is responsible for defining the correct flow and pressure requirement for a main firefighting pump, but he is not held responsible or accountable for the weight and dimensions of these pumps.

That functional subdivision is a problem in terms of configuration management, as this requires, in practice, ownership of all item properties within a single owner, if only from an efficiency point-of-view. That is because, as you can imagine, the data source for information pertaining to a configuration item is concentrated at one place (for example, technical manual of a pump contains the QH-curve as well as a dimensional drawing). So, it would only be logical for a specialist to own all data related to that pump. Even more so, when considering that all that 'secondary' information will only change when the primary specialist makes a design change.

This requirement for workflow alignment entails that specialists within the department should start acting as general system owners instead of purely functional owners, whereby their responsibilities lie in all system parameters, not just the functional ones. This transition further demands a reevaluation of incentives to encourage specialists to take ownership across all system parameters. Finding the right motivators will be pivotal in driving this change, enabling a more efficient and cohesive configuration management approach.

### ***Software Support Workload***

Implementation case (b) has clearly highlighted the distinction between our expertise as shipbuilders and that of professional software developers. Our excursion into creating a proof-of-concept provided invaluable insights into the intricate dynamics of software development, and especially software maintenance.

Upon venturing into programming software intended for a broader user community, software that surpasses the complexities of typical online programming tutorials, we encountered the many challenges that software developers will surely recognize, such as outdated third-party source code packages, evolving library versions, deprecated functionalities, and the continual need for adaptation within our source code. Programming for a larger user base also highlighted the increased need for meticulous software documentation and ditto reliability. This underscored the necessity for extensive source code documentation to ensure sustained functionality, irrespective of the original creator.

In the end, it became apparent that continuing this trajectory would necessitate the establishment and ongoing maintenance of dedicated resources to support the tool we developed. This signified the integration of software development into the core activities of our department, which was, in hindsight never the intention.

## **CONCLUSIONS**

Our first exercises with third-party and our own (attempt to create) software in support of configuration management has taught us that the road ahead of us to find that sweet spot where tools are at their peak of added value is going to be a long one still. Within a landscape where the tooling surrounding such attempts is also evolving rapidly, it is unavoidable that any attempt to build something sustainable will require a high level of flexibility and future adaptability to new interfaces.

Given that data sources are very dispersed during concept design, data entry will remain a matter of manual labor for the foreseeable future. As such, software performance in terms of speed and responsiveness is a key requirement for successful implementation of such.

Furthermore, the use of a configuration management concept has shown us that we can no longer rely on traditional functional ownership of systems across disciplines. Instead, we need to change our attitude towards data correctness to systemwide ownership, where specialists no longer care only for the functional performance of the systems they design, but also for every consequential aspect associated therewith.

Although the goals set before implementation cases (a) and (b) were largely met, the lessons learned described in this document have shown that continuing those paths is not preferable, yet the premise of configuration management for concept design does warrant further exploration.

Implementation case (c) as described above is the next iteration being considered. The views depicted in this paper will serve in a large part as additional boundary conditions, goals and requirements in that project. Implementation case (c) is seen as a hybrid between cases (a) and (b), whereby the aim will be to find a piece of software which is developed and managed by an external partner on the one hand (avoiding the maintenance burden of software identified in implementation case (b)), but which is, by design, sufficiently open to allow flexible data access and visualization (for example, one which provides a full-access external API that allows manipulating, importing and/or exporting or reading data using small scripts, or maybe a strong interface to MS Excel). At the time of writing this paper, implementation case (c) was in the initial start-up phase. Feedback from that case was thus not yet available for further evaluation.

## **DECLARATION OF GENERATIVE AI AND AI-ASSISTED TECHNOLOGIES IN WRITING**

During the preparation of this work the author(s) used ChatGPT 3.5 to improve grammar and overall conciseness of writing style. After using this tool/service, the author(s) reviewed and edited the content as needed and take(s) full responsibility for the content of the publication.

## **CONTRIBUTION STATEMENT**

**S. Bedert:** Conceptualization; writing – original draft. **R. Hoogenboom:** Supervision; writing – review & editing

## **ACKNOWLEDGEMENTS**

First and foremost, the author would like to acknowledge Claassen, J.P. for his continued support in the exploration and implementation of this work within his department and the projects under his care. Further acknowledgement is made to the pilot user group for their patience and valuable user feedback for implementation scenario A; (de Jong, F.; Den Engelsman, J.; Ferea, V.; Lukasse, R.; Van de Voorde, L), as well as Schouten, G. for providing enthusiastic external feedback, proving that we are on (the right) track with the concepts we came up with. Further thanks goes out to N. Gheorghe for her hard work in programming our own efforts for CM as scenario B.

# Naval Wargaming as a Requirements Elucidation Tool for Warship Design Teams

Nick Bradbeer<sup>1,\*</sup> and David Manley<sup>2</sup>

## ABSTRACT

*This paper discusses some of the challenges of setting the requirements for a future warship program and how manual naval wargaming might be employed to make the process more efficient and structured. It goes on to describe some case studies where UCL's wargame "A Balanced Fleet" was applied to requirements-phase problems, in particular the ASW Barrier wargame conducted for the NATO Specialist Team on Naval Ship Systems Engineering. The paper concludes that wargaming is a useful tool in the requirements phase, in particular for helping to direct subsequent and more detailed operations analysis work.*

## KEY WORDS

Operations Analysis; Requirements; Wargaming; Warship Design

## INTRODUCTION

In 2016 a series of wargames conducted in the UK and focussed on low intensity naval operations demonstrated the initial value of wargaming as a concept assessment tool. In this case, wargaming was used to explore facts of Mission Modularity when applied to a naval force, comparing its effectiveness with a force comprising more traditionally designed ships. The games involved members of the NATO Specialist Team on Naval Ship Systems Engineering (ST/NSSE) who sought to formalise the use of wargaming in their suite of concept assessment and analysis tools.

The work was initiated due to concerns in ST/NSSE, that project teams were launching into expensive and time consuming Operations Analysis (OA) without having conducted their own pre-analysis work aimed at refining the OA questions they were posing. This has the potential to allow the OA to unintentionally stray away from prime areas of interest. ST/NSSE's previous exposure to wargaming as a tool to demonstrate and investigate aspects of Mission Modularity gave rise to the thought that it could be broadly applied by projects at an early stage in concept development to test hypotheses and concepts, and thus allow follow on, comprehensive OA, to be better focussed.

Over the same period, UCL has developed a series of naval wargames as teaching tools for use in its MSc-level warship design programmes. One of these wargames, "A Balanced Fleet" has been further developed from a teaching tool into one suitable for application to requirements elucidation problems and was used in support of ST/NSSE's ongoing research.

This paper outlines the challenges that face a warship design team in the requirements elucidation phase, before going on to describe the development of ABF and how it has been used in several case study applications, including a week-long game series run for ST/NSSE. The paper concludes with the conclusions drawn from these series, indicating that wargaming may be a useful tool to assist requirements elucidation, and highlighting features which are desirable in such a wargame.

## THE REQUIREMENTS ELUCIDATION PROBLEM

Defining the requirements for a new type of a warship is a challenging task. It is oft said in design circles that “the customer doesn’t know what they want”; this is meant as no slight on the customer, who usually has to juggle a large set of mutually interacting mission goals while constrained by funding. This is often a complex problem with opaque interactions and synergies between mission goals, to the point where it is often impossible to understand what a sensible compromise design would look like until some design work has been done. The process of setting the requirement is therefore often called Requirements Elucidation since it is less a process of deciding what desired requirement is, and more a process of gaining understanding about how the different requirements interact and what would produce a harmonious compromise that falls within budget.

If using a Systems Engineering framework, requirements are usually initially defined in a User Requirements Document (URD) in terms of Measures of Effectiveness (MoE) - statements of capability which can be expressed numerically and which relate directly to how capable the ship is at completing mission tasks. A MoE might be phrased as “defend a High Value Unit against an attack by X missiles of Y type, with at least Z probability of defeating all missiles.” In order to relate these values to things that a ship designer can easily quantify, Measures of Performance (MoP) are defined, being quantities which can be numerically expressed and measured or estimated directly from the design – quantities like top speed, radar horizon, or number of vertical-launch system cells. To relate the MoEs that the customer cares about to the MoPs that engineers can readily provide some kind of model is required. This is usually the domain of Operations Analysis (OA), which can provide mathematical models which take MoPs as inputs and deliver predicted values of MoEs that result.

OA is a powerful field, but the complexity of the problems mean that it is usually reliant on making assumptions, which in turn are reliant on correctly framing the scenario to be modelled. How to frame these scenarios is the first problem of Requirements Elucidation.

The second problem is the complex nature of the interaction between different MoEs and MoPs. A warship will usually have a range of quite disparate missions, the relative importance of which is difficult to define. Different capabilities on the ship will usually contribute, in different degrees, to more than one mission. There may be synergies – an ASW helicopter also provides very useful maritime surveillance, liaison, and resupply capabilities at no additional cost. There may be capabilities which both contribute to a mission but do not synergise well – high ship speed and onboard aviation for a surface search mission, for example. Understanding the interplay of these capabilities is challenging, and typically customers rely on the judgement and experience of subject matter experts (SMEs). SME judgement offers good utility for relatively low cost but can have limitations; bias in favour of systems or approaches the SME is personally familiar with can often be observed, and novel systems can present a problem if there is nobody with experience in operating that kind of system.

An important tool in squaring the Requirements Elucidation circle is the Concept of Employment (CONEMP.) This is a document which outlines the missions that the ship is expected to undertake, and how it will undertake them. As with the requirement set, deciding the CONEMP is not straightforward; it is sensitive to cost/capability trade-offs and interactions between capabilities, and like the requirement set can usually not be pinned down until some exploratory design work has been done to understand the relationship between various Measures of Performance, the relevant Measures of Effectiveness, and procurement cost. The CONEMP should therefore be a living document subject to revision during the early stages of design.

Two potential pitfalls arise when defining the CONEMP. First, that it does not describe the whole of the mission and skips past some mission phase which turns out to be a vital driver of capability. (This may be most likely to occur around “boring” mission phases like deployment or extraction rather than the more kinetic central phases of the mission.) Second, it is very important to ensure that the entire design team share the same vision of the CONEMP and easy to get this wrong, especially if the CONEMP is a living document, of which several revised versions have existed.

Finally, humans are in general bad at visualising speeds, distances and times when expressed numerically, and these factor centrally into most CONEMPs. Allowing the team to properly understand the position and movement of the new design, relative to allied and enemy units, is a vital part of ensuring the CONEMP is workable.

## WHAT IS WARGAMING

Wargaming is a term for which there is no single agreed definition within the community of practice. For the purposes of this work, the authors have used the definition used in the UK Wargaming Handbook (Ministry of Defence, 2017):

*“A scenario-based warfare model in which the outcome and sequence of events affect, and are affected by, the decisions made by the players.”*

Wargaming may use a computer model or may use a more manual approach with physical maps, pieces representing ship and other units, and a set of rules to adjudicate the outcome of uncertain events. These rules may be based on expert judgement to adjudicate each situation (open mechanics) or the generation of a probabilistic model and generation of random numbers (rigid mechanics.) The wargames described in this paper all used a manual approach, using paper maps, wooden blocks or models to represent ships, and a rigid ruleset. Some subjective adjudication was required, usually to decide edge cases outside the core areas the game rules represented.

The boundaries between wargaming and operational analysis are somewhat blurred, and different definitions draw their boundaries in slightly different places. Operational analysis seeks to provide numerical outputs to inform decision making, which can be obtained through a wide range of analytical approaches. Wargaming exists on a spectrum from very analytical games which seek to provide numerical data, through to very non-mathematical games modelling human interaction, especially in politics, where only very subjective data gathering can occur. Naval wargames used for requirements elucidation tend to fall somewhere between these extremes; the technology-centric nature of naval warfare means that some degree of rigid numerical rule mechanics is required, but the problem space tends to be too poorly defined to allow very analytical wargaming.

## “A BALANCED FLEET” – A FAMILY OF WARGAMES

### ABF as a Teaching Tool

A Balanced Fleet is a naval wargame which started life as a teaching tool for use on UCL’s Naval Architecture and Marine Engineering MSc courses (Bradbeer 2022), (Manley 2023). Initially named “A Simple UCL Wargame”, or ASUW, it was developed to help student ship designers who often lacked background domain knowledge, to understand the engineering factors which make for a good or bad fighting ship. Initially delivered as a whole-class extra-curricular wargame running through an afternoon and evening, it was soon integrated into the teaching curriculum to meet three objectives:

- Develop students’ understanding of the modern naval warfare context
- Allow students to rapidly explore possible design options for their capstone ship design exercise (SDX)
- Allow students to informally assess the effectiveness of their SDX ships at the end of the exercise.

To meet these objectives, a game would need to reflect the impact of design engineering choices on capability, in as transparent and granular a way as possible. It would also have to support a robust and transparent workflow for characterising an arbitrary (and often quite unconventional) student design. Finally, it would have to support between two and twenty-four players, to allow for small group design explorations and whole-class capstone games. A search for a suitable commercially available game turned up nothing, so ABF was developed internally.

The teaching incarnation of the game focussed on missile combat in deep water between surface ships with their organic aviation, with very limited modelling of gunnery combat, land units, land-based aircraft and submarines. Game scale was adjusted over time, but settled on turns representing one hour of time, map hexes representing 10 nautical miles of space, and opposing forces comprising between one and ten ships each. Large games were found to take approximately six hours to play.

Parts of the game were necessarily complex in order to represent the impact of design choices in a meaningful way. To preserve enough simplicity to be playable, other parts of the game were deliberately kept simple. For example, the representation of the ship’s layout was kept very detailed, resulting in a complicated control sheet for each ship (Fig. 1), while all anti-ship missiles were considered as one of only three types: lightweight subsonic, subsonic, or supersonic.

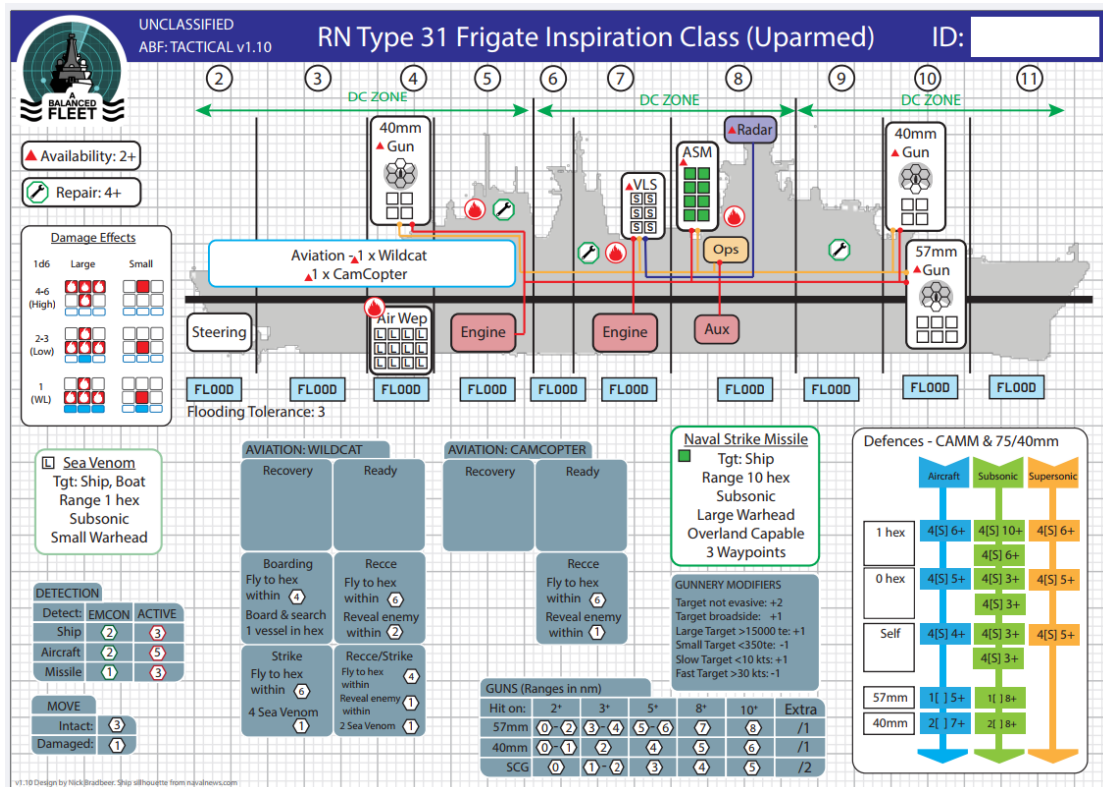

Figure 1: A ship record sheet from ABF: Tactical.

The game was designed with a modular architecture (Fig. 2); the game mechanics themselves were simple models designed to reasonably well match the outputs of more complex OA models, which themselves drew on a database of information about various units and their performance. This structure allowed for transparency in showing why the various game mechanics worked the way they did, as well as allowing the game to be adapted readily, either by changing out an OA model for a different one or by using a different database. This allowed the game to be incrementally improved since, for example, gunnery combat could be improved as better OA models were available, without impacting other parts of the game. While the game was developed around an unclassified database of open-source information, in principle it would be straightforward to substitute a database containing proprietary or classified data if required. (Every incarnation of the game described in this report used the unclassified database, keeping all the games unclassified.)

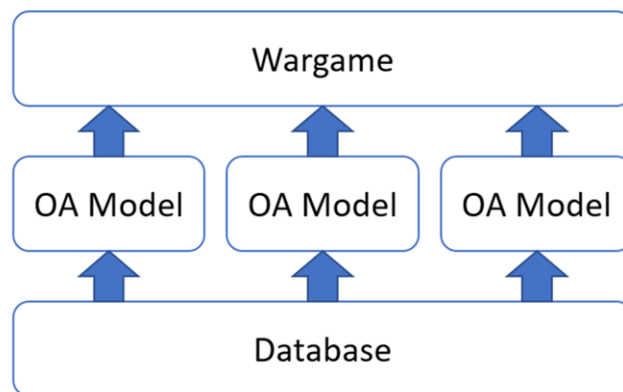

Figure 2: Architectural structure of ABF

# Developing ABF Into a Requirements Elucidation Tool

Since 2022, ABF has been developed further to broaden its applicability, including a focus on making it a more useful tool for Requirements Elucidation.

The first major change was in expanding the range of game scales both upwards and downwards from the tactical scale originally chosen. The use of 8-hour game turns and 40 nautical mile hexes allows for play on an operational scale, with task forces in place of individual ships. This expanded scope allows for changes in weather, for ships to return to port after action to rearm, and for logistics chains to matter. Conversely, the use of 6-minute game turns and 1 nautical mile hexes allows for tactical ASW to be modelled in detail. Procedures exist to allow telescoping time scales, allowing operational level games to pause the action elsewhere and zoom in to resolve a tactical ASW engagement.

Secondly, the game was adapted to support a play-redesign-play cycle. This was originally adopted because repetition of scenarios is good practice to support learning, and because the ability of students to make changes to their ships and see the effects of those changes was useful. The first approach taken was to pre-prepare a set of baseline ships and then a set of (usually 3) variant designs which improved some feature. Players would play once with the baseline ships and then use their experience from the first game to select a mix of variants to play again. This was useful but felt limiting and players tended to want to express their own design choices instead. An interim approach was to play the first game, conduct a groupwide brainstorming session to suggest options, apply estimated costs to each option and then allow each team to select options up to a budget limit. Baseline ship sheets would then be modified (rapidly, by hand, using Sharpie markers) and the game replayed. The loss of production value was considered worth the gain in versatility.

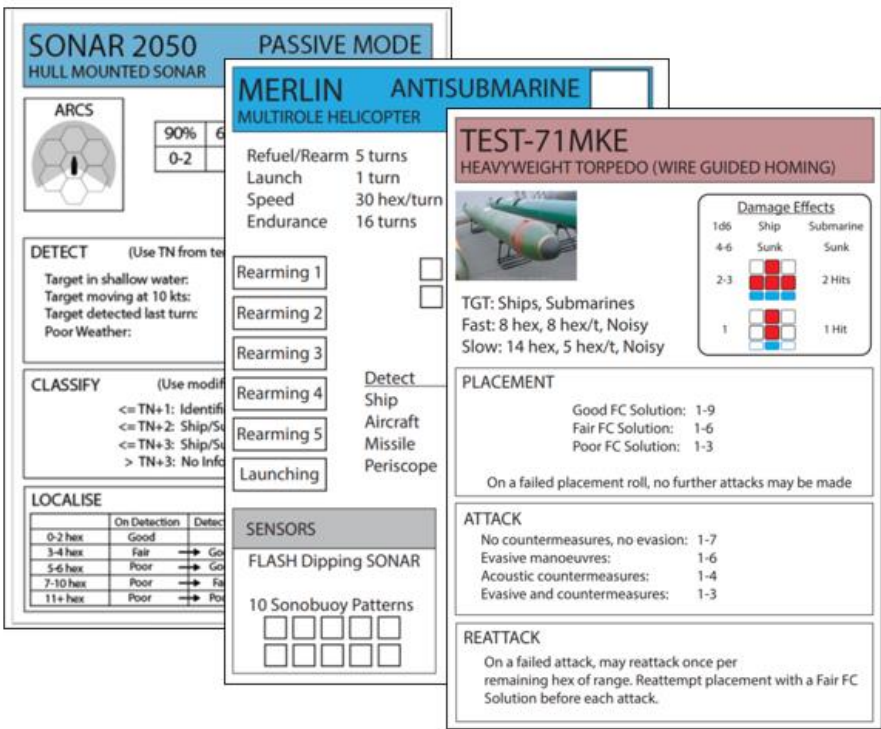

Figure 3: ABF Capability Cards

The most recent iteration of the game disconnects individual capabilities from the ship design. Originally the ship control sheet contained all the data needed to operate the ship, including detection ranges, performance of offensive missiles and the ship's air defence system. These have since been removed from the ship record sheets onto individual capability cards (Fig 3), so a baseline ship might be accompanied by cards for a particular radar and sonar, a particular offensive missile system, helicopter and air defence system. Creating a variant with a different combat system is then just a process of selecting a different combination of payload capability cards. (Within the bounds of practicality, of course.) Variations in layout or subdivision still require adjustment to the ship control sheet, but the use of capability cards certainly simplifies the adoption of different sensor and weapon systems, not to mention increasing legibility over performance numbers scrawled in Sharpie.

The third major change made to the game was to develop rules for additional unit types and operations, to broaden the range of missions ABF could model. The most significant addition was the creation of rules for submarines and ASW, requiring a detection model for sonars, rules for ASW weapons, acoustic signatures and the impact of water depth and weather on ASW detection. Sonar detection is inherently a very complicated process with many important variables, and the game's ASW model is still considerably more involved than the missile combat model, but it does allow for the simulation of tactical ASW engagements in a reasonable time frame.

In part driven by the need to model ASW systems and in part by the demands of a game with 6-minute game turns, a model for persistent aircraft was developed, in contrast to the original ABF model which considered air missions to be essentially instantaneous events. This allowed for helicopters to conduct lengthy ASW search missions, as well as Airborne Warning & Control missions.

Finally, a (very simplified) system for land/amphibious operations was developed, centring on amphibious transport capacity and logistics rather than units' land combat capabilities.

## **CASE STUDY GAMES**

ABF has been applied to a number of problems in the requirements space for a variety of client organisations across several nations. With the exception of the week-long game run for the NATO Specialist Team on Naval Ship Systems Engineering described in the next section, client confidentiality means that only limited detail can be presented about each of these, but they serve to illustrate the range of ways in which wargaming can be employed by design teams in the early stages of specifying a new ship.

### **Game 1 – Team Building**

The authors delivered an event for a shipyard who design and build naval ships. The shipyard was standing up a new team to develop a warship from the outline design provided by their government customer, into a detailed design suitable for building. The team comprised mostly early-career engineers who were specialists in a particular area of ship design.

The wargame event had two functions; first to serve as a teambuilding event, and second to introduce the specialist engineers to the whole-ship design considerations that drive cross-cutting capability areas like survivability. ABF as-designed already had a number of features to support that objective; the centrality of layout and zoning to the ships' representation in the game and how those factors affect survivability required no alteration to the game.

This was the first time that the Play-Redesign-Play cycle was explicitly used in ABF. The sixteen players were divided into four groups of four and each group played the introductory ABF scenario "Shell Game", based around a Board, Inspection, Search & Seizure (BISS) operation in the Western Pacific. Shell Game pits a multinational force of three frigates attempting to find a contraband shipment against three frigates attempting to prevent them. The game used the basic ABF Tactical ruleset (1 hour turns, 10 nautical mile hexes) and took roughly two hours to play through.

After the first playthrough, when the players had a feel for how the game worked and the relative strengths and weaknesses of their ships, they were given the opportunity to replace each ship with one of three pre-prepared variant designs; each variant improving some aspect, generally either offensive weapons, defensive weapons or vulnerability reduction features. Teams were then shuffled so each pair of players had a new opponent, and the scenario was replayed. Increased familiarity with the game meant the second playthrough took roughly one hour, and it was in fact possible to fit three games into the day.

Aside from working well as a teambuilding experience, the game proved to be a useful way to give system specialists an overview of whole-ship considerations like layout and subdivision. In particular, participants said it helped them understand the reasons for some of the demanding naval standards they had to comply with. The event was considered successful and a follow-up event has been requested.

### **Game 2 – CONEMP Exploration**

The authors developed and delivered a wargame for a government warship design project. The project was in a preliminary stage and working on a ship with a relatively novel mission set and incorporating new technologies with which the customer

had limited experience. Lacking experienced personnel who could make informed judgements, the team looked to other approaches to help explore the CONEMP.

The purpose of the game was twofold; to allow an initial workthrough of the CONEMP with the whole team, and to evaluate whether wargaming was a worthwhile tool to apply to the problem.

This game used the basic ABF Tactical ruleset, although a new scenario was developed around the candidate ship's CONEMP. The one-day event contained a briefing in the morning followed by 2v2 playthroughs of the introductory "Shell Game" scenario to give the participants familiarity with the game rules. This was followed after lunch by a playthrough of the CONEMP scenario, with the group divided between four simultaneous games.

While there was no repeated play of the CONEMP scenario, the outcomes of the four games were fed back in a hot washup discussion. While this sort of wargaming should never be considered predictive, the fact that several of the games identified the same difficulties with certain parts of the CONEMP was useful, directing focus and further analysis onto those parts. The event was considered successful in meeting both its objectives; participants reported an increased understanding of their CONEMP and the team's design goals, and a more formal follow-up program of analytical wargaming was initiated.

### **Game 3 – Force Development**

A third client was a national defence research agency interested in conducting exploratory force development experimentation with a view to shaping the requirements of future platforms procured across the sea, air and littoral/land domains. The objective of this game was primarily to explore how useful wargaming could be to assist with these force development planning activities.

The ABF Tactical ruleset was modified slightly for this game to include maps of the desired areas of operation and current platforms for the client and potential adversary forces. A scenario was designed to model a typical operation of interest to the customer. The wargame could then be used to play that scenario through with existing platforms and weapon systems, then replayed using potential future force mix options, to better understand how the capabilities offered by each option contributed to the mission, against current and expected future adversary forces.

At the time of writing, this project was still ongoing, so no conclusions can be reported.

## **ST/NSSE WARGAME CASE STUDY**

The NATO Specialist Team on Naval Ship Systems Engineering (ST/NSSE) requested a wargame to explore whether wargaming could form a useful part the concept assessment and requirements elucidation process, specifically whether it could help give shape and structure to the initial stages of operational analysis, saving time and cost in the programme. The team were of the opinion that wargaming could be used as a "precursor" event, allowing projects to conduct initial evaluation of the value of their developing concepts, allowing initially attractive but unfeasible options to be discounted, whilst more credible options were refined and developed. This would allow for a more targeted approach to the conduct of formal OA, making more effective use of OA resource and enabling savings and efficiency in the use of research budgets. The outcome of these considerations was the proposal of a wargaming element within ST/NSSE's programme of work (Manley & Logtmeijer 2023).

In order to maximise the benefit of the work it was felt that any wargames conducted should be based on areas of interest to the NATO maritime community, although it was accepted that, at this stage, any work would need to be conducted at an unclassified level. This would create an atmosphere of familiarity with the subject when calling for support and discussing outputs with seniors. It was decided to use Anti Submarine Warfare (ASW) as the subject for study, and more specifically the conduct of ASW using uncrewed offboard systems in place of or supporting more traditional ASW assets. This is an area of considerable current interest, with a dedicated NATO Strategic Defence Initiative (SDI) project in place as well as several independent national studies being undertaken. It was hoped that, as well as demonstrating the validity or otherwise of wargaming in the intended role, that the outputs could inform, albeit at low classification, these various work streams.

UCL's ABF wargame formed the core of the wargaming engine, but this required significant development to cover some of the specialist areas required for the ASW-focussed games. These included the mechanics, sensors, weapons and tactics of ASW itself as well as a more detailed consideration of the management of uncrewed systems, in particular launch and

recovery. Environmental aspects were felt to have a more significant impact on smaller uncrewed assets hence a meteorological model was required to be developed.

## NSSE Case Study Scenario

The specific operation chosen as the subject for the wargames was the use of an ASW barrier protecting a naval force against potentially hostile submarines and mine warfare forces. The series of games to be played would test the deployment, sustain and eventual recovery of the ASW assets through a number of stages of a mission.

Two forces would be considered, a “future force” comprising vessels designed specifically to operate uncrewed assets, and a “legacy force” made up of vessels broadly comparable to vessels currently in service. This would allow a direct comparison of the relative effectiveness of the new approach and the old. The future force was allowed to iterate, in that lessons identified in one game could give rise to mitigations that were then implemented in following games. The scope of improvements was moderated by the game management team to keep developments within realistic scopes in terms of cost and performance (the sudden development of “wonder weapons” was not allowed).

The overall campaign scenario selected was a Non-combatant Evacuation Operation (NEO) conducted in an environment where there was a potentially hostile submarine threat (surface threats were also considered as these could have an effect on the ASW assets, but the primary focus was the enemy’s submarines. The wargame campaign was set in the fictional countries of Florin and Guilder (it was felt that assigning names to countries and locations would create a deeper player engagement). Florin was a nation in the grip of both a civil war and the outbreak of a deadly epidemic. Meanwhile, Guilder was a nation seeking to benefit from florin’s misfortunes up to and including the use of military force to force territorial gains. “Blue Force”, the ASW-focussed side, was asked with conducting an evacuation of NATO citizens from a port in Florin, protecting the evacuation force from the threat of Guilder’s submarines (which constituted “Red Force”)

Blue Force was required to escort the high value units (HVUs) conducting the NEO to the area, protect them for five days of operations, and then depart. This provided a particular challenge for handling time throughout the scenario since the game would have to cover a week, but ASW operations have a decision cycle measured in minutes. This required a new “telescopic” approach to managing game turns, where time would be stepped through in units of 8 hours, 1 hour or 6 minutes depending on how much detail was required at any given moment. During phases where Red was waiting for a weather window to attack, large timesteps were used, stepping down to smaller ones as submarines manoeuvred into position and smaller again at time when there was a risk of detection and ASW combat.

**Figure 4: Playing area and pieces for the NATO ASW Wargame**

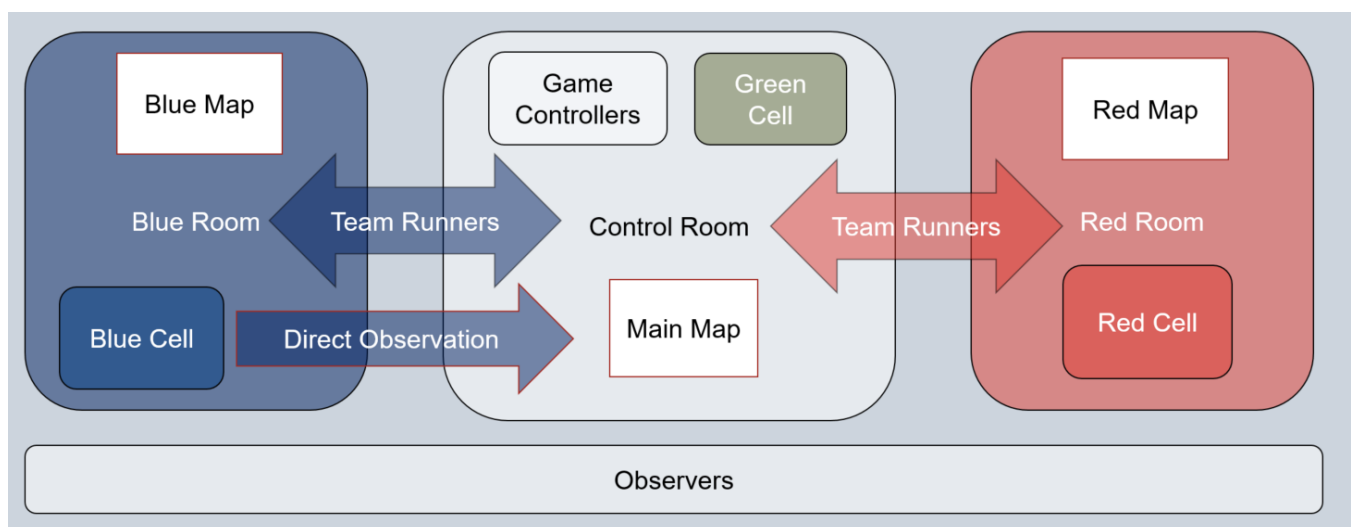

## Game Management

The game's players were divided into three teams, broadly in accordance with normal professional wargaming practice. The teams, or "cells" comprised the Blue Team (ASW team), Red Team (Guilder's submarine force) and the White Team, where the game management staff and controllers sat. Each cell was located in a different room in the building so that they could not overlook each other's playing areas. Red and Blue cell players were restricted to their rooms, White cell were able to roam if needed to confirm their view and knowledge of the game state of play if necessary.

The White Cell was made up of the following participants:

- The Game Controller – responsible for maintaining the overall running of the game, timekeeping, turn flow, etc. They were also responsible for managing "injects" – specific events that both sides would need to react to, and for resolving any ambiguous or conflicting situations that may arise, often by drawing on the judgement and experience of SMEs.
- Green Cell Controller: controlling the actions of civilian units in the area, "background noise" and the friction of war. The Green Cell controller was necessary to turn the battlespace from a sterile environment containing only Red and Blue units into a more realistic situation where units could hide among everyday activity.
- The Adjudicators, or "Team Runners". At least one and ideally two members were allocated to act in this role as the link between the White Cell and Blue and Red Cells. They collected orders and other information from the cells and resolved the outcome of those on the White Cell map. They then fed back the results of their adjudications to their respective cells. Their roles became quite demanding when interaction between Red and Blue occurred, for example when Red was conducting a torpedo attack, or Blue ASW assets had detected and were prosecuting one of Red's submarines.

Red and Blue Cell participants comprised two to three players dedicated solely to the actions of their side in the game.

**Figure 5: ASW Game Team/Cell Organisation**

## Game Execution

The wargame campaign was executed over a three-day period, with a fourth day set aside for evaluation, analysis and planning the next steps. Each playing day was made up of two sessions, one in the morning, the second in the afternoon, with a "wash up" taking place after each session.

A session was made up of the following events:

- A briefing for all players at the White Cell map, explaining the broad outline of the scenario. On completion all participants withdrew to their respective cells.

- Mission Planning; teams developed plans for their assets including locations, courses, speeds, and action to be taken in the event of a contact with enemy forces.
- Mission Execution; Adjudicators would then compare plans in the White Cell to determine where encounters occurred and would then begin resolution of those events, feeding back to Red and Blue as necessary and receiving updates orders or reactions to events. Missions were played to their conclusion, i.e. to the point where either Red or Blue had successfully completed their mission, or where mission completion was clearly not achievable.
- Recording – during each element of the games, players would record the rationale for their actions and decisions. This would form a key element of post-game analysis.
- Post game wash up; all cells were brought together at the White Cell map where the Game Controller briefed on what had actually in the game. This was also the opportunity for feedback, consideration of concept details and consideration for amendments. Again, this was recorded for post-game analysis.

Six game scenarios were planned as follows:

- Game 0 – A simple training game for all participants to give them familiarity with the game mechanisms. This game was not part of the formal concept assessment and hence was not recorded
- Game 1 – Approach Phase- Blue Force, using the conventional fleet construct, enters the Operational Area (OA) and clears the evacuation point and approaches of any Red submarines.
- Game 1a – a repeat of Game 1 but Blue Force uses the new modular force employing offboard systems.
- Game 2 – Evacuation Phase – Blue uses the conventional force to establish and maintain its ASW Barrier whilst Red submarines attempt to penetrate and interrupt the ongoing NEO.
- Game 3 – Evacuation Phase – a repeat of Game 2 but with Blue using the modular offboard-enabled force.
- Game 4 – Evacuation Phase – a modified version of game 3, with Blue able to amend its force mix based on experience from Game 3
- Game 5 - Exfiltration phase – Blue uses its evolved force from Game 4 and tempts to bring the evacuation force away from shore to safety.

It was originally intended to run each game once, but the players quickly became familiar with the rules and game execution so it was decided to run two parallel instances of games 2 to 5 in order to increase experience, evidence and learning opportunities

At the end of each day a more extensive “hot wash” discussion was carried out to consider learning points for the day and to consider whether any changes were required for the following day’s games, including the inclusion of any new capabilities. An example of this was a deployable seabed sonar array (based loosely on a system advertised by Sonardyne), and a mobile hard kill anti torpedo system for defence of the evacuation anchorage (which was named “Palisade”). In both cases relevant SMEs were consulted for likely performance parameters and these were converted into game parameters overnight.

## Capabilities Investigated

Blue Force was initially made up of conventional anti-submarine frigates, analogous to UK Type 23 or the Canadian Halifax class. They were equipped with towed array and hull mounted sonars and a capable ASW helicopter. After the initial games these were replaced with frigates using mission modularity concepts to embark offboard systems as well as their integral sensors. The offboard capabilities examined included:

- Uncrewed Undersea Vehicles (UUV). These were equipped with thin line towed array sonars. They were able to operate at the same depths as the threat submarines, but being small they were unable to process their own data. As a result they were required to go to periscope depth at preset intervals to transmit their recorded data back to their motherships for processing. This introduced inevitable data latency into the ASW problem. Being small and slow, however, meant they were extremely quiet and difficult to detect so a threat submarine was unlikely to be aware of their presence.
- Uncrewed Surface Vehicles (USV). These were small (8-11m) fast craft using the same thin line towed arrays as the UUVs. Again, due to their small size and lack of power they were unable to process their own

sonar data, but as they were operating on the sea surface they were able to transmit data back for processing on a continual basis.

- Uncrewed Aerial Vehicles (UAV). Large quadcopters or small helicopter-style aircraft capable of embarking and deploying up to four sonobuoys or a single lightweight torpedo. Their speed and endurance was limited whilst carrying heavy payloads such as torpedoes, but they were able to stay in flight for long periods of time and could work effectively in concert with each other or supplementing larger manned helicopters (the latter being Blue's preferred mode of use).

As mentioned earlier, lessons identified in the games led to proposals for new capabilities to be fielded. These included:

- Deployable seabed sonar system – a “spoke and hub” design was suggested featuring six passive hydrophone arrays (“spokes”) radiating from a central buoy (“hub”) that maintained communications with command and control assets such as the modular frigates where signal data processing could take place. The system parameters set by the White Cell proved to be too effective, forming an impenetrable screen (although this did demonstrate the considerable benefit should such a high capability system be developed). The system was cumbersome and took time to deploy and recover, hence the Blue Team abandoned many of their arrays during the final scenario as recovering them would have left the force exposed for a significant time.
- USV-based torpedo defence system. In early games Blue was required to position its ASW frigates some distance from the evacuation port in order to be able to react quickly to submarine detections. Unfortunately this left the evacuation anchorage undefended and if a submarine could get within torpedo range there was nothing available to protect the evacuation ships. The frigates were already able to select a modular torpedo hard kill system so it was suggested that such a system could also be deployed in an 11m surface craft to provide local protection.
- Seabed communications network – a portable sonar based undersea communications network was discussed during the game but not fielded as it was felt this was more appropriate for use in a fixed location, such as a friendly harbour and its approaches, rather than in an expeditionary scenario as the campaign presented. If it had been used then the data latency issues of the UUVs could be mitigated.

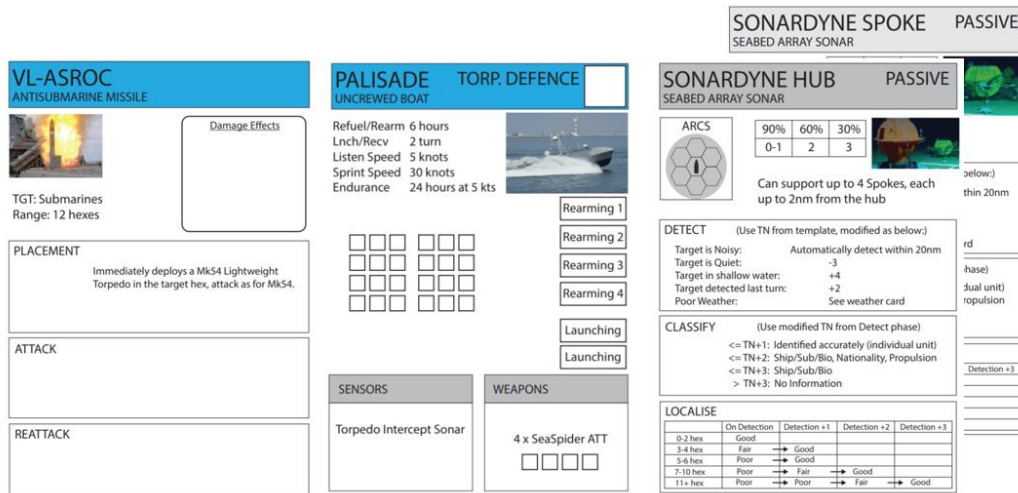

Figure 6: Examples of Capability cards created during the games

## Results and Conclusions from the NSSE Wargame

At the end of the three days of gaming it was concluded that the game system worked effectively and had given realistic results. Several ASW SMEs were in attendance and confirmed that the events in the game and various conclusions drawn were in accord with their own understandings. This was considered by some to be quite remarkable given the unclassified nature of the games.

On day 4 the UCL wargaming team and the game's NSSE sponsors conducted a deeper review of the various lessons identified during each game. The NSSE team's view was unanimous; the wargames had successfully allowed a range of ASW and force mix options to be considered, evaluated and developed in such a way that a hypothetical OA study could begin from a more focussed starting point. From the NATO customer's perspective the applicability to the concept phase of project was clear (NATO 2023).

It was noted that, as well as achieving the stated aim, wargaming brought with it a number of other benefits. System designers and stakeholders were able to observe how elements of the various concepts interacted with each other, allowing synergies (and issues) to be identified. SMEs were able to see how their particular areas of expertise fitted into the overall ASW system, providing essential operational context that they had been previously unaware of. The multi-faceted makeup of the players involved – wargamers, operators, designers and deep experts - meant that each had an opportunity for interaction with their fellow players from different backgrounds, promoting learning and development. These were seen as essential elements over and above the primary objectives of the event. In its summing up of the event the NATO team was satisfied that wargaming had been shown to be capable of being used effectively as a concept analysis and elucidation tool whilst also delivering the potential for wider benefit. As a result, ST/NSSE is now moving working to include wargaming as an essential domain-specific activity in its new naval ship design NATO standard. As an additional spinoff the UCL team has been in discussion with other UK and NATO project teams on the possibility of using ABF and other tools for “real world” project analysis.

Noting that ST/NSSE's primary objective was to demonstrate and explore the role of wargames the outcome from the games and the discussions that surrounded them and the game process were (within the restrictions imposed by the unclassified nature of the event) felt to have shown:

- the potential for an effective anti-submarine barrier using offboard assets compared with a traditional arrangement when used in a defensive posture;
- benefits and drawbacks of the component elements of the system as proposed;
- capability gaps that existed in the ASW system as well as some in wider maritime operations, along with possible mitigations and solutions;
- the power of wargaming as a method for investigating the criticality or otherwise of components and characteristics of a system;
- how complex element such as sensor interaction, data processing and reliable communications are likely to impact the viability of a solution;

It was also demonstrated that:

- wargaming requires support from experienced wargamers to ensure that the learning points, including those arising from negative experiences, are relevant,
- wargaming and modelling and simulation (M&S) serve distinct and different purposes: wargaming considers the “big picture” and therefore should not be used for the study of extensive variations of the operational problem (it would take far too much time); M&S can be used to study an operational problem in great detail with many variations, with a much smaller problem scope compared with wargaming,
- the results of modelling and simulation can be condensed into game artifacts and used to develop the wargaming model.

## CONCLUSIONS

The case studies described in this paper show four examples of ways that technically-focused manual naval wargaming has been applied to practical problems facing design teams in the requirements elucidation phase of ship design. The authors and clients have concluded that wargaming offers significant utility as a tool in this phase, in particular:

- Wargaming can help a design team understand which areas of performance will be most critical to ensuring mission success, helping to allocate subsequent and more in-depth operations analysis effort more efficiently.
- Wargaming can be an effective tool for exploring a warship's CONEMP, as well as ensuring that the CONEMP is fully understood by the whole team. Wargaming can be used as a form of active learning, which has shown to be more effective for communicating complex subjects than reading written material.
- Wargaming allows low-level technical models of novel systems to be integrated into higher level tactical or operational models, allowing assessment of those systems' effectiveness without access to prior operational experience.
- Wargaming allows the interactions between subsystems to be explored and better understood (in conjunction with subject matter experts, who remain a vitally useful resource).
- Wargaming allows the rapid exploration of the "arms race" of countermeasures and counter-countermeasures to a novel system, which can help to anticipate the future operational environment.

Some common useful features have been identified for wargames intended for use in requirements elucidation:

- Transparency about how game statistics are derived from real-world measures of performance.
- The ability to rapidly incorporate new systems and capabilities into the game.
- The ability to readily adjust the game mechanics to model different scenarios of interest.
- Credibility allowing faith in the results – most easily obtained by involvement of subject matter experts, historical data and OA models in creation and adjudication of the game.
- The ability to rapidly play the same scenario multiple times.

# Development of a Novel Codesign Method for Use in Early-Stage High-Performance Craft Design

Evan J. Branson<sup>1,\*</sup> Arend Vyn<sup>2</sup>, Kevin Maki<sup>1</sup>, and David J. Singer<sup>1</sup>

## ABSTRACT

*The performance requirements of modern vessels have increased significantly over time, introducing unique challenges in design and analysis. Driven by competition, such as in the case of racing craft, new high-performance vessels require design spaces that push the envelope of hydrodynamic technology. This optimization knowledge resides in the experience of racing experts and hasn't yet been translated into a naval architecture taxonomy. This paper seeks to bridge the knowledge gap between experienced race manufacturers and naval architects, and in doing so, delineate a design methodology. Modeling risk as a function of vessel speed, as well as coupling the design of the control system in conjunction with its physical design embodiment, allows the overall system to reach a greater point of optimality than what can be accomplished by traditional iterative design processes alone. The approach will be demonstrated utilizing the design of a University of Michigan student-led undergraduate high-speed, electric boat competition team design. The team's goal is to develop a vessel that has a top speed of 135 mph. The paper will discuss how the team used marine design methodologies integrated with a novel codesign method to create the design that is currently under construction for professional racing use by the team.*

## KEY WORDS

Codesign; Design Theory; High-Performance Craft; Racing; Speedboat.

## INTRODUCTION

Powerboating and marine racing, also known as offshore powerboat racing, trace their origins back to the early 20th century, born from the desire to push the limits of marine engineering and hull design. The major modern competitors in powerboating include both manufacturers and private teams that specialize in the design, construction, and operation of these high-performance vessels. Prominent brands in the field include Cigarette Racing, Mystic Powerboats, Skater, and MTI (Marine Technology Inc.), which have developed reputations for their racing prowess and technological innovations. In terms of racing teams, organizations MCON Racing (pictured in Figure 1) have been very successful in international competitions such as Class 1 World Powerboat Championship. The marine racing industry has also grown to accommodate a variety of classes and different types of powerboats, from outboard engines to multi-engine offshore powerboats capable of reaching speeds exceeding 200 mph.

**Figure 1: Class 1 Offshore Race Boat "Monster Energy MCON"; Source: mconracing.com (2023)**

The advent of electric power in the marine racing industry has marked a major evolution, echoing the shift toward sustainability seen in automotive racing with series like Formula E. This rise of electric racing boats is propelled by the increasing global emphasis on reducing carbon emissions and harnessing renewable energy sources. Initiatives like the UIM E1 World Electric Powerboat Series showcase the potential of battery-powered craft, which offer a powerful yet environmentally friendly alternative to traditional internal combustion engines. As battery technology has advanced, with improvements in energy density, efficiency, and charging speeds, electric racing boats have become more competitive, promising high speeds, lower noise levels, and zero emissions.

A new addition to this transition toward electric racing craft is University of Michigan Electric Boat (UMEB), a team of students attempting to break the electric water speed record. UMEB was founded in September 2019 by a small group of undergraduate Aerospace and Naval Engineers to further develop battery-electric vessel technology. As the team developed, it became apparent that the limited budget, resources, and experience in a student project meant that designing and operating like a professional powerboat manufacturer was not feasible. Instead, the characteristics of the team's operation more closely matched those of the wicked problems associated with large vessel and platform design. Thus, UMEB was presented with the following problem: translating the knowledge, best practices, and design elements developed from decades of experience of team contacts in the marine racing industry into a novel marine design methodology.

This paper delineates the methodology employed by UMEB in crafting a competitively adept racing vessel through the lens of naval architecture principles.

## CHANGING LENSES

### The Tragedy of *Snowfinkle*

The realization that UMEB needed to integrate naval architecture principles and methodologies into the design of speedboats was not immediate, and only years of failure taught the team to change. These failures began in 2021 with the team's first true attempt at a performance vessel: *Snowfinkle*.

Before the design process even began, there were reductions in the design space in that the vessel's hull form was limited to the 17-foot sailing catamaran that was donated to the team in the previous year. This meant that a successful craft would have to match the characteristics of a sailboat, which was designed purely to act in a displacement capacity and not able to plane. Electric battery systems have an inherent drawback in their low power density, which is somewhat incompatible with the dynamics of a very lightweight sailing craft. Navigating this problem is where the team made its first critical mistake in failing to assess the root cause of these problems and instead attacking the surface-level design incompatibilities. The team looked to the marine industry to find solutions, and seeing as industry offerings for battery-electric craft almost exclusively utilized hydrofoils to meet their operational requirements, the team embraced hydrofoils as a potential saving grace to the emergent design challenges. What should have been a question of what would create the best craft that met the re-

quirements quickly turned into a question of how to make hydrofoils work. Consequently, the team followed a point-based design approach, with the initial conditions being the hull form and the hydrofoils. Due to ‘walls’ being put up between the propulsion, battery, hydrofoils, and structures teams to divide the work, systems integration became a major obstacle. This manifested throughout *Snowfinkle*, emerging most obviously between the physical junction of the hydrofoils and the rest of the craft, as well as the propulsion system. The team also stumbled into an endless need for weight distribution adjustments due to the poor balance characteristics of *Snowfinkle* while foiling, leading to consistent changes in general arrangement. As the team continued following the spiral, progressively more changes needed to be made, often compromising the overall vessel mass and the functionality of the vessel’s control system. These changes often occurred after major portions of *Snowfinkle* had already been built, which further complicated the problem. No matter the decisions made, the initial conditions of the design meant that we could not converge to a point of optimality, let alone acceptability.

**Figure 2: *Snowfinkle***

The methodology used on *Snowfinkle* illustrated a failure to execute proper marine design on many levels. With a bit more design space exploration, it would have become evident that the low drag characteristics of the hull meant that the craft could have easily met its design requirements with an 80-horsepower propulsion unit and no further changes to the hydrodynamics of the hull, thus the resultant design space would have greatly differed. Even had UMEB used spiral-based design (which might have been a necessity given a new and inexperienced team with limited resources) to generate *Snowfinkle*, delaying critical decisions would have led to a greater understanding of the driving variables with which the team worked, which might have had the potential to generate better initial conditions and eventually an acceptable convergence.

In the end, *Snowfinkle* experienced a complete and total system breakdown after nearly every interface had been reworked, then reworked again to no avail. The team decided that the countless hours spent fixing the unsolvable issues was not worth their effort, and instead began focusing on eliminating the issues with *Snowfinkle* through a much more mature approach to boat design.

## **A Step in the Right Direction**

As the *Snowfinkle* was sunset, a new chapter began for UMEB. The team had grown significantly over two years both in number and in expertise, especially regarding battery, control, and propulsion systems. A growing team presence at the University of Michigan and the local community had opened up many doors in terms of resources, additions of physical workspace, and bargaining power with the school administration. Most importantly, however, the team’s leadership changed: this time with a much greater focus on designing for high-performance.

Considering the new leaders were many of the people who experienced firsthand the failures of *Snowfinkle*, there was an early push to truly understand the design errors at a fundamental level. The team first identified that a marine design ap-

proach was needed, something the aerospace students who previously ran the team did not completely recognize or understand, and therefore could not execute successfully. In other words, a much more methodical and strategic process would be needed to avoid making premature decisions that would force the team into undesirable designs. Additionally, the walls put up across subteams needed to be broken down and instead replaced with collaborative systems thinking, with a much greater emphasis on cross-functional work to ensure interfaces were accounted for.

While the new leaders understood the issues with the poor design strategy correlated with *Snowfinkle*, the team identified that there were still significant gaps in our understanding of successful marine design processes. To address these gaps, team leadership began meeting with professors in the University of Michigan Naval Architecture and Marine Engineering department, especially Professor David J. Singer.

### Requirements Elucidation

The first step UMEB took in improving its design methodology was working to better understand the speedboat design space. Due to the limited budget, timeline, and experience present in the project, there was a major need to derisk this design space and guarantee that whatever design elements were chosen would not result in emergent design failures that would compromise the project, much like what happened with *Snowfinkle*. To address this knowledge gap, UMEB performed a functional decomposition based on the team’s overarching goal to travel at 100 knots for 5 nautical miles (See Figure 3). The goal of this process was to develop a knowledge structure that could guide our end embodiment and the decisions we made along the way, following the taxonomy presented by Goodrum (2020).

To perform this functional decomposition, we employed a Andrews (2021)-style requirement elucidation process. Within this process, we started at the overarching goal of our design, and from there worked our way down through design variables with the help of taxonomies, not to reach a feasible design, but more to learn about the complex interactions within the design space and discover requirements as we went.

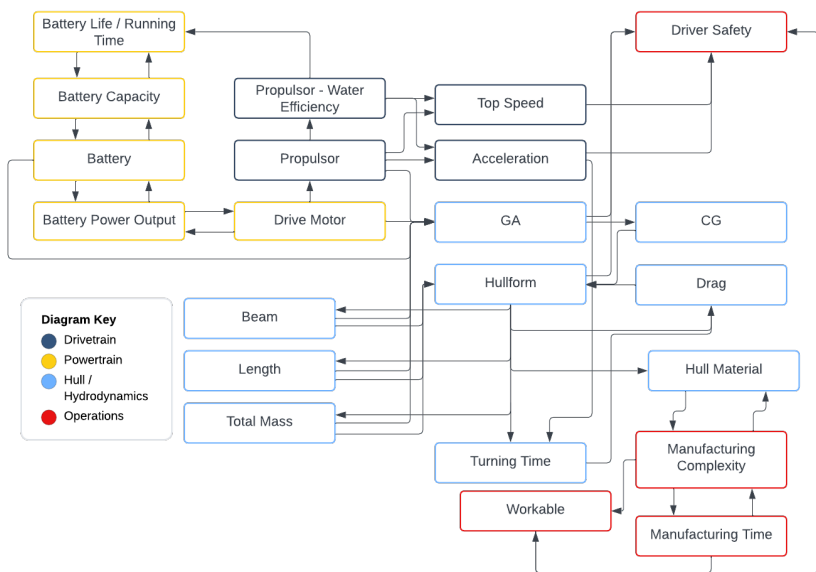

Figure 3: UMEB Functional Decomposition

One example of this was how we grew to understand lift within our design space. We knew from industry experts that lift was going to be a major part of being able to go fast efficiently, but breaking down the actual factors that drove that proved difficult. At this point, we were introduced to the sustension cube (See Figure 10) as explained by McKesson (2009), which provided us with a taxonomy to classify how different vessels produce lift. From here, we could analyze how other high-performance crafts fit onto the sustension cube. We found that the fastest craft we knew of had high passive aerodynamic and hydrodynamic lift characteristics, thus discovering the requirement that our vessel should structure its lift characteristics similarly. More specifically, we discovered the requirement that our vessel needed to have some sort of surface, be that wings, tunnels, or hull form, that would pressurize air beneath the craft and that the geometry touching the water needed to plane efficiently.

**Figure 4: McKesson's Sustension Cube**

## IDENTIFYING DISCREPANCIES

As UMEB continued the process of functional decomposition, informing our new discoveries with the knowledge gained through previous design space explorations, team members would often talk to UMEB's industry partners, especially Skater and the American Powerboating Association (APBA), using their knowledge and experience as a feasibility check for the discovered requirements and design elements. The team discovered in this process that there were discrepancies in the way that the racing professionals analyzed the design space and how naval architects would do the same. To address our findings, the team contacted the best high-speed hydrodynamics experts they could find to further explore this. Specifically, UMEB explored the missing pieces of the problem through detailed analysis with Dr. Kevin Maki and Dr. Armin Troesch. In discussions with both, a similar conclusion could be drawn, best encapsulated in the following quote from Dr. Troesch: "Even the best naval architect can only design a 90% boat; it takes a different type of knowledge to get the last 10%". When the team brought up this issue with Peter Hledin, the owner of Skater and one of the most respected offshore catamaran designers in the world, he responded with the following (albeit heavily paraphrased due to the use of expletives): "[Naval Architects] know what the boat will do, but I also know what the driver will do and I know what the APBA will let me run". Quite simply, this explanation illustrated a framework for what design tools were missing.

## Codesign

"I know what the driver will do"

With a little bit of abstraction, the role of the driver can be viewed as an active controller for the physical plant of the craft. When analyzing through this lens, there are many evident similarities to high-performance aircraft design, which uses a knowledge structure where design elements physical plant and design elements of its control system simultaneously inform each other. This aerospace concept is more colloquially referred to as codesign.

### ***Codesign in Aerospace***

Codesign has been a major tenet of aircraft design since the 1970s, specifically concerning projects within the US military black budget. Much of modern stealth fighter technology would not have proven viable had it not been for early-stage design exploration illustrating that an airframe with poor flight characteristics due to the requirement of a small radar cross-section could still be effective by combining pilot input with highly responsive flight computers according to Aronstein and Piccirillo (1997). The effectiveness of this design methodology is evident in its continued use in the defense industry despite nearly half a century of technological progress as evidenced by continued aerospace research on the topic from academic works such as Abedini et al. (2022). It should be noted that there exists very little academic research from a design theory perspective on this topic as the aerospace industry views codesign more as a strategy to address instabilities and less so as an overall methodology; the further complexity of the marine design space demands a more comprehensive approach.

### ***Codesign in Marine Research***

The use of codesign is not a foreign idea in the marine academic sphere; it should be noted that the most complete mathematical example comes from Castro-Feliciano (2016). This paper illustrates the potential benefits of coupling an active control system to the design of a planing craft, specifically concerning dimensional and numeric figures such as the longitudinal center of gravity. It can be argued that the math used by the authors is limited in scope to implementation in planing craft with very geometrically simple hull forms, as is standard. This becomes a problem within the research scope of this paper as many, if not all, of the racing vehicles that make use of advanced control surfaces, also make use of extremely complex hull forms with the addition of features like steps, multiple hard chines, and rear strakes according to Yun and Bliault (2012), not to mention multiple hulls. The highest-speed racing craft are further complicated with hull forms that in addition to planing also make use of the ground effect (often referred to in the industry as “packing air”) through the use of tunnels, Venturi tubes, and wing surfaces. The greatest benefit of Castro-Feliciano’s version of codesign concerning racing craft comes from his point that control systems can take advantage of traditionally undesirable dynamic nonlinearities and instead use them to increase vessel performance. Take porpoising, for instance. Without a control system, porpoising can lead to significant inefficiencies due to a change in lift characteristics and drag, which sharply limits the top speed of a vessel, or in more extreme cases, can lead to a crash. Despite the aggregate effect of porpoising being negative in terms of vessel performance, there is a point in the oscillation in which the craft is further out of the water and has lower overall drag than achievable without dynamic instability: this is where well-integrated control surfaces come in. If a control surface can provide lift during the periods when porpoising would force the craft downward, then the net effect of this controlled nonlinearity is less drag and therefore greater top speed. One problem with this approach is that it requires a working understanding of exactly what function a control surface will perform, which is sometimes not possible to derive in early-stage design. This approach can be reversed, however; by defining a control surface in terms of the function it must perform, which thus can generate design knowledge without reducing the design space.

### ***Codesign in Marine Racing***

Given that competition drives a need for designs to perform as optimally as possible, as many feasible designs as possible need to be considered when determining dominance. We can visually represent how codesign can be useful for expanding the set of feasible designs using Figure 5, which illustrates a hypothetical feasible set within an imaginary design space. Note that there exists a boundary where designs exit the realm of feasibility due to failure to meet a requirement.

**Figure 5: Hypothetical Design Space Example**

This becomes problematic when we start comparing these designs, as there exist spaces in which the most dominant designs lie on the boundary due to a requirement acting as an active constraint. This can be visualized in Figure 6, where we can see the most optimal designs lying nearest to the boundary.

**Figure 6: Design Space Dominance Example**

With this in mind, there becomes a vested interest in expanding this boundary of feasibility to reach a higher performance but satisfactory design. This is where codesign can provide some advantages in the racing sphere. By taking advantage of designs that might not be conventionally feasible due to factors such as poor stability and then pairing them with a control

system (be that a computer or a human driver) that can address this, a certain previously infeasible set of designs can once again enter the realm of feasibility. Following the other presented figures, Figure 7 illustrates the inclusion of more designs into the feasible set.

**Figure 7: Feasibility Boundary Expansion Example**

It should be noted that while controls can solve some level of instability, control authority is a design variable in itself and there are countless instances where the control requirements to reach stability are infeasible in themselves. To determine the feasibility of a control system, further modeling with the dynamics of the rest of the vessel is needed, thus requiring a mathematical model for codesign. This will be further explored in the implementation section of this paper.

### The Risk Model

“I know what the APBA will let me run”

The second missing piece of the racing design problem comes from the inherent need for a craft to be competitive. In order to win, a racing craft must be pushed to its absolute performance limits. Simultaneously, an ideal racing craft should completely disintegrate as it crosses the finish line, which means that every component is being designed to be just robust enough to finish a race. This creates several problems, as pushing a craft to these performance limits with limited knowledge can be very irresponsible, given that the line between winning and dying can be very thin. This problem is well documented; according to Atwal (2024), seven of the thirteen people who have attempted to break the water speed record have died during their attempts.

Because of this, managing risk within the vessel’s engineering becomes the designer’s responsibility. Like any risk model, such as a HazID (see ABS (2020)), we can identify threats to the vessel with both their likelihood to occur and the associated consequences if they do. As a vessel has to exert greater performance, the consequences of failure as well as the likelihood of failure increase, thus coupling these two factors. Consequently, vessels operating with lower performance targets can exhibit fewer mitigation and prevention measures, often contextualized as safety features. For instance, the APBA (2022) states that cockpits on boats designed to travel faster than 150 miles per hour require a cockpit structural strength of

8,000 Newtons whereas cockpits designed for lower speed boats only require 2,000 Newtons. In conclusion, as a vessel's performance requirements increase, the degree of risk that can be taken significantly decreases.

One system that we have developed to understand and track this risk-based design space is a tool we call a Vessel Integrity - Vessel Speed (VI-VS) plot. Vessel speed, in this context, is a broad term that describes the inherent performance metric that a racing craft is trying to meet; for an endurance craft, this might be vessel velocity at range, for a circuit track craft, this might be velocity maintained through a turn, and for a drag boat, this might be acceleration over short distances. The other component of this relationship is vessel integrity; this is a measure of how likely the vessel is to experience an extreme event that would prevent it from continuing normal operation, "blowing over" or an engine failure for example. This plot helps a designer characterize both designs and requirements simultaneously. One critical piece of using a VI-VS plot to its full advantage is plotting a curve that represents the acceptable risk associated with a craft as it relates to increasing performance, or, in context, vessel speed. This is written as the minimum allowed the integrity of a design at a given "speed". As discussed previously, these minimum requirements almost always increase with speed, but the exact quantization and form of this relationship often come from competition rules, careful design consideration, and the quality of the relationship between the craft owners and their insurance companies. Once placed on the VI-VS plot, we refer to the relationship as the Acceptable Design Risk (ADR) curve. An example of a VI-VS curve with a sample ADR curve is shown in Figure 8. Further definition of how these plots are generated will be illustrated in UMEB's implementation of this concept.

**Figure 8: VI-VS Curve Plot (Acceptable Design Risk Only)**

## IMPLEMENTING NEW DESIGN TOOLS

With a greater understanding of what needed to be done to develop an optimal craft, UMEB moved forward in their design process, using a set-based design process based on Singer et al. (2010) including a novel codesign component to derisk the design and ensure the team would not experience another system-level failure. Improving on the walls of the past, UMEB used its subteams - powertrain (batteries), drivetrain (power transmission), and structures (safety and hydrodynamics) - as specialties to base our set conversion.

### Expanding Feasible Design Sets through Codesign

UMEB used a very basic initial pass of designs using top-speed estimations based on Gerr (2001); afterward, the analysis became much more complex. While examining designs, UMEB focused extensively on seakeeping, as finding designs that wouldn't destabilize and flip over or crash proven to be the main limitation on feasibility. Because of this, the team first implemented codesign within a general stability equation. Given that the scope of the project is limited to racing craft that would only travel across extremely clean water (Sea State 1.5 or less), a linearized approach should suffice given that hydrodynamic disturbances due to waves will be minimal. With that information, Equation 1 defines a fairly accurate model of the dynamic relationships across the design space of vessels UMEB explored.

$$[m]\ddot{x} + [c]\dot{x} + [k]x = 0 \quad (1)$$

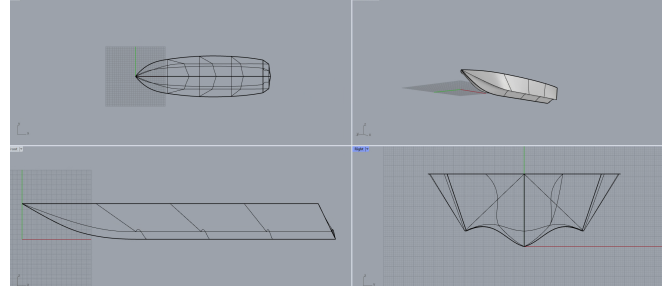

We will further expand this definition with Equation 2, Equation 3 and Equation 4. Note that this expansion includes all 6 degrees of freedom.

$$[m]\ddot{x} = \begin{bmatrix} m_{xx} & m_{xy} & m_{xz} & m_{xk} & m_{xm} & m_{xn} \\ m_{yx} & m_{yy} & m_{yz} & m_{yk} & m_{ym} & m_{yn} \\ m_{zx} & m_{zy} & m_{zz} & m_{zk} & m_{zm} & m_{zn} \\ m_{kx} & m_{ky} & m_{kz} & m_{kk} & m_{km} & m_{kn} \\ m_{mx} & m_{my} & m_{mz} & m_{mk} & m_{mm} & m_{mn} \\ m_{nx} & m_{ny} & m_{nz} & m_{nk} & m_{nm} & m_{nn} \end{bmatrix} \begin{bmatrix} \ddot{x} \\ \ddot{y} \\ \ddot{z} \\ \ddot{\phi} \\ \ddot{\theta} \\ \ddot{\psi} \end{bmatrix} \quad (2)$$

$$[c]\dot{x} = \begin{bmatrix} c_{uu} & c_{uv} & c_{uw} & c_{up} & c_{uq} & c_{ur} \\ c_{vu} & c_{vv} & c_{vw} & c_{vp} & c_{vq} & c_{vr} \\ c_{wu} & c_{wv} & c_{ww} & c_{wp} & c_{wq} & c_{wr} \\ c_{pu} & c_{pv} & c_{pw} & c_{pp} & c_{pq} & c_{qw} \\ c_{qu} & c_{qv} & c_{qw} & c_{qp} & c_{qq} & c_{qr} \\ c_{ru} & c_{rv} & c_{rw} & c_{rp} & c_{rq} & c_{rr} \end{bmatrix} \begin{bmatrix} \dot{x} \\ \dot{y} \\ \dot{z} \\ \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} \quad (3)$$

$$[k]x = \begin{bmatrix} k_{xx} & k_{xy} & k_{xz} & k_{x\phi} & k_{x\theta} & k_{x\psi} \\ k_{yx} & k_{yy} & k_{yz} & k_{y\phi} & k_{y\theta} & k_{y\psi} \\ k_{zx} & k_{zy} & k_{zz} & k_{z\phi} & k_{z\theta} & k_{z\psi} \\ k_{\phi x} & k_{\phi y} & k_{\phi z} & k_{\phi\phi} & k_{\phi\theta} & k_{\phi\psi} \\ k_{\theta x} & k_{\theta y} & k_{\theta z} & k_{\theta\phi} & k_{\theta\theta} & k_{\theta\psi} \\ k_{\psi x} & k_{\psi y} & k_{\psi z} & k_{\psi\phi} & k_{\psi\theta} & k_{\psi\psi} \end{bmatrix} \begin{bmatrix} x \\ y \\ z \\ \phi \\ \theta \\ \psi \end{bmatrix} \quad (4)$$

The terms inside of the matrices presented were gathered through computer simulation and estimation of existing hull forms; an example of one of the forms tested by this model can be shown in Figure 9.

**Figure 9: Example Hull Form**

Given that the operational requirements given by the team were incredibly limited, the straight-line speed at the range of the vessel proved far more important than factors such as maneuvering and endurance. Because of this, the seakeeping equation can be reduced to only include trim, roll, and heave, shown in Equation 5. This reduction grants us sufficient knowledge to make design decisions while reducing the computational cost to simulate large numbers of design options; however, it should be noted that a more complex physics simulation is necessary when developing the final control system.

$$\begin{bmatrix} m_{zz} & m_{z\phi} & m_{z\theta} \\ m_{\phi z} & m_{\phi\phi} & m_{\phi\theta} \\ m_{\theta z} & m_{\theta\phi} & m_{\theta\theta} \end{bmatrix} \begin{bmatrix} \ddot{z} \\ \ddot{\phi} \\ \ddot{\theta} \end{bmatrix} + \begin{bmatrix} c_{zz} & c_{z\phi} & c_{z\theta} \\ c_{\phi z} & c_{\phi\phi} & c_{\phi\theta} \\ c_{\theta z} & c_{\theta\phi} & c_{\theta\theta} \end{bmatrix} \begin{bmatrix} \dot{z} \\ \dot{\phi} \\ \dot{\theta} \end{bmatrix} + \begin{bmatrix} k_{zz} & k_{z\phi} & k_{z\theta} \\ k_{\phi z} & k_{\phi\phi} & k_{\phi\theta} \\ k_{\theta z} & k_{\theta\phi} & k_{\theta\theta} \end{bmatrix} \begin{bmatrix} z \\ \phi \\ \theta \end{bmatrix} = 0 \quad (5)$$

The reality of the design space when discussing the craft of extreme speed regimes is that instability is near guaranteed at some point, thus there is a point at which the seakeeping dynamics of the craft do not converge to zero as they do in Equation 5. There are many reasons for this occurring, but often this has a lot to do with the hull form characteristics changing across different dynamic domains at different speeds. Mathematically, an error term appears in the equation to model how small disturbances while in a high planing state can propagate into instabilities or extreme events. This emergence of instability generates Equation 6.

$$\begin{bmatrix} m_{zz} & m_{z\phi} & m_{z\theta} \\ m_{\phi z} & m_{\phi\phi} & m_{\phi\theta} \\ m_{\theta z} & m_{\theta\phi} & m_{\theta\theta} \end{bmatrix} \begin{bmatrix} \ddot{z} \\ \ddot{\phi} \\ \ddot{\theta} \end{bmatrix} + \begin{bmatrix} c_{zz} & c_{z\phi} & c_{z\theta} \\ c_{\phi z} & c_{\phi\phi} & c_{\phi\theta} \\ c_{\theta z} & c_{\theta\phi} & c_{\theta\theta} \end{bmatrix} \begin{bmatrix} \dot{z} \\ \dot{\phi} \\ \dot{\theta} \end{bmatrix} + \begin{bmatrix} k_{zz} & k_{z\phi} & k_{z\theta} \\ k_{\phi z} & k_{\phi\phi} & k_{\phi\theta} \\ k_{\theta z} & k_{\theta\phi} & k_{\theta\theta} \end{bmatrix} \begin{bmatrix} z \\ \phi \\ \theta \end{bmatrix} = e(t) \quad (6)$$

Given the idea that a control surface can provide a certain degree of authority to force a system into stability, this error term can sometimes be a surmountable obstacle. To determine if the vessel can reach stability through controls, a term can be added to the seakeeping equation to represent the required effort of a control system to maintain stability through changing dynamic domains. This action is illustrated in Equation 7 and Equation 8.

$$\begin{bmatrix} m_{zz} & m_{z\phi} & m_{z\theta} \\ m_{\phi z} & m_{\phi\phi} & m_{\phi\theta} \\ m_{\theta z} & m_{\theta\phi} & m_{\theta\theta} \end{bmatrix} \begin{bmatrix} \ddot{z} \\ \ddot{\phi} \\ \ddot{\theta} \end{bmatrix} + \begin{bmatrix} c_{zz} & c_{z\phi} & c_{z\theta} \\ c_{\phi z} & c_{\phi\phi} & c_{\phi\theta} \\ c_{\theta z} & c_{\theta\phi} & c_{\theta\theta} \end{bmatrix} \begin{bmatrix} \dot{z} \\ \dot{\phi} \\ \dot{\theta} \end{bmatrix} + \begin{bmatrix} k_{zz} & k_{z\phi} & k_{z\theta} \\ k_{\phi z} & k_{\phi\phi} & k_{\phi\theta} \\ k_{\theta z} & k_{\theta\phi} & k_{\theta\theta} \end{bmatrix} \begin{bmatrix} z \\ \phi \\ \theta \end{bmatrix} = e(t) - C(t) = 0 \quad (7)$$

$$\begin{bmatrix} m_{zz} & m_{z\phi} & m_{z\theta} \\ m_{\phi z} & m_{\phi\phi} & m_{\phi\theta} \\ m_{\theta z} & m_{\theta\phi} & m_{\theta\theta} \end{bmatrix} \begin{bmatrix} \ddot{z} \\ \ddot{\phi} \\ \ddot{\theta} \end{bmatrix} + \begin{bmatrix} c_{zz} & c_{z\phi} & c_{z\theta} \\ c_{\phi z} & c_{\phi\phi} & c_{\phi\theta} \\ c_{\theta z} & c_{\theta\phi} & c_{\theta\theta} \end{bmatrix} \begin{bmatrix} \dot{z} \\ \dot{\phi} \\ \dot{\theta} \end{bmatrix} + \begin{bmatrix} k_{zz} & k_{z\phi} & k_{z\theta} \\ k_{\phi z} & k_{\phi\phi} & k_{\phi\theta} \\ k_{\theta z} & k_{\theta\phi} & k_{\theta\theta} \end{bmatrix} \begin{bmatrix} z \\ \phi \\ \theta \end{bmatrix} + C(t) = e'(t) = 0 \quad (8)$$

### ***Distilling Control Requirements from $C(t)$***

$C(t)$ , as defined in the previous section, is at its core a measure of the error between desired and actual dynamic characteristics. To pull more specific information out of  $C(t)$ , it needs to be decomposed into error terms in each direction, which is shown in Equation 9. These functions can be fairly easily picked apart using a linear regression model using data points from the simulation.

$$C(t) = e_z(t) \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} + e_\phi(t) \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} + e_\theta(t) \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \quad (9)$$

From this point, two key pieces of information are needed to determine the feasibility of the control system: the first of these is the required effort of the control system. This can be found by finding the maximum value of  $|e_z(t)|$ ,  $|e_\phi(t)|$ , and  $|e_\theta(t)|$  across the selected time domain. For instance,  $\max(|e_z(t)|)$  might return a value of 2000 Newtons, which tells us that our control system must be able to produce 2000 Newtons of lift when all surfaces are fully extended. This does not necessarily mean one control surface has to do this, but the aggregate effect of the control surfaces must produce that effect.

From here, the reactivity of that control system must be determined, or in other words, the speed at which the control sys-

tem must fight a disturbance. the first step of determining this information is taking the derivative of the error functions, returning  $e'_z(t)$ ,  $|e'_\phi(t)|$ , and  $e'_\theta(t)$ . From there, the maximum magnitude of the derivative of the error function should be found,  $\max(|e'_z(t)|)$  for instance. The last step is to determine the time domain in which controls must be able to engage. Generalized control reactivity values in the context of the reduction used by UMEB can be found in Equation 10, 11 and 12.

$$t_z = \frac{\max(|e_z(t)|)}{\max(|e'_z(t)|)} \quad (10)$$

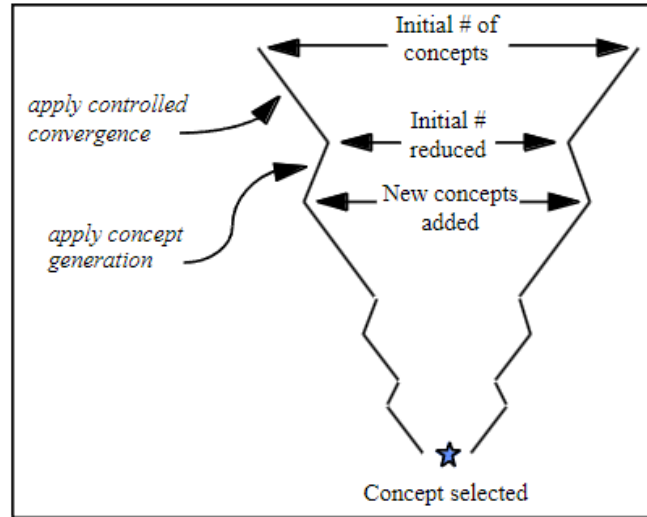

$$t_\phi = \frac{\max(|e_\phi(t)|)}{\max(|e'_\phi(t)|)} \quad (11)$$

$$t_\theta = \frac{\max(|e_\theta(t)|)}{\max(|e'_\theta(t)|)} \quad (12)$$

This process during simulation should give enough information to determine the feasibility of a control-enabled design and avoid its loss to set reduction. Following this process, UMEB was left with a feasible set of designs that included the effect of control surfaces on vehicle dynamics.

## Dominance through Risk Modeling

Once UMEB had a clearly defined range of design variables that was deemed to produce feasible results, the question of execution became increasingly more important. While the team had grown both in personnel and resources significantly, there were still limitations. The greatest block in the design process was that there were many components that the team knew were going to be impossible to manufacture in-house, which meant we had to purchase them; specifically, the hull and primary drive motor were both components that had to be purchased and not designed, thus creating anchors within the design space. There were a limited number of commercially available hull forms and drive motors that fell within the realm of feasibility, which discretized some of the design variables. Additionally, while all of these designs were feasible, UMEB wanted to pick the most competitive design possible in order to increase our chances of winning the electric boat arms race. Because of this, UMEB realized that comparison and dominance would have to be achieved through a method beyond set-based design. The team settled on the usage of Pugh's method of controlled convergence, shown in Figure ??, to develop this knowledge, first laying out all of the commercially available hull forms and motor options that fell within the feasible set. To determine the dominance of designs, an evaluation criteria had to be used, which is where the VI-VS risk model became useful.

**Figure 10: Visual for Method of Controlled Convergence from Bernstein (1998)**

### ***Quantifying VI-VS***

As discussed earlier, Vessel Integrity and Vessel Speed both represent composite functions of many factors that contribute to safety and performance respectively. The team determined these functions in a manner very similar to AHP, where they subjectively categorized how important each element of each criterion was over another. Following this, they generated the comparison matrices found in Table 1 and Table 2.

**Table 1: Preference Matrix for Vessel Integrity**

	Trim Stability	Roll Stability	Driver Capsule Strength	Powertrain Stress (C-rate)
Trim Stability	1	7	4	3
Roll Stability	1/7	1	1/3	1/5
Driver Capsule Strength	1/4	3	1	3
Powertrain Stress (C-rate)	1/3	5	1/3	1

**Table 2: Preference Matrix for Vessel Speed**

	Top Speed	Turning Radius	Acceleration	Range
Top Speed	1	7	4	3
Turning Radius	1/7	1	1/5	1/6
Acceleration	1/4	5	1	1/3
Range	1/3	6	3	1

From here, the team took the eigenvectors of these matrices to determine a weight vector, with results shown in Equation 13 and Equation 14.

$$w_{VI} = \begin{bmatrix} 0.88 \\ 0.09 \\ 0.38 \\ 0.26 \end{bmatrix} \quad (13)$$

$$w_{VI} = \begin{bmatrix} 0.86 \\ 0.07 \\ 0.23 \\ 0.44 \end{bmatrix} \quad (14)$$

Similar to TOPSIS as defined by Sen and Yang (1998), the designers identified an upper and lower bound for each of these metrics; by normalizing these values throughout the process, a nondimensionalized measure is gained for both vessel speed and vessel integrity which can each be plotted as single variables.

### Comparison with VI-VS

From this point, it became necessary to define an acceptable design risk curve that would act as the optimization goal. The team agreed that due to the policies of the University of Michigan, there was a baseline level of Vessel Integrity that was independent of Vessel Speed. There was also agreement that as Vessel Speed increased beyond around 0.500, there was no reason to increase the required Vessel Integrity much further as an extreme event at that level of performance would spell disaster regardless of the mitigation, prevention, and safety measures in place. For this reason, the team decided that the best way to model this behavior was through a square root relationship. Plotting this on the VI-VS curve generates Figure 11.

**Figure 11: Decided ADR Curve**

Once an ADR was established, the team moved onto using the VI-VS curve to analyze the dominance of individual designs by characterizing how Vessel Integrity changed across the domain of Vessel Speeds. Much of this was done subjectively or using simple curve fits from known points. Once a surrogate model had been established, dominance was determined based on the intersection between a design's VI-VS curve and the ADR curve. Take *Snowfinkle* for instance; due to the anhedral hydrofoils and poor weight distribution, *Snowfinkle*'s stability degraded quickly with increased performance, generating Figure 12.

**Figure 12: *Snowfinkle* VI-VS Plot**

This can be extrapolated further by looking at the VI-VS curves for further designs in Figure 13. By analyzing the problem through this lens, one can determine that “Design Alternative 2” dominates the others, as it can extract the most performance without an unacceptable risk of an extreme event occurring.

**Figure 13: Sample VI-VS Plots**

This kind of analysis drove the remainder of the early-stage design process for UMEB, and the team was left with a set of design elements that they were confident were strong enough to be competitive. Thus came the second, and much more entertaining, problem: how to take the chosen design from a spreadsheet to a working boat.

## EXECUTION

First began the monumental task of figuring out how to pay for a 24-foot race boat. Due to the frontloading of the design work, UMEB had a very clear vision of what our end product was going to be; this was advantageous as it was much eas-

ier to illustrate this vision to potential sponsors compared to past UMEB projects. Through building connections and sharing the plan, the team built more and more allies: powerboat builders, electric vehicle manufacturers, consulting firms, and software companies to name a few; UMEB's net worth passed a million US dollars within six months of starting fundraising.

With financial resources unlocked, the team experienced a shift in November 2023, as the time had arrived to start physically putting together the parts of the craft. This was kicked off by the arrival of the hull, which the team had to travel to pick up from a sponsor across the country. As the new craft was pulled into the team workspace, the team announced to the world the name of the project: *TiDE*. As the project progressed and grew in physical scale, more external eyes found the craft UMEB had created. Working with the resources and technical support of Skater Powerboats, the team was able to complete a structural canopy that met the required APBA rules. At the same time, UMEB worked with a Slovenian hypercar manufacturer to source a motor powerful enough to drive the craft.

**Figure 14: *TiDE* in UMEB's Workshop**

The team continued building and making component-level decisions, eventually leading to the creation of three patentable technologies, specifically concerning the extremely advanced battery system developed to address mass requirements. In less than a year, better leadership and design methodologies had turned around the trajectory of the team, pivoting from its greatest failure to its greatest success thus far. Most of these successes can be attributed to the extensive work done early on to characterize *TiDE*'s design space, unlock a broader range of feasible designs through advanced control theory, and use a careful process to lock in a final design. UMEB is a testament to the application of Naval Architecture and Marine Engineering to the racing world.

## CONCLUSIONS

It is an understatement to say that there are a lot of gaps between how marine designers and high-performance racing teams create craft. Viewing racing through an academic lens has the potential to open a lot of doors in the realm of optimization, marine control theory, and uncrewed applications. Translating their methods into a space understood by naval architects,

with concepts like risk management and codesign, we can better analyze extremely high-performance systems and learn from them. Additionally, developing a framework to marine design methods, like set-based design, opens the door for more optimal racing craft to emerge. An understanding of the bridge between these two worlds is important in furthering advanced marine technologies.

## CONTRIBUTION STATEMENT

**EJB:** conceptualization, lead designer for UMEB, methodology; writing – original draft. **AMV:** conceptualization; methodology; writing – review and editing. **KM:** Conceptualization; **DJM:** conceptualization; supervision; writing – review and editing.

## ACKNOWLEDGEMENTS

An immense amount of gratitude should be extended to Dr. Norbert Doerry, Dr. Armin Troesch, Dr. Jonathan Page, and Dr. Thomas McKenney. Without their assistance, many of the concepts of codesign and risk identification used in this document would not have become evident or defined well within the context of marine design. A point of recognition is extended to our friends at Skater Powerboats, Peter Hledin and Robert Bloom, who have acted as guides and mentors in the realm of powerboating. The authors would also like to thank their team members on University of Michigan Electric Boat for allowing us to use their project as a platform for the proof of concept of our novel design methodology.

# Data Models in Ship Design and Construction - Insights from 4D BIM

Janica A. Bronson<sup>1,\*</sup>, Ícaro A. Fonseca<sup>2</sup>, Henrique M. Gaspar<sup>3</sup>, and Fernando H. P. Luz<sup>4</sup>

## ABSTRACT

*The lack of a cohesive understanding of a ship product data model, from design to operations, is currently a limiting factor in realizing more efficient ship lifecycle management and design processes. The paper sheds light on the history and gaps in realizing an integrated, interoperable, and multi-domain ship product data model. It also explores practices from BIM (Building Information Modelling) as an inspiration for solutions to overcome challenges related to information modeling, integrated design environment, and 4D engineering and planning.*

## KEY WORDS

Ship product data model, Building Information Management (BIM), Lifecycle Management

## THE IMPORTANCE OF COHESIVE PRODUCT DATA MODEL

Accurately representing a product's data across its lifecycle is a challenge most industries face today. For engineer-to-order (ETO) sectors that handle the design and production (or construction) of multi-functional assets, such as manufacturing, construction, and shipbuilding, competitiveness depends on how well the product data is maintained physically and digitally (Wyman et al., 1997). Proper management enables process and operational efficiency and decreases the likelihood of technical errors that become more expensive to reconcile as the product matures (Rigterink, 2014).

Today, various international standards provide an understanding of how the data of multi-functional assets can be represented appropriately and communicated across highly dispersed teams via a product data model (ISO, 2022; DNV AS, 2023; ISO, 2004b, 2024). A product data model is a way to organize or structure relevant product data. Other terms equivalent to this concept are Common Reference Information Models (RIM) (ISO, 2022) or Asset Information Models (AIM), which are a 'collated set of information gathered from multiple sources' encompassing the structure and relationships of the data in these sources and or databases (DNV AS, 2023). Where there is no cohesive product data model, companies risk lacking the capacity for (1) efficient product lifecycle management (PLM) and (2) challenges in the integration and interoperability of asset data (Wyman et al., 1997).

The shipbuilding industry currently does not have a standard solution to tackle these gaps, as a complete view of a ship's data (from design to operations) has yet to be realized. A ship is a complex system, and both the built physical asset and digital representations of a ship are often developed in a highly modular and concurrent fashion (Koenig et al., 1997; Pal, 2015). Only upon delivery for construction is an integrated view of a ship's design realized; however, this integrated view

is often only partially complete. In managing and operating the ship, multiple stakeholders may have incomplete interpretations of the ship as a whole due to its scale and numerous onboard systems.

Other ETO industries have also developed their own solutions to tackle these challenges. For example, in the aerospace and manufacturing industries, the use of ‘digital mock-ups’ (DMUs) (Oh et al., 2008) and generic AIMS (ISO, 2004b) as the equivalent of product data models is well-established.

Despite facing similar challenges related to high regulatory intervention, multi-organization, and customization (Emblemsvåg, 2014), the architecture, engineering, and construction (AEC) industry has seen significant digitalization in design and construction practices thanks to the introduction of the Building Information Model (BIM). BIM has helped solve these interoperability issues and continues to help advance the AEC industry’s digitalization efforts (Azhar et al., 2008).

In light of the benefits of BIM, this paper aims to explore what the shipbuilding industry can learn from the AEC industry, focused on understanding potential improvements related to (1) data modeling and (2) collaborative design practices, including a temporal understanding of the system. In addition, this paper explores previous and current ship product data modeling attempts and proposes possible solutions that the shipbuilding industry can consider.

## **CURRENT PRACTICES IN SHIP DESIGN AND PLANNING**

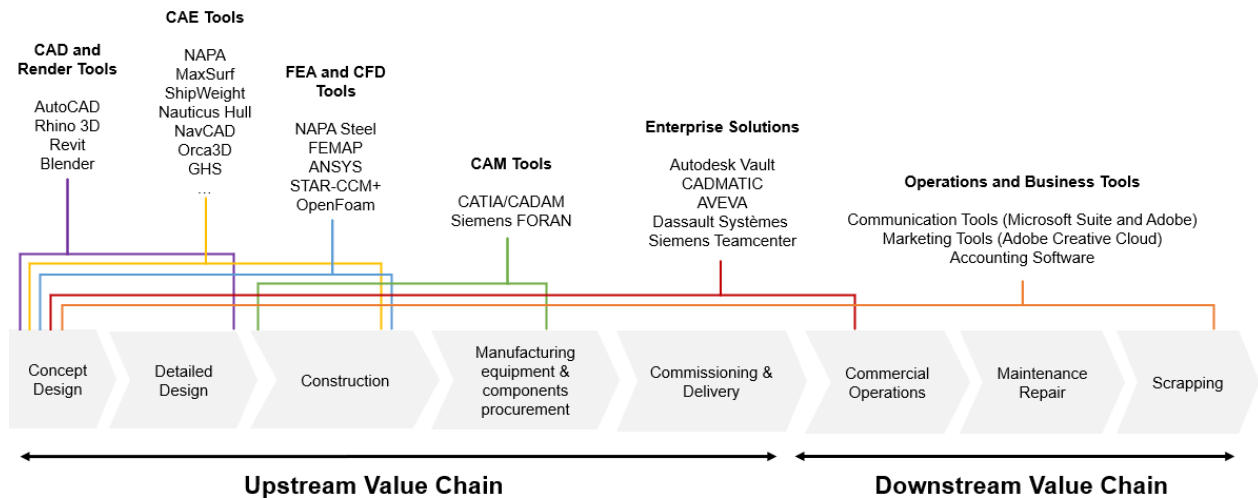

Today’s ship lifecycle involves disparate processes, tools, and needs for each phase. These phases, covering upstream design to downstream operations and maintenance, differ in the generation, usage, and transformation of information related to a ship’s product data model (Andritsos and Perez-Prat, 2000; Whitfield et al., 2003). Currently, product data models in shipbuilding are not similarly developed as an AIM according to ISO unless integrated platforms such as CADMATIC Wave and Siemens Teamcenter are used. When these tools are not used, a ship’s design data is dispersed, involving a combination of a 3D model, drawings, and digital documents. Issues related to version control and change management are common, especially when multiple instances of these files are copied, modified, and not incorporated with other drawings. These practices perpetuate ‘information silos’ and decision-making with incomplete information (Stachowski and Kjielen, 2017). These gaps are most apparent in early design stages, where design uncertainty is high, but the most expensive decisions are made (Love and Sing, 2013; Mavris and Delaurentis, 2000).

While the lack of product information is the critical risk faced in early design, manual data integration is the concern in detail engineering. In detailed engineering, technical information is rapidly received from multiple cross-disciplinary sources, often in various file types and formats, as the focus shifts to technical evaluation and increasing design granularity. Where file formats are incompatible, manual exchange or conversion is expected. Dedicated integration engineers are often hired to ensure that all relevant drawings, documents, and models are consistent and incorporated into a technical package for delivery to a client or yard (NAVSEA, 2012; Gale, 2003).

Meanwhile, during construction, a shipyard’s shopfloor planners are mainly concerned with developing transitional work packages that suit available resources, people, and time. Hence, the concern is not related to integration but to the translation and reorientation of design data into process data. Developing a bill of materials (BOM) and bill of processes (BOP), along with work packages, further leads to a ballooning of information that now incorporates planning and operations details (Pal, 2015). Post-commissioning, ship information must still be maintained in the downstream value chain to track the health of ship systems. All of this information remains in disparate onboard equipment and physical or digital copies managed by ship operators. Unfortunately, this type of data typically never goes back to ship designers to improve product information.

The differences in data management needs across a ship’s lifecycle have led to the development of highly distinct and specialized software tools addressing particular ship design and planning functions, as shown in Figure 1 (Andritsos and Perez-Prat, 2000). However, this has also led to a paradoxical problem where, while there is now a greater range of ship design tools, the methods for exchanging data between these tools are outdated. It is not uncommon for these tools to have their own model and representation of a ship that remains isolated and spread organizationally or globally, with different levels

of detail (LOD) (Erikstad and Fathi, 1999; Whitfield et al., 2003). The separation of ship data domains, continually being persisted by these disparate software, has led to a business culture where technical data development can be detached from the management and operations of such development process.

**Figure 1: Disparate Tools with Overlapping Use Across the Shipbuilding Lifecycle**

Integrating disparate ship data to produce a unified ship model is a highly complicated task. Before delving into the history of shipbuilding attempts, it is essential to note the following concepts on data exchange and management that shed light on the complexity of maintaining a product data model.

- **Data Modeling** – Data modeling focuses on how information is structured and how data relationships are represented (ISO, 2023, 2003). Typically, these relationships can be defined with human-readable diagrams, including IDEF, NIAM, etc. (Wyman et al., 1997), but they can also be represented in schemas such as relational database schemas and graphical database schemas (Härder, 2005) that are codified in implementation languages such as Basic, FORTRAN, C, C++, Java and EXPRESS. Several standards exist to help define what these schemas are, including the Knowledge Interchange Format (KIF), Web Ontology Language (OWL), and Resource Description Framework (RDF), which provide reasoning over how information can be represented in that domain (Rachuri et al., 2008). Concerns related to data modeling are typically focused on ensuring that product data models capture most of the information. Therefore, integrating information and managing increasing granularity or data fidelity are important considerations. This can cover product or even full enterprise integration, incorporating company and other resource planning data (Whitfield et al., 2003).
- **Data Exchange** – Data exchange is focused on the transfer of data across different applications and programs. To enable this, machine-interpretable syntax (defined in data formats) must be used to encode and share data digitally (Edelman et al., 2018) or direct translators are used when data formats are incompatible across software (Whitfield et al., 2003). The use of neutral file formats that can be interpreted by different software, as opposed to native file formats that are designed to be usable for only specific software, is therefore advisable. These neutral data formats for storage use extensions that vary based on the data contents, whether graphical (.IGES and .STL) or otherwise (.XML and .STP). When discussing data exchange, the concerns typically revolve around enabling interoperability. Hence, well-defined and formalized data models that can be used across industries ultimately help with interoperability. Hence, Open standards are typically related to data exchange, as are concepts pertaining to centralized or distributed data architectures. While there are plenty of neutral file formats, including XML and JSON, the ISO-certified format for interoperability is STEP, which uses the EXPRESS programming language (ISO, 2004a).
- **Data Management** – Data management relates to operations, systems, or tools that enable consistent and reliable data quality, security, and trustworthiness. Facilitating the use of data models and enabling data exchange is, therefore, just one of the few functions that efficient data management systems can help with (Samonas and Coss, 2014).

ISO 15926-1 defines data models relative to 3-layer database management (DBMS) architecture, emphasizing that data models should not be interpreted in isolation (ISO, 2003). The above elements can, therefore, be understood in terms of where they stack in this 3-layer architecture. Data models typically reside in the conceptual schema, data exchange is related to the dictionary and or interpreters for the conceptual schema, and data management is the infrastructure related to the database and applications or front-facing user interfaces.

## DESIGN AND PLANNING REPRESENTATIONS USED IN SHIPBUILDING

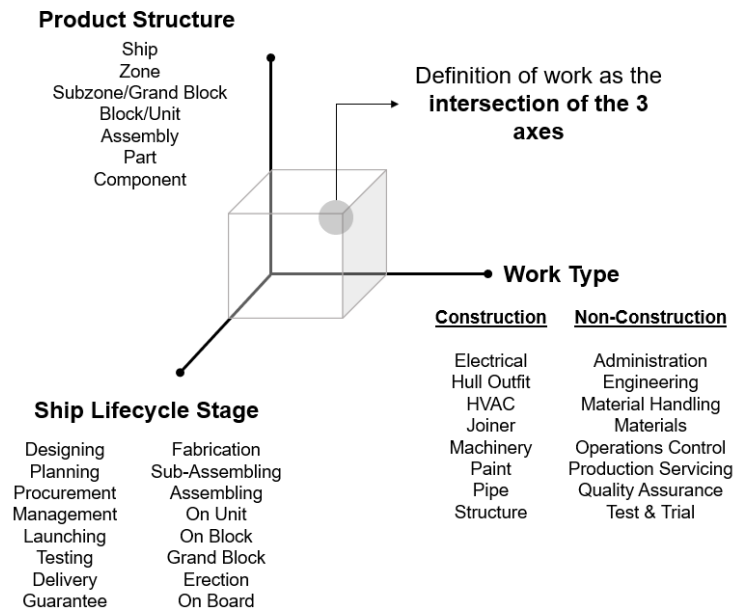

### Classification and Coding Systems

While there are now more widely accepted definitions of a product data model, it is essential to recognize the unique history of data modeling and shipbuilding. The challenge to arrive at a coherent product data model is not new; attempts have been made since the 1970s, starting with dimensional coding systems.

Ship classification and coding systems are still some of the most popular means of presenting ship data today. These systems were developed partly due to the popularity of modularity as a means to increase industrial competitiveness in the 1970s. These were heavily popularized by companies such as Boeing, who developed proprietary codes such as BUCCS-3 (Boeing Uniform Classification and Coding System) to streamline manufacturing processes. These classification and coding systems, also interchangeably called product structures, are hierarchical representations of an asset. These hierarchical product structures and modularity modernized shipbuilding, changing how shipyards were designed such that equipment and materials were laid out to enable the efficient execution of similar work types (NSRP, 1986). Coding systems are still widely used today (Oh et al., 2008) due to the relative simplicity and reliability of being used since the onset of modern shipbuilding practices.

***Ship and Product Work Breakdown Structures.*** The Ship Work Breakdown Structure (SWBS) is one of the most widely used coding systems in North America. The SBWS, first developed by the United States (US) Navy in 1977, uses a 3-digit function-based code with main group divisions including hull structure, propulsion and electrical plants, outfitting and furnishings, integration engineering, and ship assembly and support. SWBS codes can be used to organize drawing schedules, material catalogs, work planning, work orders, craft labor, and cost collection. Unfortunately, while SWBS provided a means of organizing work, it could not capture the most effective information for accomplishing work, especially when complicated work packages are involved. Addressing these limitations led to the development of the Product Work Breakdown Structure (PWBS), which included work type, manufacturing level, zone type, problem area, and stage (Koenig et al., 1997; NSRP, 1986). The development of the PWBS classification system introduced additional domains as dimensions to SWBS representation based on cost, function, and tasks – leading to a three-dimensional understanding of a ship product as shown in Figure 2. However, the implementation of this dimensional coding system was time-consuming. Without automation capabilities, the PWBS codes were generated and retrieved manually via a massive PWBS Classification and Coding book that served as a dictionary for translating these three domains. Various attempts were made to digitize this process and manage coding systems using computers. One such example is the Decision and Classification Information System (DCLASS) from Brigham Young University. This generic tree processor proved to cut 95 percent of the time for data retrieval in cost estimation exercises.

***Skipsteknisk Forskningsinstitut (SFI) Coding System.*** In Europe, the widely-used alternative to the SWBS is the SFI Code, named after the Norwegian Skipsteknisk Forskningsinstitut (SFI) that developed it. The SFI Code or System has a comprehensive product structure covering various aspects of ship and offshore specifications. SFI Code uses a 3-digit decimal code system to classify all ship and rig operation functions into ten main groups from 0 to 9 that cover the hull, equipment for cargo, and ship equipment, among others (Xantic, 2001). Officially launched in 1972 in Norway, the SFI Group was developed by a joint consortium of industry partners to establish a unilateral coding system that could be used unanimously among different shipyards and design stakeholders. The SFI Code was intentionally designed to be simple, applicable to all ships, and capable of future expansion. It was also intended to be a functional-oriented system for adaptability in design and production (Manchinu and McConnell, 1977).

## Ship Product Data Models

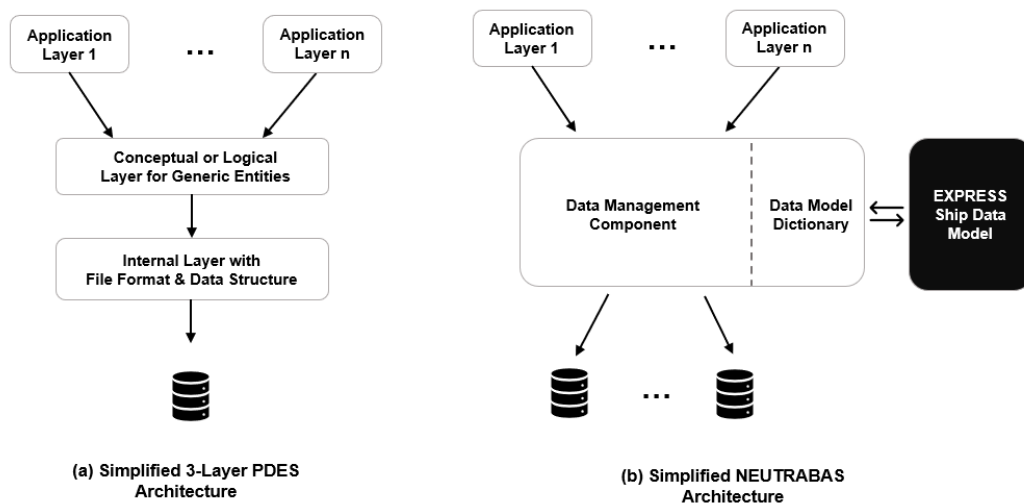

Product structures, especially with expanded domains and dimensions related to planning, faced hurdles in implementation due to the need and lack of tools to automate their usage. With the onset of computer-aided design (CAD), computer-aided engineering (CAE), and computer-aided manufacturing (CAM) in the 1980s, ship designers and yards quickly picked up on the potential of these tools in improving technical design processes, which led to the natural integration of coding systems with modeling and 3D graphics. CAD/CAE/CAM enabled the transformation from coding systems to 3D graphical product-oriented information databases (Murphy, 1992). As such, what was involved in a digital product representation of a ship was relatively malleable from the 1970s to 1990s while both shipbuilding and software engineering were evolving rapidly (Ross, 1997; Gischner et al., 1997).

One of the earliest definitions of a ship product data model comes from Martin (1980), who described it as a ‘logically structured, product-oriented database’ that supports the analysis and informational needs for a ship’s engineering, design, construction, and maintenance (Whitfield et al., 2003; Ross, 1997, 2003). The use of the term ‘common model’ was ubiquitous, as multiple ship representations with varying embellishments across different departments were typical. Hence, a ship product data model was understood to support a certain degree of information integration, which can include enterprise data. Computer-integrated manufacturing (CIM) is an example of an enterprise integration concept, enabling testing, production, and control, all within a shared database.

These growing integration needs also led to interoperability issues that called for a serious assessment of digital information exchange standards (Gischner, 2006). International Standards Organization’s (ISO) STEP (STandard for the Exchange of Product Model Data), more formally known as ISO 10303, was launched in 1986 to solve cross-platform and cross-application development issues by producing a system-independent data representation (including geometry, topology, and functionality) of design artifacts (NSRP ASE, 2007). Its development was inspired by the Product Data Exchange Program (PDES), which tried to arrive at a consensus of a data exchange standard for industrial automation (Kelly, 1985). STEP largely followed traditional Database Management System (DBMS) Architecture at this time, which included a 3-schema architecture (as shown in Figure 3a) covering External Schema with user-facing applications, a Conceptual or Logical Schema for the translation of data via mapping or other logical representations of the system of interest, and the Physical Schema which involves the physical representation of the data as stored in a database (McDermid, 2013; Kelly, 1985). In

this architecture, STEP was most concerned with the standardization of the components in the Conceptual Schema, which over time took the moniker of a data model as understood in software engineering today and as defined in ISO 15926 (ISO, 2003). The Conceptual Schema or Conceptual Model represents the view of the data negotiated between end-users and the databases, covering the meaning and the relationships of the data with each other. To facilitate this, the EXPRESS data modeling language was developed explicitly for STEP (Whitfield et al., 2003). This program prompted multiple initiatives for various industries to formalize their standards with ISO STEP in mind. In ship design and shipbuilding, the notable ones include NIDDESC and ISE from the US and NEUTRABAS from Europe.

**Figure 3: Simplified DBMS Architecture for PDES and NEUTRABAS. Adopted from Kelly (1985) and Nowacki (1995)**

**NIDDESC, 1986.** The Navy/Industry Digital Data Exchange Standards Committee (NIDDESC) was developed in 1986 as a joint effort of the US Navy (NAVSEA) and the National Shipbuilding Research Program (NSRP), which focused on creating an industry consensus on the definition of product data and ensuring that these requirements were incorporated into national and international data exchange standards. The program's result was identifying product data model content for the marine industry and developing documentation for a neutral file format that incorporates IGES' specifications with the emerging STEP standards of that time. The developed documents were known as Application Protocols (APs) that defined the requirements for a ship's product information or Conceptual Schema for a specific domain. They converged to six APs submitted for inclusion into the STEP standards covering Piping, HVAC, Electrical Distribution and Wireways, Structural Systems, Outfit and Furnishing, and Standard Parts. These APs have been further refined into AP 215 for Ship Arrangements, AP 216 for Ship Moulded Forms, and AP 218 for Ship Structures, which are still usable today (Gischner et al., 1997; Murphy, 1992; Whitfield et al., 2003).

**NEUTRABAS, 1989.** NEUTRABAS is an EU ESPRIT-funded project to develop a neutral product understanding for ships and similar large multi-functional products. The NEUTRABAS project worked collaboratively with the NIDDESC program, which preceded it two years earlier. The project aimed to meet the following: (1) a formal definition of a ship product information model, (2) specifications for a neutral database technology, (3) implementation of a neutral database, and (4) the development of a prototype for pre and post-processors for neutral data exchange. (Welsch et al., 1991; Nowacki, 1995). The ship product data model they developed was written in EXPRESS and required a bespoke data management component (DMC) to facilitate communication between one system-specific format and any other system, as seen in Figure 3b. The NEUTRABAS effort was, therefore, one of the first to describe how a neutral model can be implemented outside purely providing recommendations on the Conceptual Schema. Regarding the model itself, NEUTRABAS and NIDDESC were similar and focused on the development of reference models but differed in the degree of integration between their reference models. While NIDDESC developed multiple models for different functional domains with discrete APs for piping, structures, etc., NEUTRABAS adopted the position that integrating all current and future shipbuilding APs required the standardization of a single comprehensive and high-level Ship Application Reference model. They deemed this a prerequi-

site to the interoperability of all APs (Nowacki, 1995; Welsch et al., 1991). This position helped to make a significant point about the importance of assessing the data structure to effectively manage the exchange of information across various complex and heterogeneous ship development applications.

**ISE, 1999.** The Integrated Shipbuilding Environment Consortium (ISEC) was established in 1999 with a group of shipyards and CAD vendors. It aimed to develop information interoperability solutions for US Naval shipbuilding in a series of NSRP initiatives called the Integrated Shipbuilding Environment (ISE) projects (Gischner, 2006). Specifically, the goal was to develop the next-generation Integrated Product Development Environment (IPDE). This open architecture information system supports the delivery of integrated acquisition, engineering, and logistics products for the naval ship lifecycle (Oh et al., 2008). It is understood to be the family of systems that maintains the digital product data model. With the growing popularity of enterprise software such as Product Data Management (PDM) and Product Lifecycle Management (PLM), these tools were naturally considered as implements to enable the IPDE capability.

## **Latest Initiatives (Early 2000s-Current)**

The realization of a product data model with capabilities related to integration, interoperability, and data exchange remains a challenging task that is continually being addressed today. Central to this problem is the need for more clarity in defining how ship data should be presented and what domains of ship data should be incorporated (Gischner, 2006). These shifts are presented in Figure 4. Data modeling practices and paradigms have also grown and developed much faster than they could be formally implemented in this context. The evolution of data modeling paradigms is also presented in Figure 4 adopted from Patni et al. (2021).

STEP's EXPRESS language follows a hierarchical and entity-relationship-based paradigm, which requires rigid, well-defined relationships. For this reason, adapting and expanding the ship product data model with definitions based on AP 215 (for Ship Arrangement), 216 (for Ship Moulded Forms), and 218 (for Ship Structures) was a cumbersome process (Whitfield et al., 2003; Gischner, 2006; Kramer et al., 1992; Rando, 2001). Gischner (2006) states that it takes, on average, about 3 to 5 years to implement STEP. These STEP APs, in addition to needing plenty of information and time to implement, also required a constant effort to finalize and update to 'avoid stagnation and improve general uptake across the industry' (Whitfield et al., 2003). Ross and Garcia (1998) describe that multiple special-purpose tools are needed for STEP, one of the main inhibitors for broad acceptance into the industry. These challenges were recognized by ISO themselves, as reflected by the multiple changes done on the APs - from isolated guidelines to plug-and-play modules - to make them easier to adopt.

XML or eXtensible Markup Language was determined to be a credible alternative to the STEP EXPRESS language due to its broader support in the IT industry and more noticeable structure and hierarchy. However, while XML has more advanced data-sharing operations, such as enabling persistent storage of ship data from application to application, it is constrained by the amount of storage space it requires (Rando, 2001). This is a limitation with the massive amount of digital data involved in most ship design and shipbuilding programs today. A modern commercial vessel may be expected to have an associated product data model of 2 to 10 gigabytes in size, depending on its complexity (Whitfield et al., 2003).

Outside XML, extensive industry-led work has been done to define a standard exchange format, with the inception of the OCX (Open Class 3D Exchange) Consortium in 2021. OCX as a format was developed in 2016 by the APPROVED Industry project involving partners such as Aveva, Hexagon, Siemens, and NAPA aimed towards defining a format that can address the unique data exchange needs amongst classification societies and shipbuilders. Although some additional work is still required to support the use of OCX, the consortium is actively promoting its use with the aim of industry-wide adoption (Zerbst, 2023).

Along with these developments, interest has also risen in the concept of digital twins applied in maritime systems over the past decade. Digital twins are virtual prototypes of physical assets that have garnered attention for their ability to enable remote operations and co-simulation (Grieves, 2022; DNV AS, 2023). As of 2023, DNV published DNV-RP-A204, which provides best practices for implementing, assessing, and maintaining the functional elements (FE) toward realizing a digi-

tal twin. At the heart of the digital twin is a consolidated AIM, which incorporates multiple data domains per ISO 81346’s class libraries. Along with the definition of the desired AIM, they also stipulate advanced change management processes (MOC+) to ensure the trustworthiness of the ship AIM throughout its usage. While they do not present specifics on the software side, this latest development recognizes the regulatory and class societies’ perspectives on best practices to arrive at a cohesive model. Additional understanding and research on the challenges of digital twin implementation from a data modeling perspective, specifically in data fragmentation stemming from the transition from upstream to downstream lifecycle, are also studied deeper in Bronson et al. (2024).

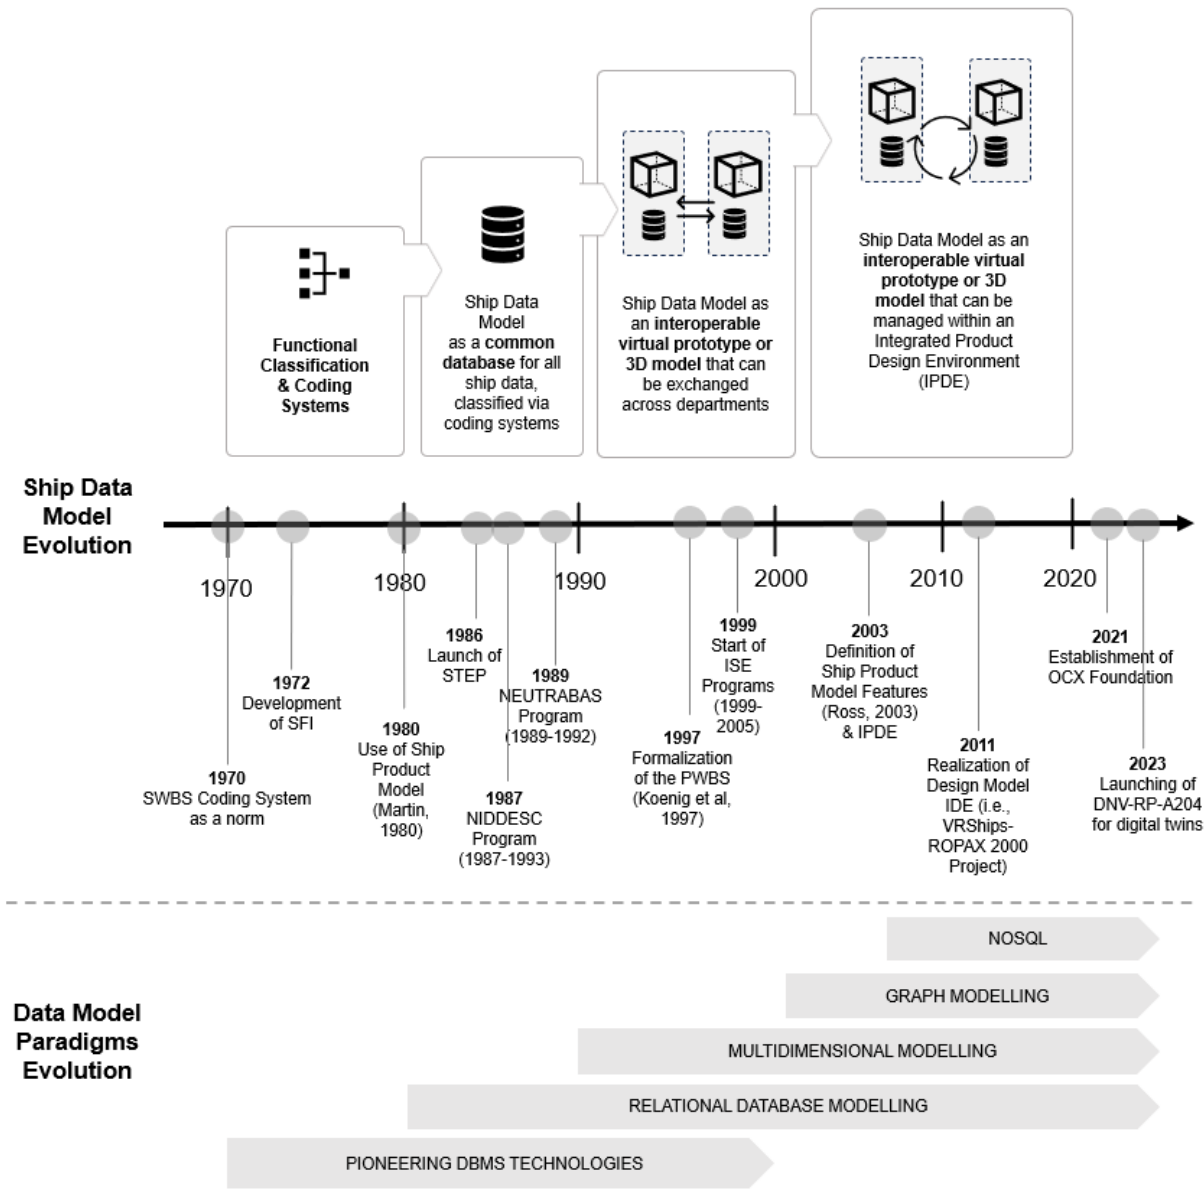

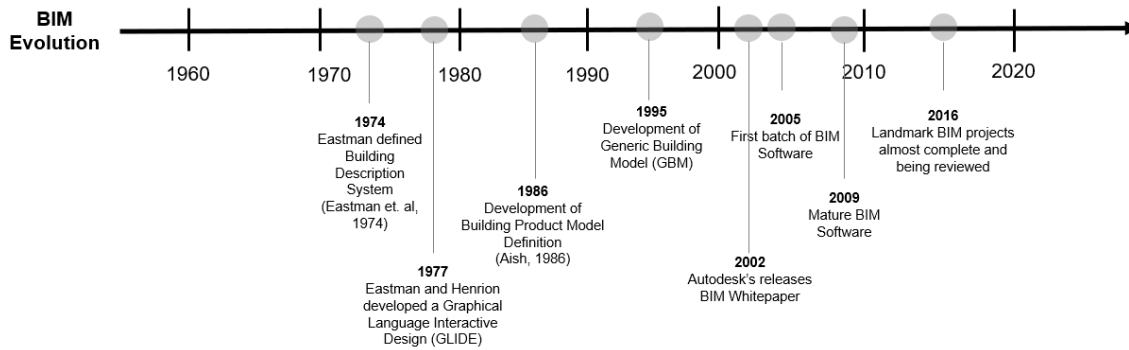

Figure 4: Evolution of Ship Data Concept

## BUILDING INFORMATION MODELING (BIM)

Today, there is no tangible equivalent for the definition of a ship AIM except for that described by DNV for digital twins. In the AEC industry, the equivalent full building product data model is that of BIM. Like shipbuilding, the AEC industry had a notoriously long history of tackling data integration and interoperability issues, as shown in Figure 5.

**Figure 5:** History of BIM, Adopted from Sinoh et al. (2020)

In a study by the US National Institute of Standards and Technology (NIST) in 2004, up to about USD 15.8 billion was lost annually due to ‘the highly fragmented nature of the industry, the industry’s continued paper-based business practices, a lack of standardization, and inconsistent technology adoption among stakeholders’ (Gallaher et al., 2004). Although the knowledge of a cohesive building description system has been well-understood since the 1970s (Eastman et al., 1974), its formal implementation is a recent phenomenon. The original definition of BIM included three main elements: the structuring of design data, a digital model, and other non-graphical data, which were realized by bespoke tools such as RUCAPS in the 1970s (Aish, 1986). The implementation and broad commercialization of BIM as it is understood today were pioneered by commercial software companies such as GraphiSOFT, Bentley Systems, Autodesk, and Nemetschek AG (Autodesk, 2002; Wierzbicki et al., 2011). Autodesk’s 2002 Whitepaper on BIM was one of the first to formalize a software strategy to implement digital databases, change management functions, and abilities to reuse information. In addition to formalizing a strategy, Autodesk also led the formation of IAI (Industry Alliance for Interoperability), now buildingSMART to understand the industry’s take on data classes that can support integrated application development. This led to the development of IFC, in partial response to the slow adoption of STEP, as a neutral AEC product data model catered to the industry. Laakso and Kiviniemi (2012) describes this as one of the most ambitious standardization efforts in IT at that time. In addition to this formalization, the wide dissemination of BIM’s practical uses has also influenced its success. As Azhar et al. (2008) cited, several case studies continue to encourage the use of BIM. Along with the iterative implementation and continued improvement of BIM came the modern understanding of it today as both a process and a tool.

According to the ISE (2021), BIM is a collaborative process enabled by technology, covering the whole lifecycle, from design and construction to asset operations. As a process, BIM allows the cohesive understanding of building data and fosters inter and intra-disciplinary collaboration. As a tool, BIM facilitates building data management across different lifecycle stages. Azhar et al. (2008) suggests the following benefits of BIM: (1) visualization, (2) fabrication and shop drawing support, (3) code reviews, (4) cost estimating, (5) construction sequencing, (6) conflict and collision detection, (7) forensic analysis, (8) facilities management, (9) quality take-off, (10) model-based estimating, (11) feasibility analysis, (12) alternative development, and (13) environmental analysis.

As there are different use cases for the application of BIM throughout a building’s lifecycle, the qualitative and quantitative impacts of BIM overall are challenging to assess. However, in his study, Azhar et al. (2008) was able to share various scenarios where BIM has helped reduce costs in building projects. For example, the Atlanta Aquarium Hilton Garden Inn used BIM to plan the clash and collision detection. It identified about 55 clashes, resulting in a cost avoidance of over 124,500 USD. Similarly, BIM was used by the Emory Psychology Building for sustainability analysis, particularly in determining

the most suitable building orientation, skin option, and position. In all these cases, BIM provided relative cost savings due to the ability to view and rapidly simulate different design possibilities.

**Figure 6: Synchro4D Project Simulations (SYNCHRO, 2017)**

The overall trajectory of BIM development is focused on complete lifecycle management, as suggested by BIM dimensionality or ND modeling. This philosophy assigns informational dimensions of data to the building information model based on purpose. The current dimensions are accepted as 3D (for two spatial dimensions), 4D (for the inclusion of time), 5D (the inclusion of costs), and 6D (the inclusion of facilities management) (ISE, 2021). Although there is ambiguity surrounding BIM beyond the 4D version, it has piqued interest due to its potential to integrate scheduling data. The capabilities of 4D BIM, which enable simulated planning, is one of the most attractive features marketed by most BIM software today. For instance, Synchro4D, shown in Figure 6, displays the potential of viewing the physical model with task codes and time simulations from design to production (SYNCHRO, 2017). The advantages of 4D BIM have been realized in some projects to date, including the planning of Peachtree Mansion in Atlanta, Georgia. Determining how all resources should be coordinated and how the construction sequence can be optimized was highly beneficial (Azhar et al., 2008). This simulated design and planning is a functionality that other industries are not yet able to realize today, including the ship design and shipbuilding industry.

The following section goes through the critical features of BIM in terms of the product data model it uses and the collaborative processes surrounding the maintenance of such a model.

## Features of BIM

**Collaboration Mandated by BIM.** BIM relies heavily on collaboration, which is well-established with BIM's definition of Levels of Maturity (LOM). BIM's LOM is defined as 'measures of how well each party's information is structured for use in the federation by a collaborator without requiring significant remodeling for their purpose' (ISE, 2021). There are currently three levels of BIM based on LOMs: Level 0 is unstructured, Level 1 is partially structured unfederated data, Level 2 is a structured federated information model, and Level 3 is a server-based object information model hosted on a queryable database. To meet Level 2 standards, which is the stage mandated in the UK for public projects (Cotter, 2023), data needs to be available for contractual client demands and stored in information-rich and federated 3D models. Other non-graphical formats should also be agreed upon, along with an execution plan to use and exchange data with such formats. Acceptable file formats include COBie or Construction Operations Building Information Exchange (for exchanging meta-data) and other native data formats as long as they are specified in the BIM Execution Plans (BEPs) (ISE, 2021).

**Structured and Federated Information Models.** To cater to the specific needs of the construction industry, the IFC-neutral data schema was developed by IAI (currently buildingSMART) as a framework for the exchange of building information. IFC consists of multiple entities organized into an object-based inheritance hierarchy. The implementation of IFC into BIM solutions comes in the form of defining attributes for building components already present for the user in a BIM software. The benefit of using IFC is that the substantial number of these descriptive entities can enable a comprehensive view of building information. The IFC contains four conceptual layers in its building model: domain, interoperability, core, and resource. These layers follow a strict referencing hierarchy or ladder to ensure that the information is complete and easily maintainable (buildingSMART, b; ISE, 2021). Compared to STEP's AP 225, which is STEP's product model definition for building construction, IFC is also considered to have more representation possibilities (Chen, 2012; Burkett and Yang, 1995).

The latest version of IFC is the IFC4, which includes a definition of construction scheduling task via the *ifcTask* (buildingSMART, a). This entity enables the linking of building elements to the task of a construction schedule for simulation, as shown in Figure 7. Other entities in IFC4 include *ifcresourcetime*, which captures the time-related information about a construction resource, further linking time data with planning information. These definitions are the backbone of 4D BIM functionalities, as shown in Figure 6.

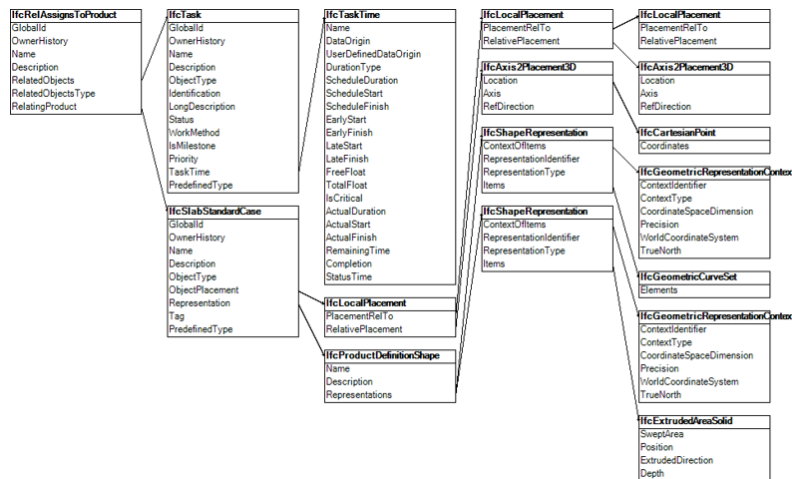

Figure 7: Definition of a IFC4 - *ifctask* Entity (buildingSMART, a)

**Defined Process for Implementation and Maintenance.** It is crucial for companies implementing BIM to have a well-defined pipeline that encourages collaboration and ensures compliance with BIM mandates. Without the use of BIM workflow, the benefits of BIM would not be realized. Several documents are necessary for implementation – including the Exchange Information Requirements (EIR) and BEPs. Hence, in trying to execute BIM, companies must ensure that (1) a clear articulation of what information is required from each participant is contained in the EIR document and (2) a defini-

tion of how each participant will provide such information is written in the BEPs. Defining goals, project milestones, and procedures for data exchange is therefore crucial in the BIM process (ISE, 2021).

To help facilitate these processes, a shared data environment called Common Data Environment (CDE), as shown in Figure 8, is used. In BIM, a CDE is a centralized system that compiles, manages, and distributes all project documentation. CDE also defines the states for developing and sharing a version of the design before it is handed over to the client. Without proper enforcement of these procedures, the risk still exists of creating isolated islands of information and outdated versions of the building model in the process (ISE, 2021; Borrmann et al., 2018).

Due to the availability of platforms that enable a seamless adoption of BIM today, BIM has become a standard practice in countries like Finland, Singapore, South Korea, and the US. BIM is mandatory for government projects in some countries, such as the UK (Cotter, 2023). Client demands and regulations have led to a vast proliferation and development of tools that deliver BIM capabilities, which today include Autodesk Revit, Autodesk Navisworks, GraphiSOFT ArchiCAD, Bentley Arch, and TEKLA, among others (Rice, 2010).

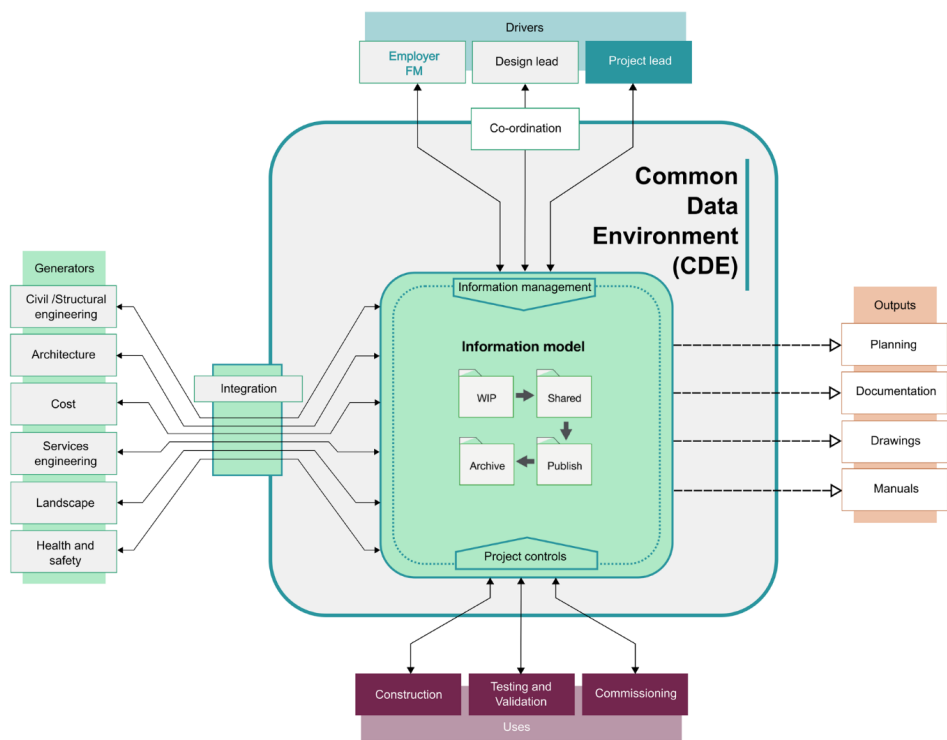

Figure 8: BIM Common Design Environment (ISE, 2021)

## DISCUSSION AND COMPARISON

This paper has so far highlighted the ongoing efforts of both shipbuilding and AEC industries to improve asset information management. While the AEC industry has made significant progress with the use of BIM, the shipbuilding industry still needs to catch up in developing and adopting a standardized ship product data model. While both industries are unique, there is potential for cross-industry learning, especially from the shipbuilding side.

In both AEC and shipbuilding, the definition of the product data model is more or less analogous to each other. The differences mainly lie in the development and maintenance of such product data models. While current efforts, as with DNV-RP-A204’s adoption guidelines (DNV AS, 2023), provide policies and aspirational procedures for addressing these gaps, the

actual implementation has not been fully realized. We converge to four gaps in the adoption of a cohesive ship product data model, including an assessment of where BIM's solutions stack in addressing these gaps:

1. Undefined ship product data model representation that is unable to incorporate multi-domain ship data incorporating time, process, and functional information
2. The lack of industry-wide data exchange standards impeding interoperability
3. The lack of an IPDE that impedes collaboration
4. The lack of data management protocols to support the IPDE, modeling standards, and exchange standards

***Inflexible Ship Model Representation and undefined exchange standards.*** Current data modeling standards are outdated to suit the shipbuilding industry's needs. The rigid representations defined in ISO standards, unfortunately, impose the following challenges: (1) they are not easy to customize for the wide range of shipyards today, and (2) they are not flexible for the diversity of projects (proposals vs. detailed) in a single company that has varying LODs. The latter also applies to the variety of customers ship designers may need to cater to, whether commercial or government clients. Customizing a product data model, as it is structured today based on ISO standards, to suit these diverse needs is infeasible, and the reuse of a ship product data model as a template is not practical unless ship systems are entirely transferable (Oh et al., 2008). The amount of disclosure that is possible based on client preferences or security protocols also impedes the transfer or reuse of design templates. Pollini and Meland, in a 1997 paper where they developed a bespoke Smart Product Model (SPM) for a shipyard, expressed that creating a product modeling system bespoke to a yard took an enormous amount of effort, where 'over 30,000 methods and object-oriented databases on the order of 2.5 gigabytes of data' were generated (Whitfield et al., 2003).

Well-defined product data models that are widely accepted help enable interoperability. Consistency in expressing data increases the successful exchange of information. Currently, the standardization required for information exchange remains vague, and ISO ship APIs are limited to their respective domains, so there is limited focus on a comprehensive and holistic view of ship design information.

BIM manages the balance between collaboration and information security by utilizing tools and standards to create detailed and robust building information. In addition, it requires parties to define the extent of collaboration and agree upon neutral or native formats to use in the project through the use of BEPs and EIRs. BIM does not enforce a single solution but is flexible enough in implementation to suit the needs of the parties involved, whether these parties themselves have strict data security protocols or otherwise. This flexibility is reflected in the degrees of LOMs that clients can choose from. A similar framework can be applied to the shipping industry, whereby the level of federation in the data model and the degree of interoperability can vary to suit the diversity in the project types and client preferences. This can also cover various diverse LODs within a ship design company so that a lower level of federation can be applied for designs or early concepts with minimal design granularity. For more mature designs involving multiple parties, a high level of federation could be applied.

While this flexibility exists, BIM is still able to provide reliable and robust means to generate a comprehensive view of the building data via the IFC model. To compensate for the challenges of manually defining the model, IFC is intended to be used complementary with BIM software where .ifc files can be generated easily. This software can be used at various stages of maturity of a design, such that it is compatible with designs with low and high data fidelity.

***Lack of Data Management Protocols and Integrated Development Environment (IPDE).*** Provided formats exist to enable data exchange, an environment that allows and facilitates this exchange can only be fostered with collaboration. Enabling this environment is not yet well understood in commercial and large-scale contexts in shipbuilding, as open standards are not the norm and shipbuilding stakeholders are heavily dispersed. Luming and Singh (2015) cites that the shipbuilding's position in collaboration can best be described with the One-CAD Solution, which is a mentality focused on using the same CAD tools to reduce interoperability and communication issues. This mentality, however, locks shipyards to specific proprietary software.

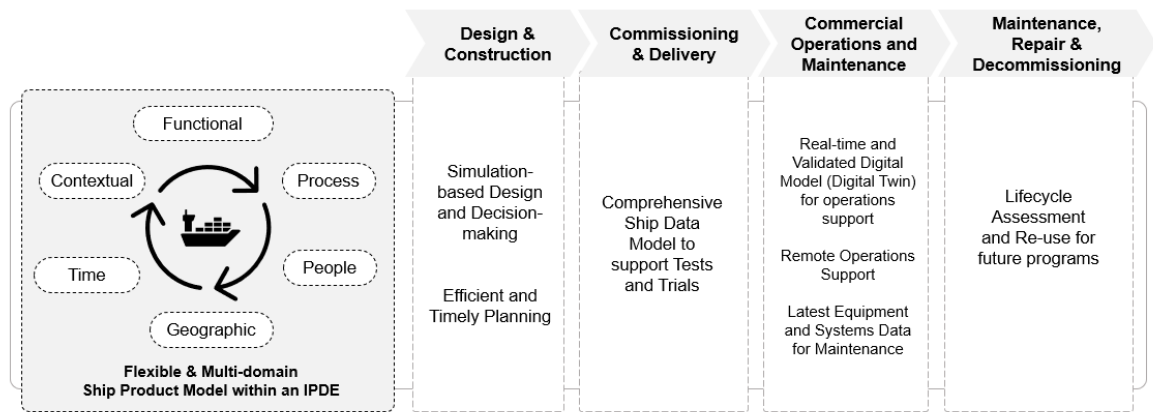

BIM addresses these issues by primarily focusing on collaboration. The success of BIM implementation relies heavily on two factors - the availability of BIM tools and the shared ownership of the BIM process among the technical team and management. These BIM tools are intended to provide a secure and common design environment or CDE, covering the database and data management components. The shared ownership of the BIM process incentivizes the disciplined use of these tools to make the most of their capabilities.

### NOTES FOR DEVELOPERS

Shipbuilding has a long history of attempts to handle dense technical and planning databases. This has presented an ironic dilemma where the industry has a good understanding of the challenges that come with big data but needs to have updated data management solutions. This paper converges to reevaluating what is possible with technology-driven and culture-driven changes related to product data management. Specifically, highlighting the following considerations for future developers:

- 1. Implementation of industry-acceptable data modeling and data exchange standards custom to shipbuilding needs
- 2. Development of an IPDE environment for managing custom ship product data models

A BIM-like solution that incorporates multi-domain product data models specific to the industry and managed within a collaborative IPDE environment can help realize 4D Shipbuilding akin to 4D BIM. Despite the challenges that already exist in the definition of a ship product data model, as listed in the previous section, investing in the potential of a BIM-like solution is still worthwhile, provided the aspirational capabilities this model can provide, as summarized in Figure 9.

**Figure 9: A Multi-domain and Federated Ship product data model to support various lifecycle phases**

Today, no single tool has transformed the ship design and shipbuilding industry like BIM. An ongoing project that aims to fill this gap is the EU HORIZON SEUS Project, addressing inefficiencies in ship design and operations using computational tools (Gaspar et al., 2023). Gleaming into software practices, the project aims to tackle the challenges of defining, using, and managing a ship product data model throughout its entire lifecycle to reduce the time of ship production by 20 to 30 percent.

A current paradigm the project is investigating is graph data modeling. By investigating a more flexible data modeling paradigm, as opposed to the existing rigid entity-relationship models commonly used today, it may be possible to establish connections across multiple data domains with minimal effort. In addition to investigating ways to develop a multi-domain

ship product data model, the project aims to understand interoperability solutions and create a PLM software to encourage collaboration among various stakeholders. Other considerations it aims to note include data quality and security of the model, noting risks that may be posed by lack of data accuracy and cyber security. These developments are done with close industry and academic collaboration, hoping to explore solutions that can realize the same impacts BIM has had in the AEC industry.

## CONCLUSION

This paper reviewed the history of initiatives related to adopting and understanding a cohesive ship product data model. It was found that despite shipbuilding's long history of tackling interoperability issues, actual solutions to address these problems remain limited. The inflexibility of ship product data models, the lack of technology enabling an integrated design environment (IPDE), and the absence of data exchange standards in the industry were consistently determined to be limiting factors in the realization of ship product data models.

BIM, especially the concept of 4D BIM from the AEC industry, poses a refreshing take on solutions to address these issues in their sector. It demonstrates the importance of standards related to product data modeling. BIM's CDE, a digital centralized platform for developing and sharing building design and operations data, can be a template for shipbuilding's IPDE concept. Additionally, IFC, as BIM's modeling schema that currently encapsulates not only geometrical data but also time data, proves the possibility of a multi-domain product data model that can be used to integrate planning and design domains. Future developers can take inspiration from these elements to create a platform, bespoke for shipbuilding, that addresses interoperability in today's software practices. The success of BIM, not only as a tool but also as a process, may also encourage ship design and shipbuilding managers to incorporate technology-enabled collaboration for more efficient ship design and operations.

# Modular Ship Design: Rapid Prototyping and Enhancing Efficiency through Design Modules

Minjoo Choi<sup>1,\*</sup> and Jaekyeong Lee<sup>1</sup>

## ABSTRACT

*In this paper, we introduce a modular approach to ship design, utilizing design modules to streamline the initial design phases. Ships are conceived as combinations of a primary 'ship module' and various 'design modules' tailored for specific spaces. These modules encompass predefined geometries, layouts, and equipment configurations. We introduce an optimization model that integrates decision variables for ship attributes and configuration variables for module selection. Through this framework, we aim to simplify design complexities, accelerate the production of detailed drawings, and foster innovation in ship design methodologies.*

## KEY WORDS

Modularity, Configure-to-order, Ship module, Design module, Modular ship.

## INTRODUCTION

Modularity, as elucidated by Baldwin and Clark (2000), embodies a structured design framework wherein parameters and tasks intricately interconnect within modules, while retaining independence across them. These modules act as discrete units within a system, facilitating integration or separation through standardized interfaces, thereby offering manifold advantages across the lifecycle of modular ships.

In the realm of ship design, modularity emerges as a pivotal approach fostering innovation and efficiency. It enables designers to capitalize on previous designs and streamline representations within modules to effectively navigate the inherent complexities of maritime vessels (Papanikolaou, 2010). This simplification is paramount given the multitude of subsystems and diverse stakeholder requirements inherent in comprehensive ship designs. Moreover, principles underlying design building blocks (Andrews, 2011) and the packing approach (Van Oers, 2011), which employ independent design elements termed 'blocks' and 'objects', respectively, closely align with the concept of modularity.

Furthermore, modularity significantly influences ship production processes. By enabling parallel manufacturing and testing of modules, it reduces production timelines and enhances the efficiency of dry dock operations, a vital resource for shipyards. Additionally, standardized interfaces foster expanded outsourcing opportunities, further streamlining production processes.

In the operational phase, modularity facilitates concepts like 'evolutionary acquisition' and 'mission flexibility,' as delineated by Abbott et al. (2003). Unlike conventional ship acquisition processes, evolutionary acquisition defers investment decisions for modules until more information becomes available, aligning investment decisions with operational needs.

The SIMOSYS project from 2014 to 2018, spearheaded by Erikstad and Choi, proposed optimization models for the design of modular ships, leveraging modularity to navigate uncertainties in the operational phase, dubbing such ships as modular

adaptable ships (MASs). However, in the design of MASs, complexity may arise in valuating flexibility due to their dynamic nature in responding to contextual changes. Addressing this challenge, Choi and Erikstad (2017) and Choi et al. (2017) present optimization models combining module configuration and valuation problems of MASs. Additionally, Choi et al. (2018) propose an optimization model for the design of the platform module of MASs, which serves as the basis accommodating various mission-related modules.

This paper is in alignment with the objectives set forth by the SIMOSYS project, placing a significant emphasis on enhancing module configuration and valuation methods while taking into account the layout, geometry, and scalability of modules. Scalability plays a pivotal role in augmenting the reusability of modules to effectively address the diverse requirements of stakeholders. As a result of addressing these optimization challenges, the overall design layout can be derived, facilitating a comprehensive solution to the design problem at hand.

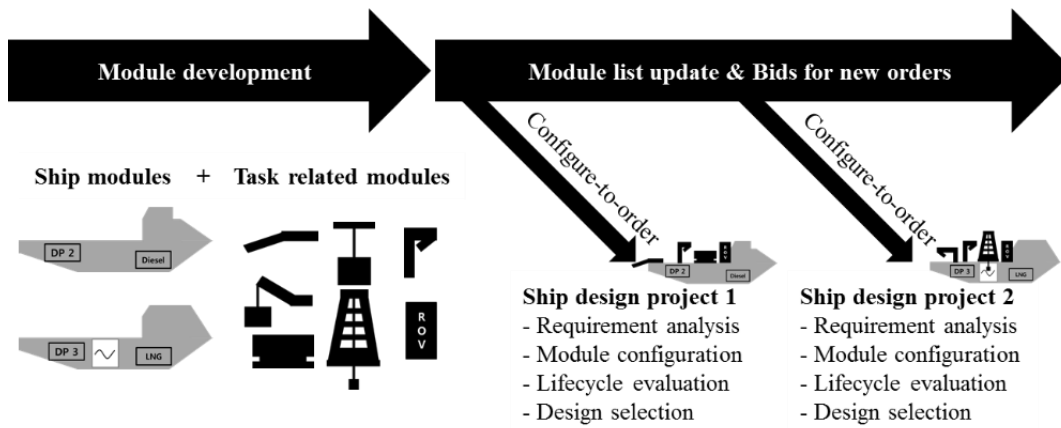

## DESIGN PROCESS OF MODULAR SHIPS

According to Ulrich (1995), modularity can be categorized into different types based on interface diversity and the presence of a main body. These types include sectional, bus, and slot modularity. Salvador et al. (2002) further elaborate on slot-type modularity, distinguishing between combinatorial modularity and component-swapping modularity. For the design of MASs, component-swapping modularity is often suitable, as the hull serves as the main body accommodating various module configurations. Unlike bus modularity, component-swapping modularity does not necessitate identical interfaces, making it a more versatile option. Figure 1 provides a visual representation of these four types of modularity.

**Figure 1: Four Types of Modularity Defined by Salvador et al. (2002).**

The traditional ship design process follows a top-down approach, where designers refine options for a benchmark ship iteratively, ultimately reaching a finalized design. This aligns with a ‘build-to-order’ strategy, aiming to deliver customized products to each customer. Conversely, the module-based design process operates bottom-up. Here, design alternatives are generated by configuring predeveloped modules, indirectly determining design characteristics through module configuration. This facilitates the ‘configure-to-order (CTO)’ strategy, where multiple design projects utilize standard modules developed prior to confirmed orders, based on demand forecasts. Implementing the CTO process allows design teams to reduce development time and costs while enhancing design reliability with tested technologies. Additionally, rapid prototyping enhances customer communication, crucial for defining appropriate key performance indicators for design projects. Figure 2 depicts ship design projects employing the CTO process.

**Figure 2: Ship Design Projects Based on the Configure-To-Order Strategy (Choi and Erikstad, 2017).**

While Figure 2 offers valuable insight into the CTO process for modular ships, a deeper exploration is warranted to elucidate the intricate steps involved in obtaining detailed designs, such as general arrangements, through this method.

## SHIP MODULES

Ship modules are the main body of modular ships in the component swapping modularity. In an optimization point of view, ship modules can be represented by decision variables and parameters, in which the decision variables indicate the attributes the value of which needs to be determined in the design problem, and the parameters indicate constant attributes the value of which are given. The choice of which design variables and constants to use to represent a ship module depends on the intended use of the ship module.

A ship module has its own properties but also spaces that are relatively high-level topology and geometry information acting as interfaces with other modules. Figure 3 describes an example of the ship module, in which the ship module has 7 spaces: steering gear room, main deck, store, stern deck, deck house, bow deck, and deck house up.

**Figure 3: An Example of a Ship Module.**

## DESIGN MODULES

Because spaces in a ship module have only their boundary shape, the spaces need to be divided into more smaller subspaces. This is a highly complex problem that requires simultaneous consideration of geometry and topology. As the complexity of the

problem increases from an optimization perspective, finding good solutions becomes increasingly challenging. Therefore, this study introduces the concept of design modules to reduce the complexity of the problem.

The design modules are predeveloped partial designs which comprise subspaces. Each subspace has its geometry information and could have a set of equipment and its lower-level subspaces. Figure 4 describes examples of design modules of main deck and Figure 5 presents the schematic diagram that illustrates the relations between ship module, space, design module, subspace.

Figure 4: Two Design Module Alternatives of the Main Deck Space.

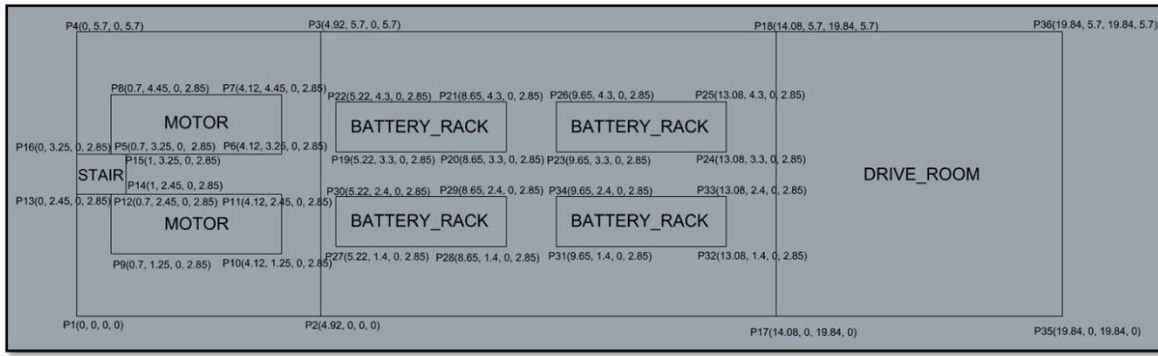

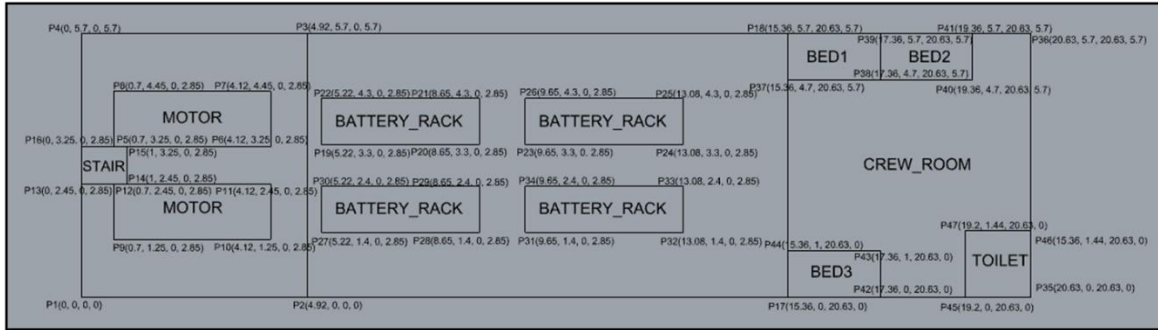

Figure 5: Schematic Diagram Between Ship Module, Space, Design Module, and Subspace.

Let's delve deeper into these alternatives. Figures 6 and 7 depict alternative 1 and 2, respectively, of the main deck space. A notable distinction between these alternatives lies in the presence or absence of the drive room and accommodation space. The selection of each module can vary depending on the specific accommodation requirements for the main deck space.

**Figure 6: Design Module Alternative 1 of the Main Deck Space.**

**Figure 7: Design Module Alternative 2 of the Main Deck Space.**

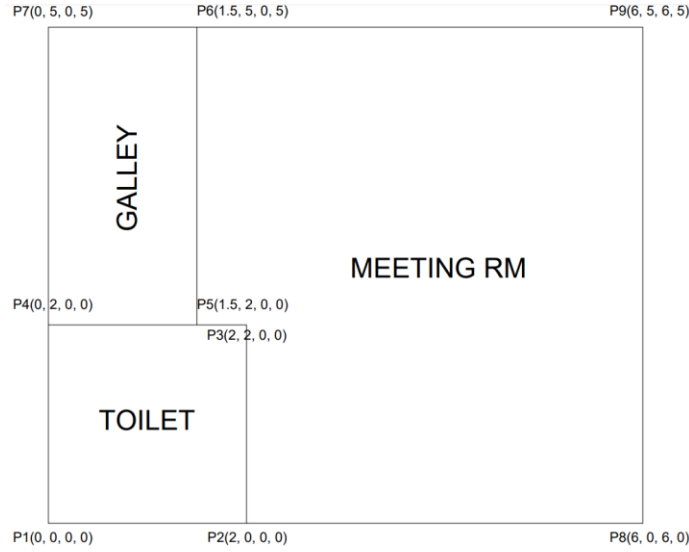

Because the design modules are predeveloped designs, the scale of the design modules needs to be adjusted to fit to the space where the design modules are assigned. Design modules are developed with scalability in mind to compensate for differences in basic form and allocated space size. The vertices of the detailed compartments constituting the design module are comprised of four pairs of values (x, y, a, b), where each value sequentially represents the x-coordinate, y-coordinate, x-scale factor, and y-scale factor. Here, the x and y coordinates denote the coordinates in the basic form, while the scale factors a and b are used to define the scalability of the design module, determining the new coordinates of the vertices through Equations 1 and 2.

$$\text{New } x = x + (\text{length of space along } x\text{-axis} / \text{length of ship module along } x\text{-axis} - 1) * a \quad [1]$$

$$\text{New } y = y + (\text{length of space along } y\text{-axis} / \text{length of ship module along } y\text{-axis} - 1) * b \quad [2]$$

Let's examine a more detailed example. In Figure 5, the design module includes spaces for a galley, toilet, and meeting room. The galley's shape can expand or contract based on the length of the allocated space along the y-axis, causing P6 and P7 to move vertically. However, its dimensions along the x-axis remain constant regardless of the allocated space's length in that direction. Conversely, alterations in the allocated space's dimensions along both the x and y axes do not affect the shape of the toilet. However, adjustments in both the x and y axes of the allocated space impact the configuration of the meeting room. Specifically, changes along the x-axis cause P8 and P9 to shift horizontally, while variations along the y-axis prompt vertical movements of P6 and P9. Notably, P2, P3, and P5 remain unaffected by adjustments in the dimensions along both axes of the allocated space.

Figure 8 illustrates the geometric alterations observed in the toilet. The x-scale factor and y-scale factor values for the toilet's vertices are set to 0, signifying that vertex coordinates remain constant regardless of the design module's allocation to different spatial configurations. Determining the scale factor values allows design module creators to accurately convey their design intentions.

**Figure 8: An Example of a Design Module That Comprises a Galley, Toilet, and Meeting Room.**

**Figure 9: Geometry Changes When the Design Module Is Combined with a Space.**

## MATHEMATICAL MODEL FOR MODULAR SHIP DESIGN USING DESIGN MODULES

In this section, we introduce an optimization model tailored specifically for addressing design challenges inherent in modularity through the utilization of design modules. It is important to note that our approach assumes a static design problem, wherein dynamic changes occurring during the operational phase are not explicitly accounted for.

Sets:

$S$	Set of spaces, indexed by $s$
$M_s$	Set of design modules of space $s$ , indexed by $m$
$P$	Set of capabilities, indexed by $p$
$P^{MAX}$	Subset of capabilities that need to be maximized, indexed by $p$
$P^{MIN}$	Subset of capabilities that need to be minimized, indexed by $p$
$P^{GOAL}$	Subset of capabilities that have a goal value, indexed by $p$
$x$	Set of ship variables, indexed by $x_i$
$y$	Set of module selection variables, indexed by $y_{sm}$

Parameters:

$R_p^{MIN}$	Minimum requirement of capability $p$
$R_p^{MAX}$	Maximum requirement of capability $p$
$L_i^X$	Lower boundary of basic variable $x_i$
$U_i^X$	Upper boundary of basic variable $x_i$
$W_p$	Weight of capability $p$
$W_p^-$	Weight of negative deviation of capability $p$
$W_p^+$	Weight of positive deviation of capability $p$

Variables:

$x_i$	$i$ -th ship variable
$y_{sm}$	1 if design module $m$ is selected for space $s$ , 0 otherwise

Model:

$$\text{Min} \quad \sum_{p \in \mathbf{P}^{MIN}} W_p f_p(\mathbf{x}, \mathbf{y}) - \sum_{p \in \mathbf{P}^{MAX}} W_p f_p(\mathbf{x}, \mathbf{y}) + \sum_{p \in \mathbf{P}^{GOAL}} W_p^- d_p^- + W_p^+ d_p^+ \quad [3]$$

$$\text{s.t.} \quad \sum_{m \in \mathbf{M}_s} y_{sm} = 1 \quad s \in \mathbf{S} \quad [4]$$

$$f_p(\mathbf{x}, \mathbf{y}) + d_p^- - d_p^+ = G_p \quad p \in \mathbf{P}^{GOAL} \quad [5]$$

$$d_p^-, d_p^+ \geq 0 \quad p \in \mathbf{P}^{GOAL} \quad [6]$$

$$R_p^{MIN} \leq f_p(\mathbf{x}, \mathbf{y}) \quad p \in \mathbf{P}^{MIN} \quad [7]$$

$$f_p(\mathbf{x}, \mathbf{y}) \leq R_p^{MAX} \quad p \in \mathbf{P}^{MAX} \quad [8]$$

$$x_i \in \{0, 1\} \quad \text{if } x_i \text{ is a binary variable,} \quad i \in \{1, \dots, |\mathbf{x}|\} \quad [9]$$

$$L_i^X \leq x_i \leq U_i^X \quad \text{otherwise,}$$

$$y_{sm} \in \{0, 1\}. \quad s \in \mathbf{S}, m \in \mathbf{M}_s \quad [10]$$

Equation [3] serves as the objective function, encompassing the overarching goals of the design process. It balances the minimization and maximization of various capabilities essential for the ship's performance while ensuring convergence towards a desirable outcome. Equation [4] guarantees the integrity of the design by stipulating that only one design module can be selected for each space, preventing redundancies or conflicting configurations. Equation [5] establishes a connection between the desired goals for specific capabilities and their actual achievement, employing negative and positive deviation variables to quantify the extent of any discrepancies. Equation [6] enforces the non-negativity constraint on the deviation variables, ensuring that any deviations from the desired goals are expressed as positive values, reflecting a proactive approach to addressing deficiencies. Equations [7] and [8] set the boundaries for the minimum and maximum requirements of each capability, respectively, ensuring that the design satisfies essential performance thresholds while avoiding over-specification. Equations [9] and [10] define the feasible ranges for the ship and module selection variables, allowing for binary decisions regarding the inclusion or exclusion of specific design elements within the overall configuration.

## CONCLUSIONS

The modular approach presented in this paper offers several notable advantages in ship design methodologies. By employing design modules and optimization models, the design process is streamlined, leading to enhanced efficiency and innovation. Here, we discuss the implications and potential future directions stemming from this research.

Firstly, the use of modular design significantly simplifies the initial design phases. Instead of starting from scratch for each new ship design, designers can leverage predeveloped design modules, saving time and resources. This streamlined process accelerates the production of detailed drawings and prototypes, facilitating rapid prototyping and iteration cycles.

Secondly, the optimization model introduced in this paper enables optimal selection and configuration of design modules based on specific ship requirements. By considering both ship attributes and module configurations simultaneously, the model ensures that design decisions are made with the overarching goals of the ship's performance in mind.

Furthermore, the scalability of design modules enhances their reusability across different ship designs and types. This scalability not only improves design efficiency but also fosters innovation by allowing designers to experiment with different configurations and arrangements to meet diverse stakeholder needs.

However, it is important to acknowledge the limitations of the proposed approach, particularly in the context of 3D design. While the optimization model and design modules offer significant benefits in 2D design spaces, translating these concepts into three-dimensional environments poses challenges. Future studies could explore methodologies for extending the modular approach to 3D design, addressing issues such as spatial constraints, interface complexities, and computational requirements.

In conclusion, the modular ship design framework presented in this paper offers a promising pathway towards more efficient and innovative ship design methodologies. By simplifying design complexities, accelerating prototyping processes, and fostering innovation, this approach holds the potential to revolutionize the way ships are conceptualized and developed. Future research could focus on further refining optimization models, expanding the range of design modules, and addressing the challenges of 3D design integration.

# Characterizing Three-Dimensional General Arrangements and Distributed System Configurations Utilizing an Architecturally Normalized Current Representation

Matthew Dowling<sup>1</sup>, Willis Tarn<sup>2</sup>, Alexander D. Monahar<sup>1</sup>, Connor W. Arrigan<sup>1</sup>, and David J. Singer<sup>1,\*</sup>

## ABSTRACT

*Designing ships involves intricate layouts and multifaceted systems—ranging from mechanical to operational—that must be interdependent and thus precisely arranged. Traditional automated tools, though effective, are often too resource-intensive to be feasibly employed during the critical early stages of design. This paper builds on prior work that introduced an innovative solution: a network-based, architecturally normalized current representation, which offers a computational method to predict system arrangements in two dimensions without generating detailed vessel models. Our method's advantage lies in its ability to guide early-stage design decisions, thereby optimizing the use of subsequent, more resource-intensive design tools. This study extends the method to a three-dimensional framework, capturing more nuanced system-to-system interactions and yielding more realistic ship arrangements. A methodology was proposed to support this three-dimensional extension and demonstrate its applicability through a case study focused on the conceptual design of a naval frigate.*

Early-Stage Design; Complex Systems; General Arrangements; Distribution Systems; Design Network Analysis.

## INTRODUCTION

The advent of three-dimensional (3D) modeling in naval architecture heralds a transformative era in ship design, one that transcends the conventional two-dimensional (2D) paradigms and unlocks a new dimension of possibilities. This paper critically extends the 2D network-based approach by Shields et al. (2018), tailored for ship design, into a more sophisticated and spatially comprehensive 3D framework. The methodology by Shields et al. (2018), notable for its computational approach to guide early-stage design decisions, established a novel approach in naval architecture by simplifying the multifaceted interplay of ship layouts and systems. However, STERN et al. (2015) highlights an inherent complexity of modern naval vessels, with their intricate spatial configurations and interdependent systems, which then necessitates a shift to a 3D perspective that can encapsulate these complexities with greater fidelity.

The objective of this study is thus twofold: to validate the feasibility of transitioning to a 3D network-based ship design algorithm and demonstrate its efficacy in addressing the spatial dynamics integral to modern ship design. The transition from

2D to 3D is not just an incremental step but offers a different approach to naval architecture, one that captures the knowledge without necessarily going into high-fidelity models, which has inherent challenges as proposed by Jeong et al. (2017). This methodology is particularly advantageous in the early stages of design, where the flexibility to explore a set of configurations and their implications on the overall design is paramount.

To elucidate the practical application and efficacy of this 3D algorithm, this paper presents a proof-of-concept study centered on the conceptual design of a naval frigate. This case study, chosen for its complexity and relevance, serves as a test-bed to underscore the algorithm's potential in navigating the intricate landscape of naval vessel design. By demonstrating the algorithm's utility in a real-world scenario, the authors aim to establish its role as a pivotal tool in the modern naval architect's toolkit, contributing significantly to the evolution of ship design practices.

The migration to 3D design in naval architecture represents not just an advancement in design techniques but a paradigm shift in conceptualizing and actualizing naval vessels. Brefort et al. (2018) also highlights the need to offer the ability to preempt and address design challenges in early-stage design, and provide a knowledge-based view of the vessel's architecture. By conducting a proof-of-concept with a naval frigate design, this study aims to demonstrate how 3D modeling can enhance early-stage design decisions, offering a more comprehensive and flexible approach to naval architecture. This incremental transition offers a greater understanding into a vessel's operational and structural inter-dependencies, necessary for a design to consider during early-stage design.

## BACKGROUND

A network-based approach may utilize two types of centrality within its algorithm: betweenness centrality and eigenvector centrality, as highlighted in Shields et al. (2018)'s work. Newman (2010) defines betweenness centrality as the number of times a node acts as a bridge along the shortest path between two other nodes. A node with high betweenness centrality in a naval design network might represent a critical component or design feature that connects various subsystems or design areas, highlighting its influence on information or workflow across the design process. Eigenvector centrality considers not only the number of connections a node has but also the quality of those connections. A node connected to other highly connected nodes has high eigenvector centrality. In naval design, this could identify key components or systems that are not only well-connected but also linked to other central elements, amplifying their influence.

### Eigenvector Centrality

Eigenvector centrality  $C_E(v)$  assigns relative scores to all nodes in the network based on the principle that connections to high-scoring nodes contribute more to the score of the node in question than equal connections to low-scoring nodes. The eigenvector centrality of node  $v$  is defined as:

$$C_E(v) = \frac{1}{\lambda} \sum_{t \in M(v)} A_{vt} C_E(t) \quad (1)$$

where:

1.  $M(v)$  denotes the set of neighbors of  $v$
2.  $A_{vt}$  is an element of the adjacency matrix  $A$  of the network, which is 1 if  $v$  and  $t$  are connected and 0 otherwise
3.  $\lambda$  is a constant (specifically, the largest eigenvalue of  $A$ )

This can be represented in a more compact form using the eigenvector equation:

$$A\vec{x} = \lambda\vec{x} \quad (2)$$

where  $\vec{x}$  is the eigenvector corresponding to the largest eigenvalue  $\lambda$ , and the components of  $\vec{x}$  are the eigenvector centralities of the nodes.

In naval design, nodes (design elements of systems) with high eigenvector centrality are those that are not only well-connected but also connected to other well-connected nodes, indicating their strategic importance in the design's overall effectiveness and efficiency.

## Betweenness Centrality

Betweenness centrality  $C_B(v)$  of a node  $v$  quantifies the extent to which  $v$  lies on the shortest paths between other nodes. It is defined as:

$$C_B(v) = \sum_{s \neq v \neq t} \frac{\sigma_{st}(v)}{\sigma_{st}} \quad (3)$$

where:

1.  $\sigma_{st}$  is the total number of shortest paths from node  $s$  to node  $t$
2.  $\sigma_{st}(v)$  is the number of those paths that pass through  $v$

This metric highlights nodes that serve as critical connectors or bridges within the network, which in the context of naval design, could represent elements or systems critical to the integration or interoperability of different components.

## Impact on Centrality Metrics

Changing requirements within the network impacts the centrality metrics in different ways.

For betweenness centrality, changing a requirement may affect the betweenness centrality of certain nodes by altering the shortest paths through the network. Newman (2005) proposes that nodes that previously acted as critical bridges between different parts of the design might see their betweenness centrality decrease if the change bypasses them, highlighting alternative pathways or components that have become more critical. Conversely, the introduction of new requirements or the modification of existing ones could elevate the strategic importance of previously peripheral nodes, as they become pivotal in connecting various components of the design.

For eigenvector centrality, the eigenvector centrality of a node reflects its connection to other influential nodes. As highlighted by Newman (2006), changing a node, hence requirement, could shift the network's structure of influence, affecting which nodes are considered central. A requirement change could make certain nodes more central if they are now more directly connected to or dependent on other highly central nodes. This shift can reveal which elements of the design are gaining or losing importance in the context of the overall system architecture and where design efforts may need to be concentrated.

These changes to centralities inform the designer mathematically in 4 ways:

1. **Identifying Critical Components:** By tracking the percentage-value changes in centrality measures, designers can identify which components have become more or less critical to the design's functionality. This can guide resource allocation, highlighting where additional analysis or robustness might be necessary in the design.
2. **Understanding System Interdependencies:** Changes in centrality can also reveal previously unnoticed interdependencies between components. Designers can use this insight to anticipate potential cascading effects of changes throughout the system, leading to more resilient designs.

3. **Highlighting Opportunities for Optimization:** Significant changes in the network's structure, as reflected by centrality measures, can uncover opportunities for optimizing the design. For instance, reducing the betweenness centrality of overloaded nodes can lead to a more balanced and efficient design.
4. **Informing Design Iteration:** By quantitatively assessing how a single requirement change affects the network, Shields (2017) suggests that designers can make more informed decisions about subsequent iterations, potentially exploring alternative solutions that balance centrality across the network more effectively.

Ultimately, the iteration of designs in the representation of a network, with changing requirements, provides a dynamic tool for designers to quantitatively assess and optimize the design process. This approach not only aids in making informed decisions but also enhances the overall design by understanding and leveraging the complex interplay of its components, also concurred by Shields (2017).

To define the impact on the centrality metrics mathematically:

1.  $G = (V, E)$  as the graph representing the design network, where  $V$  is the set of nodes (including requirements, components, and systems) and  $E$  is the set of edges (representing relationships or dependencies between these elements)
2.  $C_B(v)$  as the betweenness centrality of node  $v$
3.  $C_E(v)$  as the eigenvector centrality of node  $v$
4.  $v_r$  as the node representing a specific requirement that is being changed
5.  $G' = (V', E')$  as the modified graph after changing  $v_r$

The change in betweenness centrality  $\Delta C_B(v)$  for a node  $v$  due to the modification of  $v_r$  can be represented as:

$$\Delta C_B(v) = C'_B(v) - C_B(v) \quad (4)$$

where  $C'_B(v)$  is the betweenness centrality of  $v$  in the modified network  $G'$ .

Similarly, the change in eigenvector centrality  $\Delta C_E(v)$  for a node  $v$  due to the modification of  $v_r$  can be calculated as:

$$\Delta C_E(v) = C'_E(v) - C_E(v) \quad (5)$$

where  $C'_E(v)$  is the eigenvector centrality of  $v$  in the modified network  $G'$ .

## Informing the Designer

The impact of changing a requirement on the network can be further analyzed by examining the aggregate changes in centrality across all nodes. For example, the average change in betweenness centrality can be computed to understand how the design's connectivity or integration points shift. Similarly, examining the distribution of changes in eigenvector centrality can reveal how the overall influence landscape of the design has been altered.

Quantitatively, a designer can use these percentage-based changes to make better-informed decisions:

1. **Prioritization of Components:** If  $\Delta C_B(v)$  or  $\Delta C_E(v)$  significantly increases for certain nodes, those components may require additional focus or resources.
2. **Reevaluation of Dependencies:** Large percentage changes in centrality measures might trigger the need to perform a reevaluation of dependencies and relationships within the design to optimize performance or resilience.

3. **Iterative Optimization:** By systematically modifying requirements and analyzing the resulting changes in centrality, designers can explore the design space more thoroughly and identify different configurations, and their associated trade-offs.

The mathematical representation allows designers to illuminate and quantify the impact of requirement changes in the design network, providing a basis for better-informed decision-making and optimization throughout the design process.

## METHODOLOGY

In this exploration into the three-dimensional realm, the approach was multifaceted, encompassing both theoretical development and practical application. At the heart of this methodology is the expansion of Shields et al. (2018)' two-dimensional network-based approach, reengineered to consider the complexities and spatial intricacies of 3D ship design. This progression was not a straightforward task; it required a deep understanding of both the established principles of naval architecture with three-dimensional modeling in the form of a network.

The primary challenge was to develop an algorithm capable of accurately representing a ship's layout and systems in three dimensions. This required a significant enhancement of the original 2D model, integrating vertical spatial dynamics alongside the conventional horizontal plane. The 3D model had to account for factors such as vertical access routes, stack effects, and the vertical distribution of weight, which are crucial in naval architecture but were not considerations in the 2D approach.

A crucial aspect of the methodology was the incorporation of spatial dynamics within the 3D model. This included understanding how different spaces within a ship interact, how systems are routed through these spaces, and how these aspects impact the ship's overall functionality and performance. The model needed to be sensitive to the nuances of distribution, ensuring that every probability was accounted for and computed.

To demonstrate the practical applicability of the 3D model, the conceptual design of a naval frigate was chosen as a case study. This choice was driven by the inherent complexity in frigates, which offered a fine balance between weaponry, propulsion, living quarters, and other critical systems. The case study aimed to show how the 3D model could be used to explore various design configurations, assess their feasibility, and optimize the layout for operational efficiency and effectiveness.

A key focus of the methodology was its application in the early stages of design. The ability to visualize and manipulate a ship's design in three dimensions from the outset allows for a more informed decision-making process. It opens up new avenues for exploring design options, foreseeing potential issues, and making strategic decisions that significantly impact the final design.

The final phase of the methodology involved analyzing the results obtained from the naval frigate case study. This analysis aimed to determine the effectiveness of the 3D model, its impact on early-stage design decisions, and its potential role in future naval architecture practices. The discussion also highlights the limitations of the current model and suggests areas for future research and development.

## DEVELOPMENT OF PROOF-OF-CONCEPT

In transforming the theoretical aspects of the three-dimensional naval architecture model for real-life applications, the approach was centered around developing a robust proof-of-concept. This phase was crucial to demonstrate not just the technical feasibility but the practical utility of the model in real-world scenarios. The focus was on the intricate process of translating complex naval architectural concepts into a functional and interactive 3D model, in the form of a naval frigate.

Pivotal to the development strategy was the use of centrality matrices. These matrices were employed as a means to mea-

sure "decision influence" within the ship design. Essentially, these "decision influence" matrices allowed the authors to quantify the impact of each design decision on the overall layout and functionality of the ship. By analyzing the centrality of various components and spaces within the ship, designers could understand how changes in one area might ripple through to others, thereby influencing the entire design network.

Another significant area of the development process involved the integration of 3D dynamics into the model. This was a step from the 2D scope of naval architecture, which focused more on the side layout. The aim was to fully utilize the three-dimensional space to elucidate how 3D elements such as the combination of horizontal and vertical weight distribution affect the ship's overall design and performance.

For the proof-of-concept, the naval frigate presented a sufficiently comprehensive challenge, offering a broad spectrum of variables to test the model's capabilities. The model, built upon Shield's previous work, was simulated with a design scenario to assess the design feasibility over multiple configurations and predict the operational efficacy.

The simulation process involved iterative runs to test various configurations and layouts. The model was repeatedly fine-tuned to adapt to the dynamic requirements of naval frigates, incorporating feedback loops that allowed for continuous improvement of the design process. The changes to centrality matrices were tracked and normalized in these simulations, providing quantitative data that informed the decision-making process at every step.

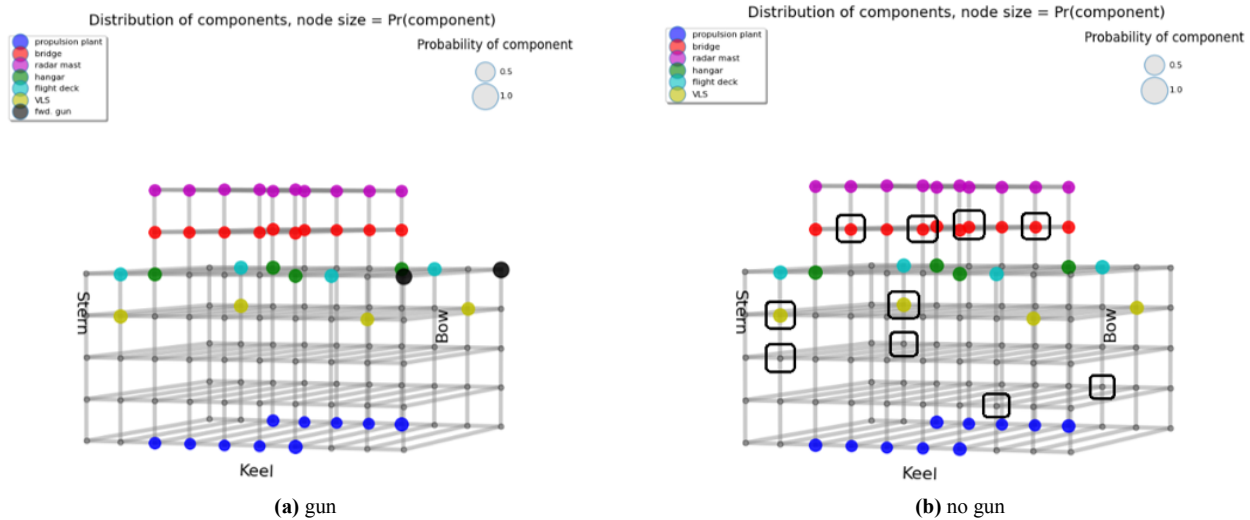

## RESULTS

The methodology, detailed in the earlier section, quantifies the resultant shifts in the network's dynamics, particularly focusing on the betweenness and eigenvector centralities of pivotal components such as the bridge, VLS, and supporting pipes. This investigation illuminates the intricate interdependencies within naval systems, showcasing how alterations in a single design element can precipitate significant reconfigurations across the network, also seen in Shields (2017) work. The enhanced roles of specific components, underscored by their changes in centralities, highlight their critical importance in maintaining operational efficiency and design integrity. This nuanced understanding of design element interplay advances our capability to navigate the complex landscape of naval architecture, fostering more informed decision-making and innovation in naval design practices.

Mathematically, Shields et al. (2018) proposes that a shift in centralities reflects a re-evaluation of the importance of certain nodes (such as the bridge, VLS, and supporting pipes) within the network. This change indicates how central a node is in the context of the entire network, taking into account not just the number of connections, but also the significance of those connections. High centrality values post-removal of the naval gun imply these components play a more crucial role in maintaining the network's functionality, highlighting their increased influence on the ship's design and operational efficiency.

By quantifying the shifts in centralities of critical components, the method offers insights into these elements' enhanced roles. This approach highlights the interdependencies within naval systems and guides more informed decision-making for future design strategies, emphasizing the importance of considering component significance and system-wide impacts in naval architecture, which is detailed in the following sub-sections. The results will first discuss the impact of design changes through eigenvector centralities, which will highlight components which has a greater influence on operations. The study will then discuss components that require greater consideration, discussion, or impact to support the design through betweenness centralities. Finally, the study will investigate the impact of fidelity on eigenvector centralities by expanding the 3-D space.

### **Eigenvector Centralities as a measure of influence and importance**

**Figure 1:** gun in the general arrangement vs no gun (eigenvector centrality)

In Figure 1(a), the presence of the gun is illustrated by a network where the gun node possesses a size proportional to its centrality. Surrounding components display varying degrees of centrality, suggesting a more dispersed distribution of influence across the network. The network appears balanced, indicating that the removal of any single component—while impactful—would not drastically destabilize the system or design.

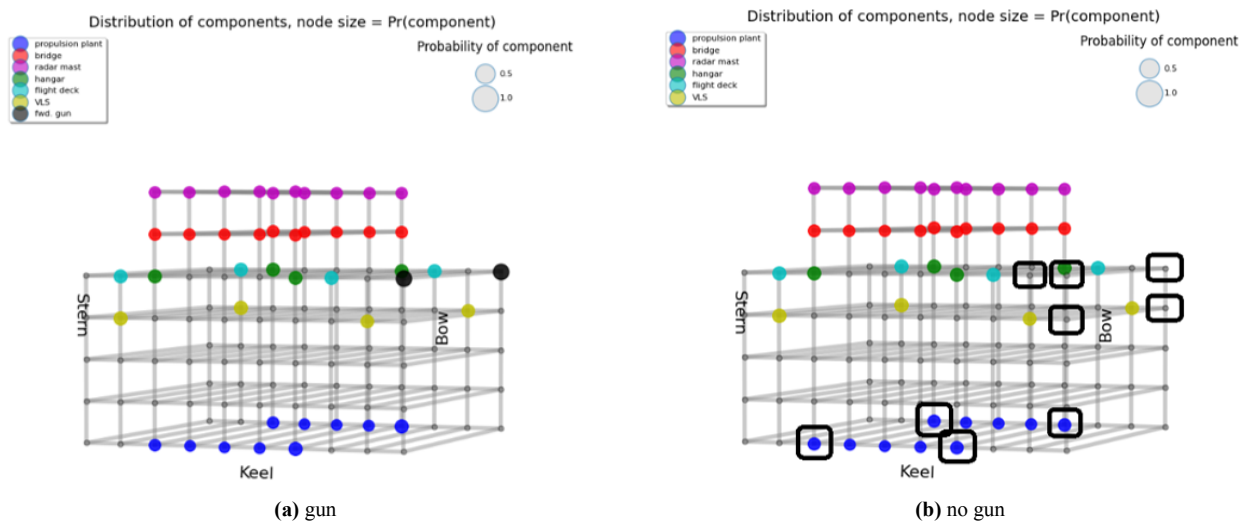

Contrastingly, Figure 1(b) reveals the aftermath of the gun's removal. Notably, the bridge, VLS, and supporting pipes emerge with significant changes to their eigenvector centralities, signified by their "highlighted" node representations. This highlights a shift towards a more centralized network architecture, where the influence is now concentrated among fewer components. Referencing Newman (2005), the resultant configuration suggests that these elements have assumed more critical operational roles in the absence of the naval gun, potentially becoming new focal points for maintaining the vessel's functionality.

The changes in centralities within the naval design network provide critical insights for designers. The changes in eigenvector centralities for key components like the bridge, VLS, and supporting pipes following the gun's removal indicate these elements have become more crucial in the network's functionality. This shift towards a more centralized network structure informs designers about potential new focal points in ship functionality, meaning:

1. **Resource Allocation:** The design team may need to prioritize the bridge, VLS and supporting pipes for further development and robustness checks, ensuring they are capable of handling their critical roles effectively.
2. **System Redesigns:** The bridge, VLS, and supporting pipes might need to add redundancy to enhance the resilience of these parts to mitigate risks associated with potential failures.

The 3D model provides a more nuanced view of system interdependencies compared to traditional 2D models, which tend to simplify complex relationships. In 3D, the spatial configuration and the relative placement of components are captured, revealing how changes in one part of the system can affect others in a way that flat representations cannot. This validation of our hypothesis underscores the importance of considering three-dimensional interactions in naval design to fully understand and anticipate the impacts of alterations within the ship's architecture. The increased centralities observed in the 3D model after the removal of the naval gun reflect this depth of analysis, validating the hypothesis that certain components will grow in operational significance when a major system is removed.

## Betweenness Centralities as a measure of criticality

**Figure 2:** gun in the general arrangement vs no gun (betweenness centrality)

Figure 2's graphical sub-section presents a visualization of betweenness centrality within the naval ship's design network, with two distinct configurations: one with the gun (a) and one without (b). The combination of Newman (2010)'s definition and Shields et al. (2018) research could then define betweenness centrality as a measure of a component's role as a conduit or bridge within the network—its importance in connecting different parts of the ship. The graphical comparison powerfully illustrates the redistribution of this measure among the ship's components.

In configuration (a), with the gun present, the betweenness centrality is relatively evenly distributed across the network, suggesting a balanced design with multiple pathways for operational flow and no single point of over-reliance. The hangar, propulsion plant, and supporting pipes exhibit centralities indicative of their role but are not overly dominant.

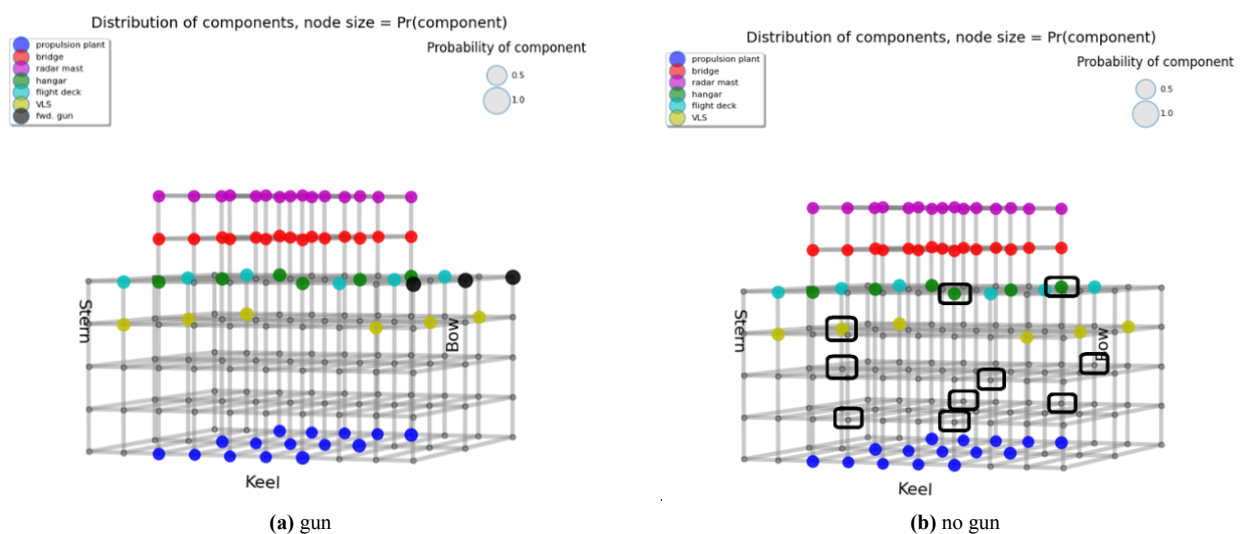

Configuration (b), however, tells a different story. Here, the removal of the naval gun has led to a significant change in the betweenness centrality of the hangar and propulsion plant, with supporting pipes towards the front also becoming more prominent. This shift points to a reconfiguration of operational pathways, now heavily reliant on these components. The increased centrality of the hangar and propulsion plant suggests they are now key nodes, critical for the ship's performance and structural integrity.

The betweenness centrality information can be utilized by naval designers in several practical ways:

1. **Identifying Key Components:** Designers can prioritize the hangar and propulsion plant for enhanced robustness and reliability in design specifications.
2. **Redesigning Flow Paths:** The hangar and propulsion plant are major conduits, which means the design team needs to ensure efficient flow paths and reduce potential bottlenecks in ship operations through these conduits.
3. **Improving Operational Resilience:** By reinforcing the hangar and propulsion either through redundancies or armor-ing, designers can improve the overall resilience of the ship, ensuring it remains operational even if key components are compromised.
4. **Strategic Modifications:** Designers can strategically plan mid-life upgrades to the hangar and propulsion plant, which could have significant impacts on the ship's functionality.

The variations between these two configurations reveal the adaptable nature of naval design networks. Referencing Newman (2005)’s research, the variations demonstrate how the removal of a single component can lead to a redistribution of functional importance across the network, necessitating a reassessment of design priorities. This validates the hypothesis that naval design is a dynamic and interdependent system, where changes in individual elements can have far-reaching impacts. By providing a quantifiable measure of component significance, the betweenness centrality analysis offers designers a powerful tool for assessing potential modifications and their ramifications. It underpins the need for comprehensive simulations and modeling in naval architecture to ensure that designs are both robust and flexible, capable of accommodating changes while understanding the trade-offs on operational effectiveness.

## Extending the 3D layers

**Figure 3:** 3 guns, eigenvector centrality gun vs no gun comparison (eigenvector centrality)

As the study extends the fidelity of the model in the analysis of eigenvector centralities depicted in Figure 3, three potential positions for the guns in the ship’s design are compared against a configuration without any guns. The three-layered representation of nodes offers a different understanding of the influence exerted by the supporting pipes within the ship’s network, highlighting a significant change in their centrality in the absence of the gun. This reinforces the point on the need for the design team to consider adding redundancies within the supporting pipes network, highlighted in the earlier sub-section.

This extension of an additional layer within the network underscores the heightened impact that supporting structures have in the absence of key offensive components, offering critical insights for future design considerations where Knight et al. (2015) highlights the need for flexibility and adaptability may be required for subsequent downstream upgrades.

The comparison between Figures 1 and 3, which illustrate the eigenvector centralities in two different configurations of naval ship design, reveals the nuanced shifts in the ship’s structural network. In Figure 1, the removal of the naval gun impacts the centrality of the bridge, VLS, and supporting pipes, demonstrating their increased operational significance. In contrast, Figure 3 expands this analysis to a three-layer node view, uncovering the broader influence of supporting pipes throughout the ship’s design, especially in the gun’s absence. This expansion provides a deeper understanding of the role that the pipes play in the ship’s resilience and design adaptability.

The information from the analysis can be used by naval designers in several ways:

1. **Prioritizing Component Enhancement:** By identifying which components like the supporting pipes gain in central-

ity, designers can prioritize these for enhancements, ensuring they are robust enough to handle increased responsibilities.

2. **Redesigning for Resilience:** Recognizing components that become more central to the ship's functionality allows designers to focus on redesigning these elements to enhance the overall resilience of the ship.
3. **Risk Management:** The analysis helps in assessing potential risks associated with the removal or modification of major components and planning mitigations accordingly.

In the context of naval design, the comparison between Figure 1 and Figure 3 suggests a shift in the functional significance of the ship's components when the naval gun is removed. Specifically, the three-layer eigenvector centrality analysis in Figure 3 emphasizes that the supporting pipes increase in importance, indicating they may take on a more central role in maintaining the structural and operational integrity of the ship. This suggests that in the absence of the gun, the ship's design compensates by relying more on other elements to maintain its performance capabilities.

## DISCUSSION

The comprehensive analysis of the naval ship design network in the absence of the gun, as demonstrated by the shift in centralities, offers an insightful perspective into the future of naval architecture. This paradigmatic observation in network behavior, where supporting infrastructural components like pipes accrue shifts in centrality, necessitates a reconsideration of their role within the structural integrity and operational efficiency of naval vessels.

From a mathematical viewpoint, Newman (2001) definition suggests that eigenvector centrality could elucidate the relative influence of a node within the network. As presented in the earlier section, as the supporting pipes gain prominence in the absence of the gun, it indicates that these components have now become instrumental nodes through which significant portions of the network's operational pathways are mediated. This increase in centrality suggests that the design's resilience is now more heavily reliant on the robustness of these elements, which may not have been primary factors in the initial design considerations.

The implications for future ship design are substantial. The conventional approach to naval architecture, as described by Pawling et al. (2017), which is generally characterized by a siloed focus on individual components rather than their interactions, may no longer be sufficient. Instead, Shields (2017)'s proposal of a holistic view that embraces the interconnectivity of all ship elements and their contributions to the overall network is required. This shift towards an integrated network perspective will enable naval architects to create designs that are inherently adaptable, and capable of withstanding the removal or malfunction of critical components without significant loss of functionality.

Moreover, the study's findings highlight Knight et al. (2015)'s point on the importance of modularity in design, where components can be removed or replaced with minimal disruption to the broader system. In the context of rapidly evolving military technologies and strategies, such modularity becomes indispensable. It ensures that ships can be upgraded or reconfigured in response to emerging threats and operational requirements without necessitating complete redesigns, thus extending the vessels' operational lifespans and enhancing their return on investment.

Furthermore, the network-centric approach to design implicates the potential impact of these findings on naval architecture education and practice. The current training may need to evolve to incorporate principles of network science and systems thinking, equipping the next generation of naval architects with the tools and perspectives necessary to design the resilient and responsive vessels required for future maritime challenges.

In conducting a detailed analysis of ship design using network science methodologies, the authors confronted significant challenges while implementing a component arrangement algorithm. The desired outcome was to programmatically determine an optimal design where specific components, such as the flight deck and forward gun, were preferentially distanced. Utilizing Newman (2005)'s random walk betweenness centrality measure, the algorithm inadvertently amplified the central-

ity scores of nodes adjacent to crucial components, regardless of the targeted arrangement. This unexpected result presented a quandary: how to penalize configurations where the flight deck was undesirably positioned near the forward gun.

The challenges were compounded by the algorithm's nature, which globally enhanced centrality scores based on proximity to key nodes, influencing unrelated calculations. A simplistic solution like removing front flight deck nodes to refocus the algorithm on aft sections contradicted the objective of establishing a proof of concept. The essence of the endeavor was to reduce manual labor in developing more efficient designs—options that are not immediately apparent to designers.

Addressing this challenge necessitated a reevaluation of the algorithmic approach. The study nuanced adjustments to the algorithm, accounting for these centrality distortions. Potential solutions involved introducing penalty factors within the centrality calculations or developing a multi-criteria optimization framework that could simultaneously consider proximity preferences alongside other design requirements.

These adjustments had to be carefully balanced to not undermine the overall integrity of the ship's network. The intricacies of the design elements' interplay needed meticulous consideration to ensure that operational efficiencies were not sacrificed. The insights derived from these explorations are vital for naval architecture, pointing towards a future where computational algorithms can significantly augment human expertise in early-stage design, leading to innovative naval vessels engineered for optimal performance and resilience.

The integration of such algorithmic solutions holds the potential impact on naval architecture. By automating complex design decisions, this approach could significantly streamline the design process, allowing for rapid prototyping and testing of various configurations. This would not only save time and resources but also enable the exploration of a broader design space, potentially unveiling novel configurations that human designers may not intuitively consider.

## CONCLUSION

Our research revealed a fundamental reconfiguration of the naval ship design network when key components such as the naval gun are altered. The significant increase in the eigenvector centralities for supporting structures like pipes upon the gun's removal indicates a shift towards a design that compensates for the loss by redistributing functional importance across the network. This insight is vital for future naval designs, where resilience and adaptability must be engineered into the vessel from the outset. It suggests that naval architecture is entering a phase where flexibility and robustness are not merely desired but required, laying the groundwork for innovative approaches in ship design. These findings pave the way for future research to develop algorithms that can more effectively navigate the complex trade-offs between design intuitiveness and computational optimization.

The advances in network-centric naval architecture presented in our study hint at transformative possibilities for future ship design. Pioneering research can progress towards developing advanced algorithms that not only predict but also adaptively recalibrate the ship's design network in response to changes in component configurations. There is potential for creating intelligent design systems that can autonomously optimize layouts for operational efficacy, considering factors such as spatial constraints and mission-specific requirements. Additionally, investigations into the resilience of these networks against unforeseen failures could lead to the evolution of ships with unprecedented structural robustness. Future research directions are poised to harness machine learning to predict and propose optimal designs, significantly reducing the iterative cycle of design and testing, and to employ virtual reality for immersive design evaluation, which could revolutionize the conceptualization phase of naval engineering.

# Improving Ship Response Estimation with Neural Networks

Samuel J. Edwards<sup>1,\*</sup> and Michael Levine<sup>1</sup>

## ABSTRACT

*The feasibility of a data-adaptive multi-fidelity seakeeping model is assessed for use in early stage design in this study. Data adaptive tuning (or correction) of lower-fidelity model predictions are implemented based on training with higher fidelity ship motion response data. Long Short-Term Memory (LSTM) neural networks are incorporated as part of a multi-fidelity approach for prediction of 6 degree of freedom (6-DOF) ship motion responses in waves. LSTM networks are trained and tested with Large Amplitude Motion Program (LAMP) simulations as a target, and SimpleCode simulations and wave time-series as inputs. LSTM networks improve the fidelity of SimpleCode seakeeping predictions relative to LAMP, while retaining the computational efficiency of a lower-fidelity simulation tool.*

## KEY WORDS

Neural Networks; Seakeeping; Extreme Events.

## INTRODUCTION

To understand how a ship will respond in different environmental conditions is vital in early stage design. Consideration of the operating conditions can be made in the form of a developing a database that covers a comprehensive set of ocean wave conditions. Within the database is a collection of ship response statistics as a function of ship heading, speed, and wave conditions. Operational limits are determined based on relationships between these statistics and maximum allowable responses. Generating large databases containing many possible combinations of ship headings, speeds and wave conditions allows for more robust operational guidance ability.

To identify and compare against operational limits, extreme event analysis must be performed. The most straightforward approach to estimating extreme ship response characteristics is through Monte Carlo simulations. However, for most tools of reasonable fidelity, the computational cost is far too expensive when considering potential extreme events for longer return periods and simulation run times on the order of real time. Extrapolation methods, generally based on Weibull distributions, can be explored with a limited dataset. However, this approach requires prior knowledge of the response distribution with particular focus on the tail of the distribution.

Other methods to identify extreme behavior efficiently without overextending assumptions have been developed. One such method is the Design Loads Generator (DLG) (Alford 2008, Kim 2012). DLG was initially developed for linear systems with stochastic Gaussian input, and drew from modified phase distributions based on Extreme Value Theory to generate ensembles of extreme realizations for a given return period.

Another method that has been explored is a lower-fidelity simulation tool that retains major nonlinearities to identify extreme conditions, and then running the identified conditions with a higher-fidelity simulation tool (Reed 2021). In this framework, a surrogate model does not need to be identified but requires a high level of correlation of the peaks between the two simulation tools employed.

An approach with Long Short-Term Memory (LSTM) to correct lower-fidelity ship response data to the level of higher fidelity ship response data was developed in Levine et al. (2024). In the paper, statistics generated by two different training methods were compared between the LSTM and the higher fidelity responses with good results. However, only three degrees-of-freedom (3-DOF) were applied in the ship simulation software solvers.

In this paper, the method outlined in Levine et al. (2024) is further refined to produce predictions with 6 degrees-of-freedom (6-DOF) simulations. The method applies two seakeeping simulation tools of lower and higher fidelity, which are SimpleCode (Weems and Wundrow 2013) and the Large Amplitude Motion Program or LAMP (Shin et al. 2003), respectively. By running the lower fidelity code (SimpleCode) under the same conditions as the higher fidelity code (LAMP), the motions predicted by SimpleCode can be improved to approximate those from LAMP through a Long Short-Term Memory (LSTM) neural network. However, the forces in the 6-DOF simulations acting on the SimpleCode-simulated ship differ from the LAMP-simulated ship and the simulated ships diverge in space over time. To account for the difference in experienced conditions under the same seaway, a first stage LSTM neural network is introduced to learn the ship path of the LAMP model with the SimpleCode simulation as input. In this approach, all ship motion degrees-of-freedom are considered in the hydrodynamic solvers and are used in the training of the neural networks. After training the LSTM networks, many LAMP-quality ship simulation realizations can be generated with LSTM-corrected SimpleCode results in a much more computationally efficient manner.

In the following sections, the network architecture for training a framework of LSTM networks with SimpleCode as input and LAMP as a target is described. Then, a case study with the David Taylor Model Basin (DTMB) Model 5415 (Moelgaard, 2000) is described and results from the application of the framework are presented.

## METHODOLOGY

### SimpleCode and LAMP

SimpleCode is a reduced-order seakeeping code that can quickly produce acceptable results (Smith 2019). One of the key simplifications is in the local variation of wave pressure, where the hydrostatic and Froude-Krylov equations can instead use volume integrals rather than integrating over the surface of the ship (Weems and Wundrow 2013). With pre-computed Bonjean curves, the instantaneous submerged volume and geometric center; therefore, sectional hydrostatic and Froude-Krylov forces can be calculated quickly.

LAMP is a higher fidelity code that considers all forces and moments acting on the ship in the time-domain within a 6-DOF, 4th order Runge-Kutta solver (Shin et al. 2003). Central to the code is the solution of the 3-D wave-body interaction problem. Within LAMP, the complexity of this solution can be altered. LAMP-3 is utilized in the current work, where the perturbation velocity potential is solved over the mean wetted hull surface and the hydrostatic and Froude-Krylov forces are solved over the instantaneous wetted hull surface. Additionally, LAMP-3 allows for large lateral motions and forces. LAMP has effectively estimated motions comparable to model tests (Lin and Yue 1991) but is, of course, much more computationally expensive than a lower-fidelity code like SimpleCode. Through some parameters e.g., number of wave frequency components, free surface panel definition, hull offsets, can be altered, LAMP-3 runs at nearly real time i.e., 30 minutes of wall-clock time is required to generate 30 minutes of simulated data. In the same 30 minutes and the same number of frequency components, SimpleCode can produce upwards of 5,000 independent realizations of 30 minutes.

SimpleCode can produce an approximation of LAMP, especially with tuned radiation and diffraction forces included (Weems and Belenky 2018, Pipiras et al. 2022). However, a fidelity gap exists, especially when considering a bimodal wave spectrum. In this study, the 6-DOF implementations of SimpleCode and LAMP were both used. Using the 6-DOF solvers in both SimpleCode and LAMP provides a more accurate representation of the pertinent degrees of freedom as the simulated ship is allowed to move more realistically and the forces act on the ship accordingly. However, only the three vertical degrees of freedom (heave, roll, and pitch) were for comparison. These degrees of freedom have the greatest applicability to the evaluation of typical design criteria.

### Long Short-Term Memory (LSTM)

One of the major drivers of the presented method is the Long Short-Term Memory (LSTM) neural network (Hochreiter and Schmidhuber 1997). An LSTM neural network is a recurrent neural network that incorporates both long- and short-term effects that are learned and developed during the training process. These memory effects are stored in weight matrices where they, along with other operations, transform input matrices to the target output matrices. The causal nature of marine dynamics and inclusion of memory effects make LSTM networks particularly well suited for the presented problem. The following set of equations describe the operations that occur in an LSTM layer.

$$f_1 = \sigma(W_{f_1}x^{[t]} + U_{f_1}h^{[t-1]} + b_{f_1}) \quad [1]$$

$$f_2 = \sigma(W_{f_2}x^{[t]} + U_{f_2}h^{[t-1]} + b_{f_2}) \quad [2]$$

$$f_3 = \tanh(W_{f_3}x^{[t]} + U_{f_3}h^{[t-1]} + b_{f_3}) \quad [3]$$

$$f_4 = \sigma(W_{f_4}x^{[t]} + U_{f_4}h^{[t-1]} + b_{f_4}) \quad [4]$$

$$c^{[t]} = f_1 \odot c^{[t-1]} + f_2 \odot f_3 \quad [5]$$

$$h^{[t]} = f_4 \odot \tanh(c^{[t]}) \quad [6]$$

where  $W$  and  $U$  are weight matrixes,  $b$  are the bias vectors,  $x^{[t]}$  is the input vector, standardized by the respective standard deviations and means for each input channel, by the respective at time  $t$ ,  $h^{[t]}$  is the hidden state vector at time  $t$ ,  $c^{[t]}$  is the cell state vector at time  $t$ ,  $\sigma$  is the sigmoid function,  $\tanh()$  is the hyperbolic tangent function, and  $\odot$  represents the Hadamard product. The output or target at time  $t$  is equal to the hidden state vector at time  $t$ ,  $h^{[t]}$ . The weight matrices and bias vectors are progressively learned during the training process to minimize the specified loss between the training data and the test data. The present work employs the mean-squared error in Equation 7 to quantify the error between the training and test sets.

$$MSE = \frac{1}{N} \sum_{i=1}^N (y_T(t_i) - y_L(t_i))^2 \quad [7]$$

where  $N$  is the number of points in the time series,  $y$  is the response matrix which contains the time series of heave, roll, and pitch, subscript  $T$  is the target time series, subscript  $L$  is the LSTM produced time series, and  $t_i$  is the  $i$ -th time instant in the time series.

In Levine et al. (2024), the 3-DOF SimpleCode and LAMP simulations were well correlated and the motions and wave elevation time series derived from the SimpleCode simulations could be input into the LSTM with the LAMP heave, roll, and pitch time series as the targets. However, the difference in realized forces acting on the simulated ships in 6-DOF simulations results in a difference in the global position between the SimpleCode and LAMP models. The result is a reduction in correlation between the input and output time series. To account for this lower correlation, a two-step LSTM model is introduced. First, an LSTM framework is trained to transform the 6-DOF SimpleCode motions and wave elevation time series derived from SimpleCode to the surge and sway of the LAMP simulations. These surge and sway time series are combined with the wave spectrum and phases from the given realization to estimate the wave elevation at the center of gravity of the LAMP model. In Levine et al. (2024), an LSTM framework is capable of estimating LAMP motions through a data-driven approach with only the wave elevation as input (“LSTM-Waves”). A similar effort comprises the second step of the LSTM architecture where the wave elevation generated from the estimated LAMP surge and sway are inputs into an LSTM network trained to estimate 6-DOF LAMP heave, roll, and pitch from LAMP-generated wave elevation time series. The framework is illustrated in Figure 1.

**Figure 1: LSTM Two-Step Framework Architecture**

Each LSTM architecture consisted of two layers of size 50. The characters and symbols outlined in Figure 1 are described in Table 1. Additionally, superscripts *SC* and *LAMP* indicate that the corresponding time series elements were sourced from SimpleCode or LAMP, respectively. Furthermore, Figure 1 lays out the *training* structure. In testing, the LAMP time series are effectively replaced by LSTM generated time series.

**Table 1: LSTM Architecture Parameter Definitions**

Parameter Definition	Variable
Input wave at time-step $j$	$\eta_{o,j}$
Total number time steps	$T$
$i^{th}$ degree-of-freedom at time-step $j$	$\eta_{i,j}$
$k^{th}$ gate for LSTM layer	$f_k$
Number of LSTM units per layer	$n$
Output layer cell for DOF $m$	$O_m$
Number of frequencies in spectrum	$N$
Wave amplitude for frequency $p$	$a_p$
Wave number $r$ for frequency $p$	$\kappa_{p,r}$
Frequency $p$	$\omega_p$
Phase for frequency $p$	$\phi_p$

## Numerical Experimental Setup

The model hullform for this study was the David Taylor Model Basin (DTMB) Model 5415 (Moelgaard 2000). Figure 2 is a rendering of the DTMB Model 5415 and Table 2 provides the particulars for the vessel.

**Figure 2: Rendering of DTMB Model 5415****Table 2: Particulars for DTMB Model 5415**

Particular	Symbol	Value
Length between perpendiculars	$L_{PP}$	142.0 m
Beam	$B$	19.1 m
Draft	$T$	6.2 m
Radius of gyration about X-axis	$k_{xx}$	7.1 m
Radius of gyration about Y-axis	$k_{yy}$	35.5 m
Vertical center of gravity (w.r.t baseline)	$KG$	7.5 m
Longitudinal center of gravity (w.r.t midships)	$L_{cg}$	-0.9 m
Displacement mass	$\Delta_m$	8424.4 t

For this case study, a primary International Towing Tank (ITTC) spectrum (ITTC 2002) characterizing wind-generated waves was applied with  $H_s = 4.0$  m and  $T_p = 15.0$  s (standard Sea State 5 and most probable modal period) and the relative wave heading set to bow-quartering seas ( $135^\circ$ ). Additionally, the primary ship speed was set to 10.0 knots. Proportional-integral-derivative (PID) controllers maintained speed and “soft springs” maintained heading in both the SimpleCode and LAMP models.

A total of 50 realizations each 30 minutes in duration were generated in LAMP and SimpleCode. The first stage of the framework to estimate the surge and sway was trained with 30 realizations and validated with 10 realizations. The second stage of the framework to predict the 6-DOF motions was trained with 30 realizations, validated with 10 realizations, and tested with 10 realizations. There was not any testing performed during the first stage as only the output of second stage was compared.

The average standard deviations and time series correlation coefficient for heave, roll, and pitch from the 10 test realizations generated using SimpleCode, LAMP, and the LSTM framework were compared. Equation 8 is the formula for the correlation coefficient.

$$\rho = \frac{\text{cov}(x, y)}{\sigma_x \sigma_y} \quad [8]$$

The correlation coefficient is the ratio between the covariance of two random processes,  $x$  and  $y$ , and the product of the respective standard deviations  $\sigma_x$  and  $\sigma_y$ . To further capture the reliance on strong correlation with LAMP, the relative motion at the starboard bow was also compared. In addition, the absolute relative error was a comparison metric for SimpleCode and the LSTM method to LAMP. The equation for absolute percentage error is as follows:

$$\epsilon = 100\% * \frac{|\hat{X}_L - \hat{X}_E|}{\hat{X}_L} \quad [9]$$

where  $\hat{X}_L$  represents the standard deviation of LAMP data and  $\hat{X}_E$  represents the standard deviation of the LSTM estimate or SimpleCode.

In addition to the standard deviation statistic, the estimations of peaks between mean up-crossings were compared. The peaks between mean up-crossings from each of the test SimpleCode, LAMP, and LSTM time series were tabulated and probability distribution functions (PDFs) were generated.

## RESULTS

### Framework Training

To benefit from the neural network framework, it is important to retain computational efficiency along with accuracy compared to the target. Table 3 shows the time necessary to train the network along with time necessary to generate the data. The network training was performed using a NVIDIA Quadro T2000 GPU with 4 GB of memory, the LAMP simulations were performed on a computing cluster using 8 cores each containing 192 GB of memory, and the SimpleCode runs were generated locally on a 32 GB CPU.

**Table 3: Computation Time for Data Generation and Network Framework Training**

Process	Stage	Computation Time [s]
Data Generation	SimpleCode	37
	LAMP	9,142
Network Training	Surge-Sway Prediction NN	234
	Heave-Roll-Pitch Prediction NN	705

Table 3 shows that the bulk of the process is generating the higher-fidelity LAMP data. After completing the sunk cost of training the framework, much more LAMP-quality data can be generated with the framework and the small cost of producing additional SimpleCode data.

## Statistical Comparison

To evaluate the LSTM method relative to LAMP and SimpleCode, the standard deviation from each degree of freedom was estimated from the 10 test realizations. The absolute relative error of the standard deviation compared to LAMP was also calculated to provide a quantitative comparison. Table 4 provides the standard deviation and relative absolute error between LAMP, LSTM, and SimpleCode.

**Table 4: Standard Deviation and Absolute Percentage Error to LAMP for Heave, Roll, Pitch, and Starboard Bow Relative Motion**

DOF	LAMP	LSTM	LSTM $\epsilon$	SimpleCode	SimpleCode $\epsilon$
Heave [m]	0.472	0.462	2.1%	0.507	7.5%
Roll [deg]	1.397	1.322	5.3%	3.464	147.9%
Pitch [deg]	1.154	1.142	1.0%	1.108	3.9%
Stbd. Bow Relative Motion [m]	1.567	1.547	1.3%	1.887	20.4%

The LSTM method provided an improvement in standard deviation estimate relative to LAMP for each degree-of-freedom. While SimpleCode provides a reasonable estimate in heave and pitch, the roll prediction is significantly over-estimated, which also affects the calculation of the starboard bow relative motion.

While SimpleCode was able to capture generally the heave and pitch statistics, the SimpleCode model diverges spatially in the wave field relative to the LAMP model. As a result, the ship responses between SimpleCode and LAMP are uncorrelated. Table 5 lists the average correlation coefficients for heave, roll, pitch, and the relative motion of the starboard bow between LAMP, LSTM method and SimpleCode.

**Table 5: Correlation Coefficients between LAMP, LSTM and SimpleCode for Each Degree of Freedom**

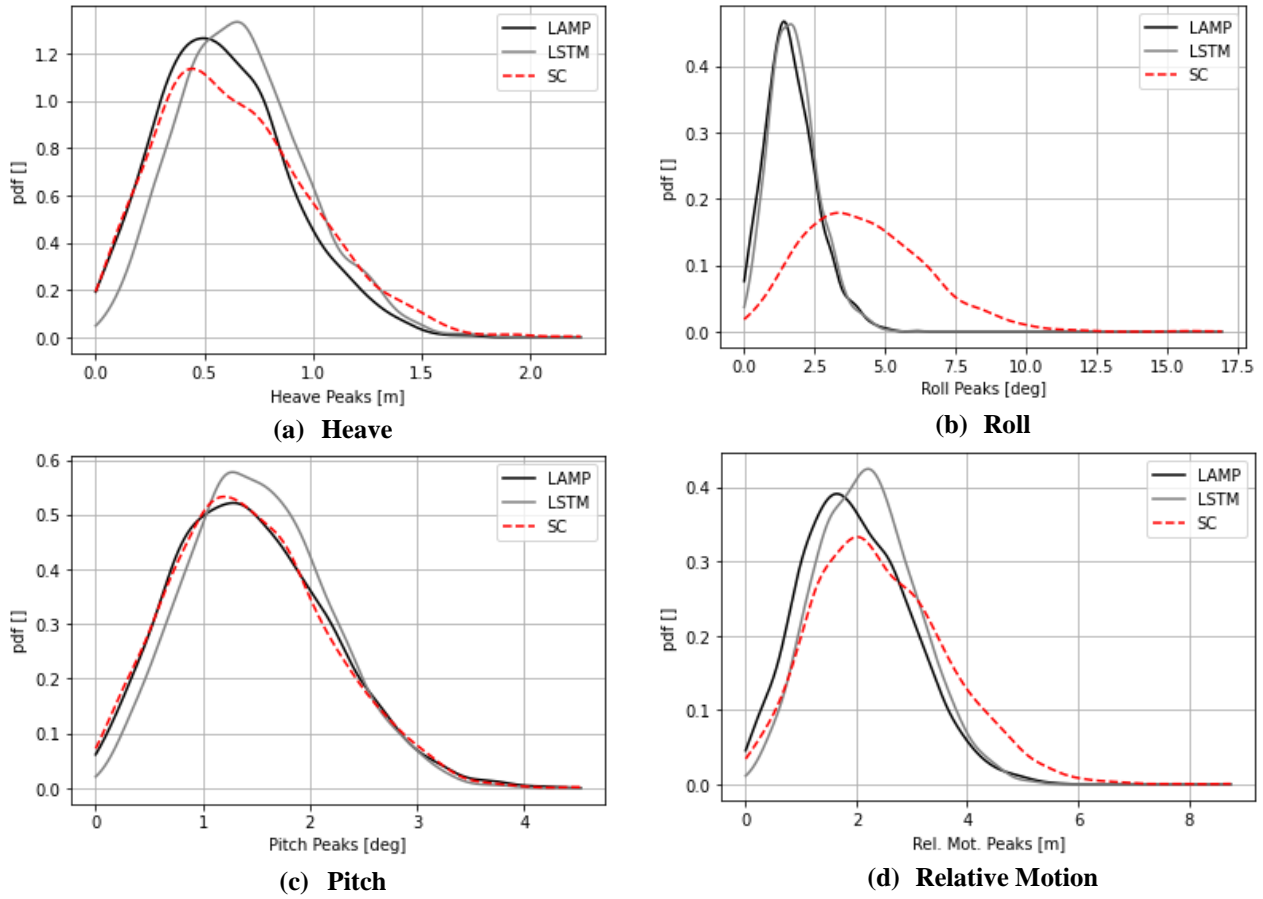

DOF	LSTM $\rho$	SimpleCode $\rho$
Heave	0.945	0.000
Roll	0.967	0.001
Pitch	0.980	0.001
Stbd. Bow RM	0.964	0.003

The LSTM method shares a very high level of correlation with LAMP across all degrees of freedom. The high level of correlation is imperative in the estimation and identification of extremes or large peak values. In the following section, the peak and time series maxima behavior are investigated.

## Peak Behavior

To investigate the behavior of the peaks for LAMP, LSTM, and SimpleCode, the maxima between zero-up-crossings were tabulated across each test realization for each degree of freedom. Figure 3 provides the kernel density estimates of the PDFs for heave, roll, pitch, and relative motion of the starboard bow for LAMP, LSTM, and SimpleCode (SC).

**Figure 3: Peak PDF Comparison for LAMP, the LSTM, and SimpleCode**

The most probable peak magnitude (MPPM) and 95<sup>th</sup> percentile values estimated from each PDF in Figure 3 are summarized in Table 6.

**Table 6: PDF Characteristic Comparison between LAMP, LSTM, and SimpleCode**

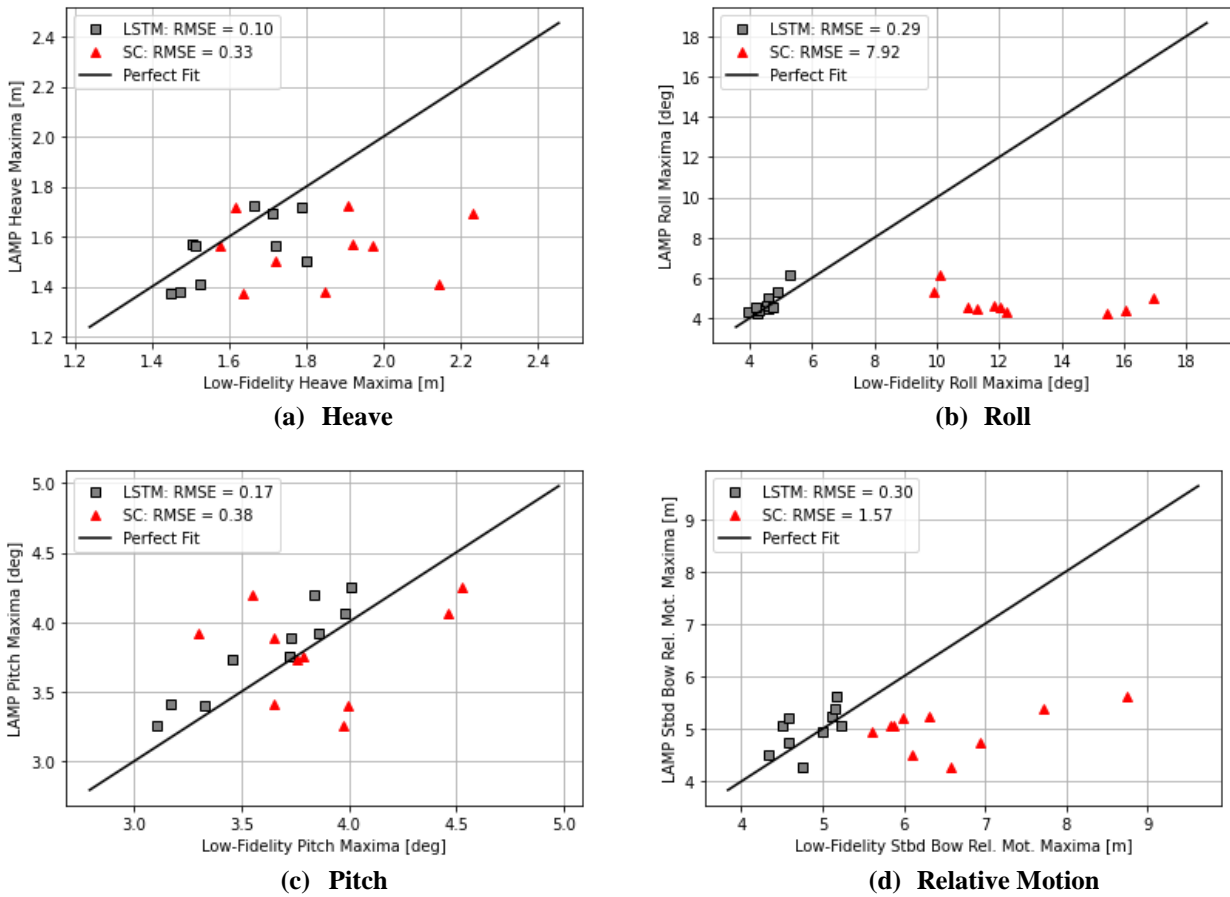

DOF	LAMP MPPM	LAMP 95 <sup>th</sup>	LSTM MPPM	LSTM 95 <sup>th</sup>	SimpleCode MPPM	SimpleCode 95 <sup>th</sup>
Heave [m]	0.50	1.14	0.65	1.22	0.44	1.28
Roll [deg]	1.41	3.36	1.65	3.37	3.35	8.22
Pitch [deg]	1.28	2.72	1.28	2.76	1.20	2.73
Stbd. Bow RM [m]	1.65	3.70	2.21	3.77	2.01	4.62

In general, the LSTM method over-estimates the most probable peak magnitude but generally captures the tail behavior produced by the LAMP simulations. The over-estimation of the moderate peaks is likely a result of a high-frequency modulation that was generated in one of the LSTM networks. An example of the modulation is in the pitch time series section in Figure 4.

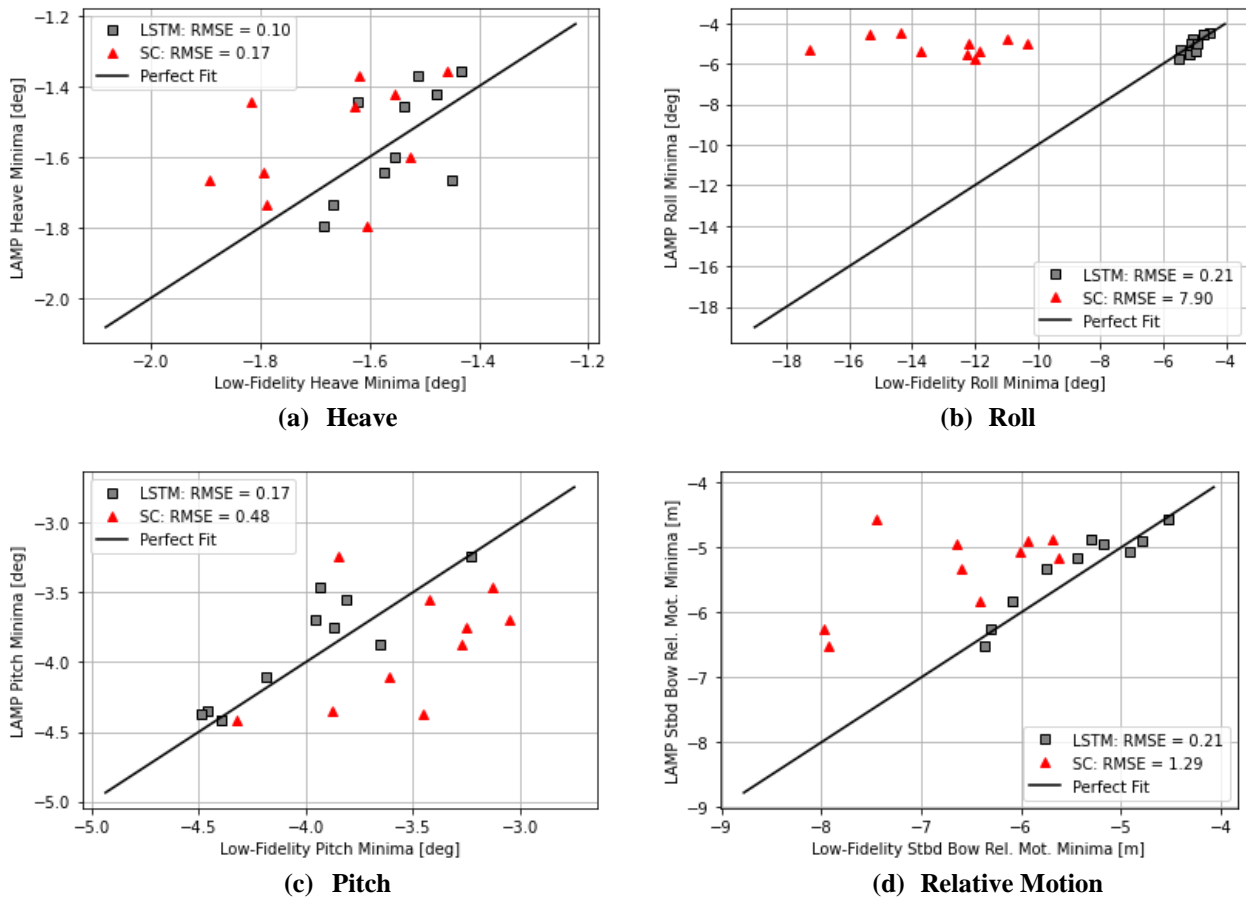

**Figure 4: Pitch Time Series of LAMP, the LSTM, and SimpleCode (SC)**

The modulation in Figure 4 near the moderate peaks could likely be attenuated with a low-pass filter. Still, the LSTM method is a good estimator of the peaks, particularly in the tail of the distribution. SimpleCode again is a reliable estimator of heave and pitch. However, the SimpleCode peaks are completely uncorrelated to the LAMP peaks and are not necessarily good predictors for a given realization. To test the predictions across realizations, the time series minima and maxima were gathered from the 10 test realizations for each degree of freedom in SimpleCode and the LSTM and compared directly to the corresponding LAMP time series maxima and minima for the given realization. Figures 5 and 6 show the maxima and minima comparisons for each degree of freedom along with the root mean squared error relative to LAMP.

**Figure 5: Time Series Maxima Comparisons**

**Figure 6: Time Series Minima Comparisons**

An important quality of a good qualitative predictor would be for the largest value in the predictor set to line up with the largest value in the test set. The wave realization that produced the largest magnitude LAMP value should also produce the largest LSTM/SimpleCode value. An absolute conclusion cannot necessarily be made with a small dataset of 10 values but the general trend of behaviors can start to be identified. In general, the largest magnitude LSTM events line up with the largest magnitude LAMP events. While the wave field in SimpleCode was produced with the exact same phases, the global position of the SimpleCode model diverges from that of LAMP; therefore, the time series maxima and minima statistics do not necessarily align with that of LAMP. To be able to identify the largest LAMP time series maxima is very important because as the sea state increases, more non-linear effects are included and SimpleCode no longer is a good quantitative estimator of LAMP. Without the ability to estimate the quantitative extremes or identify qualitative extremes, SimpleCode alone cannot reliably identify extreme conditions in early stage design. However, with the LSTM approach, the issue of identifying the qualitative extremes is addressed but further testing must be done in higher sea states for the quantitative extreme estimates.

## CONCLUSIONS

An objective of this study was to assess the potential feasibility of a data-adaptive multi-fidelity seakeeping model for use in early stage design. Data adaptive tuning (or correction) of reduced-order model predictions have been implemented based on training with higher fidelity ship motion response data. From these initial results, this approach provides a plausible means for improving the performance of a reduced-order model for ship response estimation.

LSTM neural networks have been incorporated as part of a multi-fidelity approach for prediction of 6-DOF ship motion responses in waves. LSTM networks were trained and tested with LAMP simulations as a target, and SimpleCode simulations and wave time-series as inputs. LSTM networks improve the fidelity of SimpleCode seakeeping predictions relative to LAMP while retaining the computational efficiency of a lower-fidelity simulation tool.

The LSTM neural networks trained through a hybrid approach comprised of a physics-based model and data-adaptive stage. The results indicate that the LSTM architecture is an improved predictor of the LAMP time-series maxima and first-order statistics compared with SimpleCode.

In practice, an entire matrix of condition combinations would be run through the seakeeping software to determine an operating envelope for each sea state. To account for the many combinations of conditions, especially in the early design stage, to obtain accurate but rapid estimates of these statistics is vital. The LSTM method provides a basis for addressing this problem in reducing the time to produce many realizations of different conditions quickly with a level of fidelity approaching a higher-fidelity code like LAMP. Of course, to be feasible, the method must demonstrate extensibility to other sea states, relative wave headings, and ship speeds to effectively reduce the computational effort. Still, even with training and testing on a single environmental and operating condition, the LSTM method could produce many higher-fidelity realizations in a relatively short period of time, which would be valuable for estimating extreme characteristics.

Based on the results of this study, the two-stage LSTM architecture trained to correct SimpleCode global positioning is a suitable candidate for further investigation and application to extreme event predictions.

Potential future work includes:

- For prediction structural loads, accelerations, and resistance.
- Extending assessment to cover a range of wave parameters including significant wave heights, modal periods, ship speeds, and relative wave directions.
- Application to other hull form geometries.
- Evaluation of LSTM network configurations in terms of hyperparameters and prediction performance.
- Investigation into Bayesian LSTM networks to include uncertainty in time series predictions

# Digital Shipbuilding – Needs, Challenges, and Opportunities

Jose Jorge Garcia Agis<sup>1,\*</sup> and Per Olaf Brett<sup>2</sup>

## ABSTRACT

*Ship design firms, shipyards, and ship equipment manufacturers – the shipbuilding industry or just shipbuilding, must adapt their products and services' deliverables to the steadily evolving expectations of the stakeholders in the market.*

*Digitalization and the use of computational tools have been suggested as the effective means to meet such challenges. However, many anecdotal statements and industry recognitions have expressed concern that such efforts have proven less effective than should be expected and promised, and opposite to what many application suppliers advertise. It is argued by this paper that such a situation is experienced because of, among other explanatory factors, incompatibility, lack of proper protocols for information sharing and isolated implementation efforts in single departments rather than a holistic organizational approach. The lack of full understanding of the ship designer's role and responsibility as the main facilitator of such a change process is also recognized as a clear weakness in the effort of successful digitalization of shipbuilding. It is argued that such a vital transformation process cannot be left alone to the software application providers, despite their size and dominance.*

*This paper explains and discusses why this situation is experienced and indicates what improvement measures could be introduced to counteract the opportunity loss. The article addresses five potential digital service deliverables that could complement the existing service delivery of shipbuilding operations and thereby increase competitiveness and market attractiveness. These services include a) vessel support and control centres, b) performance monitoring, c) maintenance management, d) spare part handling, and e) life cycle assessment (LCA). The article also reflects on what implications and consequences this development has on the ship designers' work and their firm's adaptation to new services' demand in the shipbuilding market. The paper concludes with some reflections on the actual implementation of these services, highlighting challenges and further opportunities.*

## INTRODUCTION

Ship design firms, shipyards, and ship equipment manufacturers – the shipbuilding industry or just shipbuilding, must adapt their data-based deliverables to the steadily evolving expectations of the stakeholders in the market, and adjust their value chain positions and interrelationship with relevant project stakeholders to achieve maximum value creation and competitiveness. This will require going beyond traditional and existing ship design and shipbuilding activities and tools. This is much in line with

our recent observations that market expectations are quickly moving towards a more integrated demand and supply situation for products and services. Such services are: - environmental performance of vessel; - performance-based and predictive maintenance; - autonomous operations; - sustainability reporting; - green loans, - emission regulations; - real-time performance evaluation and optimization; - recycling of vessels; - reuse of materials, equipment, systems equipment, vessel and fleet traffic and port operations and their complementary product tools. Efficient communication and information exchange channels must be set up between these downstream services and upstream ship design solution work activities to provide continual feedback and feed-forwarding to secure effective operational decision-making support. Hence, the complexity and uncertainty of such decision-making related to shipbuilding – ship design and erection, and ships-in-operation will continue increasing (Brett et al., 2022; Ebrahimi, 2022; Garcia, 2020).

The interrelationships among stakeholders involved in shipbuilding projects, manufacturers, other service providers, work processes and tasks performed by each engaged actor, have become a "spider-web"- type network of information exchanges and transaction-oriented situations to support the identification, collection, collation, storage, and dispersion of such information and or data. Value chain communication needs and appropriate exchange channels, tools, and formats have, therefore, grown considerably – in scope, extent, and use. A worldwide shipbuilding activity exists out there, where owners and financiers can be in one region, the ship designer in another region, the shipyard and equipment supplier in a third or fourth region, and other stakeholders like flag state, class society, and charterers (cargo owners) being in an "opposite direction of the world". There is no doubt that such a dispersed network of project actors and information exchange model could not easily function without the internet and other efficient satellite-based communication facilitating channels.

What a few decades ago was a simplistic discussion between two actors in the value chain about what engine size and type to install onboard – a choice among 2 to 3 relevant options, has today, become a much more complicated and cumbersome multi-stakeholder involved decision-making process where fundamentally different energies (fuels), energy converters (engines, fuel cells), energy storage and transfer systems came into place. Further, varying expectations and regulations as to energy usage and emissions are making the selection of the power plan of a vessel a dynamic, rather than static choice. Most of the vessels being designed today will have to make modifications to their power systems during their operational lifecycle. Similarly, the expectations of the end users of the vessels are changing, requesting much more transparency about the vessels and their operations. Emission reporting has already become a requirement for many vessels. Financial institutions, charterers, and cargo owners frequently request information about the markets within which the vessels are operating, the stature or physical condition of the assets in use, and the economic situation for the vessel and owner - and the list of information users continues. More than ever, operational and performance data and information exchange relating to capabilities and functionality have become a central element of vessels' design, ship erection, and operation, and must be well planned to maximize the benefits.

In shipbuilding, we, therefore, see a rapidly growing tendency of increased interaction among stakeholders in the maritime value chain and the need for improved information exchange. Digital connectivity increases in most organizations due to the pressure outside by customers and other stakeholders. But also, internal needs relating to work process harmonization and enhanced value creation employing new products and services are growing. Looking from a multi-modularity and interdisciplinary point of view, it is crucial to understand how to make seamless exchange interphases and data transfer protocols from one stakeholder to the other and between ship designers, shipbuilders, and system suppliers. Yet, the authors suggest that today, shipbuilding organizations should think about their digital connectivity around the system they are or represent and the new added value activities to be created step-by-step. This will mean that ship designers in their preparation of a ship design solution and the shipyard, must take into consideration these new challenges and promising digital solutions. The appreciation of current data availability, storage capacity and increasing capabilities of software applications are key drivers in opening new business opportunities, and the emergence of big data analyses and artificial intelligence (AI and generative AI) bring them further capabilities that will undoubtedly enhance our understanding of the extended potential. The way we perform design work or ship construction work today, and how we treat and store information, will enable (or constrain) the potential services that shipbuilding companies can perform in the future.

Figure 1 depicts an overall situation of shipbuilding activities, which need to be interconnected and as seamlessly as possible ensure that critical information is relayed among the elements of the digital business model or value chain elements for shipbuilding.

**Figure 1. A digital business model for shipbuilding.**

Unfortunately, there is no general framework or architecture for digital connectivity or data description to be easily enabled and implemented. Such a broader digital generic connectivity system is missing. Shipbuilding is a small and special industry, requiring specific architectures that, due to limited volume sales potential, few are interested in developing. Requiring, therefore, a strong collaboration between ship design software providers, data and document management providers and shipbuilders (Gaspar et al., 2023). Such lack of digital architecture for shipbuilding delimits the overall understanding and opportunity search for the full exploitation of digital ecosystems and their virtual interoperability. An example is the application of virtual reality (VR) tools in early concept ship design, which have been claimed to potentially provide efficiency improvements to the overall process (Schiavon et al., 2019). The author's previous recent research has concluded that the use of VR in conceptual ship design has revealed that very often its application is time-consuming and user-case limited, resulting in an extensive "nice-to-have" feature, and not a means to improve efficiency (Garcia et al., 2020). In the future data economy, the question is, therefore, not anymore who has the monopoly of the data. The question then becomes how to make the organizations interoperable and build new capabilities to exchange the data/information with the domain of their business interoperability (Arola, 2018; Keane et al., 2017).

This article briefly discusses aspects of such a new complex business situation. Certain interoperability aspects mentioned above are deliberately left out of the discussion of reasons for the consequent length and comprehensiveness of the article. This article, therefore, focuses primarily on some of the lifelong data exchange and service opportunities and reflects what implications such new business interoperability can have on the ship designer and the shipyard operations – other aspects of digitalization in shipbuilding are left out in this article. At the same time, it is fully appreciated that the development and implementation of such new technologies will be challenged by high cost, and human-resources consumption, since the industry is characterized by having a fairly short time horizon for their investments, and are deeply conservative when it comes to new ways of doing things (Keane et al., 2017). Considering these premises and difficulties of directly connecting technological developments to growth in revenue and profits - competitiveness, historically it has taken time for such improvement efforts to become realized and derivative effects to come to fruition.

### **From vessel to "system of systems"- thinking**

Given this new situation, it is tempting to make a parallel to what contemporary systems thinkers claim: " that the whole is more than the sum of its parts and that everything is interconnected" (Jackson, 2019). They suggest that you must always start with the whole system because you need to know everything to know anything. Further, unless you know the whole system, you cannot justify acting because you can never anticipate the results. When it comes to digitization of shipbuilding, it is argued in this article that, a similar systemic approach is necessary to reveal as many of the drivers and enablers elements and causal factors influencing.

Hence, expectations and demands from shipping companies as to the delivery of a vessel and the services related to it are also changing. This requires going beyond traditional ship design approaches and traditional shipyard activities and the maintenance and repair work during the lifecycle of the vessel. Market expectations are developing towards a more integrated delivery where aspects such as environmental reporting (environmental footprint in design, production, operation, and recycling phases),

performance- and predictive-based maintenance, autonomous/remote operations, etc. A traditional basic design drawings package with complementary outline specifications and supporting analysis reports is simply not sufficient any more as transaction and information documentation between the service provider and buyer. Such needs for increased information exchange and life cycle follow-up possibilities of assets or services being provided over time, must be catered for within the delivery of the vessel in the future, either by the ship designer, the shipyard, equipment supplier and or other third parties or all of them together.

Thus, what is delivered is no longer just a vessel design solution or a manufactured ship, it is a three-level information or data-producing repository: level I – the ship as a twin, level II - the ship when in operation and at level III, the ship in operation within the broader shipbuilding values chain model – a system of systems.

### **What does digital mean?**

Digital is a broad term. It is sometimes uncritically used as a badge to represent anything new. Often it is applied to distinguish from other practices, behaviours or products that are simply older (Fletcher & Adolphus, 2021). "A wider appreciation of the increasing scale and wide-ranging impact of digital technology in contemporary economic and social activity leads directly to an acknowledgement of the importance of developing and maintaining a digital presence", they conclude (Dörner & Edelman, 2015) On the other hand, argue for digital to be seen less as a thing and more as a way of doing things. In this way, they argue, "digital is an enabler for action, not a goal in itself". Examples of this interpretation are digital marketing, digital business; e-commerce; or even email. In this article, we address digital as various actions to accomplish improved competitiveness and attractiveness – making a preferred supplier in line with the Dörner and Edelman (2015) interpretation. Thus, we discuss in the further of this article, digital shipbuilding, web-based ship design, and digital ships-in-operation.

### **Digitalization – a deeper view**

What is digitalization? The use of digital technologies to change an organization's business model to provide new revenue and higher value-producing opportunities – the process of moving to a digital business (*Digitalization*, 2024).

It is already well recognized and argued by many that digitalization has and will have a profound impact on how to execute shipbuilding business and create sustainable ship design-related products and services in the future. But it is important to notice that digitalization transforms products from physical goods into tangible services, in many cases into manipulated data and data analyses results as the "product or service". It supports the increased speed at which products and services are being produced and implemented using digital processes, data, and communication channels. Digitalization efforts support viewing work processes, products, and services as a source to generate and collect more information - leading to increased value creation.

There are 12 critical elements of successful digital transformation: 1. End-to-end connectivity, 2. Data and work process management, 3. Configuration management, 4. Model-based application structures, 5. A digital thread, 6. Digital twins, 7. IOT and PLM platforms in place, 8. Changing views of product – into servitization, 9. Big data analytics, 10. Data governance and security, and 11. Digital expertise and skills transformation (MacKrell, 2024).

Among the 12 digitalization enablers, the digital thread (6) is looked upon as the most important because it relates to the communication framework that allows a connected data flow and integrated holistic view of the value chain and business concept throughout the products and or the services' delivered lifecycle across traditionally siloed functional perspectives.

Furthermore, digitalization has three powerful implications for product and service development and lifecycle management: - ensuring that all stakeholders and transformation processes are fully accessible with access to all data, - reversion of data files (documents) into data records to unlock them and reducing them as typical stumbling blocks, because nobody remembers where to find them. Finally, big data is at the heart of digitalization.

### **Digitalization has no "borders"**

The pivotal digital technology for realizing all these opportunities is the internet and satellite communication. Without this well-established, open, and global network of computing working under the same protocols and processes, what we now label digital would simply not work. Increasingly the purpose of computers, laptops, tablets, and mobile phones is to have physical touchpoints on the internet (Fletcher & Adolphus, 2021; Gaspar et al., 2014). "Exploiting the unique characteristics of the internet is at the heart of understanding how to create and capture value through a digital presence", Fletcher and Adolphus (2022) state.

This digital mindset must go beyond the traditional digitalization of design and production processes; however, it is here where it should start. The information generated during the design and production phases of the vessel should lay the foundation for the future of digital shipbuilding operations. History, however, shows us that digitalization and the use of computational tools for analysis and drawing production have proven to be less effective than should be expected and promised. It is argued by this paper that such a situation is experienced because of incompatibility and lack of proper protocols for information sharing. The authors of this paper are convinced that digitalization has been performed in silos, one activity at a time, and without an overall holistic plan. Furthermore, overambitious software application development – one system (suites) for all purposes and needs, rather than building up a step-by-step functionality and allowing a robust platform infrastructure. Also, underestimation of the time of populating these new applications and costs of training and start-to-use initiatives have among other factors contributed to the digitalization disappointment, so far. This does not mean gains cannot be met or arrived at, but it will take time, extra costs, and pain to get there.

The toolbox of shipbuilders (incl. ship design companies) typically consists of system platforms, 3rd party special applications, and internal proprietary bespoke software applications. Such systems are normally not developed with effective connection protocols for the exchange of design and production information with external receiving applications. This situation creates significant extra work and costs, deteriorating the competitiveness of the industry. Alternatively, shipbuilders can go in with a full software system supplier delivering all the tools, becoming too dependent on the single software supplier.

This paper explains, discusses, and suggests improvement measures for how to enhance the effectiveness and efficiency of these information exchange processes. Enhancements are closely linked to a better understanding of how the information stream flows among all relevant stakeholders with an emphasis on addressing commercial, operational, and technical matters. This article discusses the overall competitiveness challenge the shipbuilding industry is exposed to and the need for change to meet present and future opportunities. The availability and use of current computational tools are limiting shipbuilders in expanding their business due to this fact. This article builds on the foundation that the European-funded SEUS project (Gaspar et al., 2023) is building, and will explore complementary digital business opportunities for shipbuilding companies.

### Digitalization - "raison d'etre"

This article highlights the importance of making connections and building relationships through digital channels is part of the purpose of creating a worldwide presence as a part of competitiveness building, also it emphasizes a mindset of sharing, openness, and transparency so vital for ESG recognition. Digitalization should help us to a) improve profit margins of design, engineering, fabrication and assembly (traditional shipbuilding deliverables), and b) exploit opportunities within aftermarket activities and early design.

Figure 2 shows how the estimated average performance yield of different activities of the shipbuilding value chain for two different periods for a selection of Norwegian firms. The results for 2006/12 are the performance yield during "good market" conditions and the 2016/22 results represent "bad market". There is a significant level difference among the main value chain activities – typically, the upstream ship design-focused business produces acceptable, but low-profit margins, ship erection or hull production notoriously low partly unacceptable profit margins, and downstream "aftermarket" or life cycle-oriented services produce profit margins at encouraging and attractable high levels. When we know that the downstream value chain activities yearly and over the lifetime of the vessel, typically 20 to 30 years, bring in such high-profit margins successfully positioning oneself in that part of the shipbuilding value chain is a "no-brainer", if possible, when, and for how long.

**Figure 2. Profit margin of different activities in the shipbuilding value chain.**

Many shipbuilding companies are currently in transition wrt to what future avenues to take: i) status quo – stick to what you already are and try to make the best out of it, or ii) adapt to the new demands and transition to digital shipbuilding – develop expertise and skills to handle a new digital service portfolio. Such a transition will require a fundamental change for most shipbuilders. A new "digital mindset" (Leonardi & Neeley, 2022) must be established to understand how data, information, and digital solutions can enhance the existing business model or completely revamp it.

**A DIGITAL FOUNDATION FOR SHIPBUILDING**

Product lifecycle management (PLM) is the process of managing product-related design, production, and maintenance information. PLM integrates people, data, processes, and business systems and provides a product information backbone for companies and their extended enterprises. The word PLM is not new in the maritime industry, but to date, its implementation is scarce and to some degree not successful (Recio Rubio et al., 2023). A strong reason for the limited implementation and success is that in most cases a standard PLM structure has been pressed into a ship design and shipbuilding process. Hence, pushing ship designers and builders to change the way they were working, rather than adapting the PLM software to the peculiarities of the industry.

An internal survey among employees of a Norwegian shipbuilding firm identified some key challenges that employees considered as the anchors for further improvements in productivity and process efficiency (NA, 2018). These challenges include: i) product and design data are not organized – because every project has its peculiarities, the same information is not available for all the projects, and if so, it might have a different name or be stored in a different folder; ii) company knowledge is residing in people's heads. The experience and knowledge developed at ship design firms are primarily tacit, hence difficult to store and retain isolated; iii) very limited reuse partly because required information is hard to find. For early concept development, when a project is finished without a shipbuilding contract, the documentation is rarely reviewed and categorized. Thus, the re-use of this information is limited, as people might not be aware of it, or don't have contextual information about the project or the status of the documentation; and finally, iv) multiple specialized software packages model the product from different viewpoints, making difficult and time-consuming the synchronization of design changes. Different areas of a ship design firm and shipyard have their specialized software, which requires either a strong connectivity between software solutions, or manual work to ensure correct product definitions. The structural department might use a different hull definition than hydrodynamics, and the general arrangement might be drawn based on hull lines from the 3D rendering tool. Hence, three hull designs need to be synchronized and calibrated to secure mirror definitions.

A summary of the main challenges identified in the survey is depicted in Figure 3 below.

**Figure 3. Challenges identified on current data and project management practices at Ulstein.**

Interconnectivity among software utilized in ship design and shipbuilding activities is essential to secure a smooth and effective implementation of PLM. Figure 4 reflects the complexity of software integration. The overview does not include all the functions or software used by a ship design firm or a shipbuilding company, but the most critical ones. The integration of systems/software needs to follow a stepwise approach. Each stage of the implementation process pursues covering one of the expectations and goals defined.

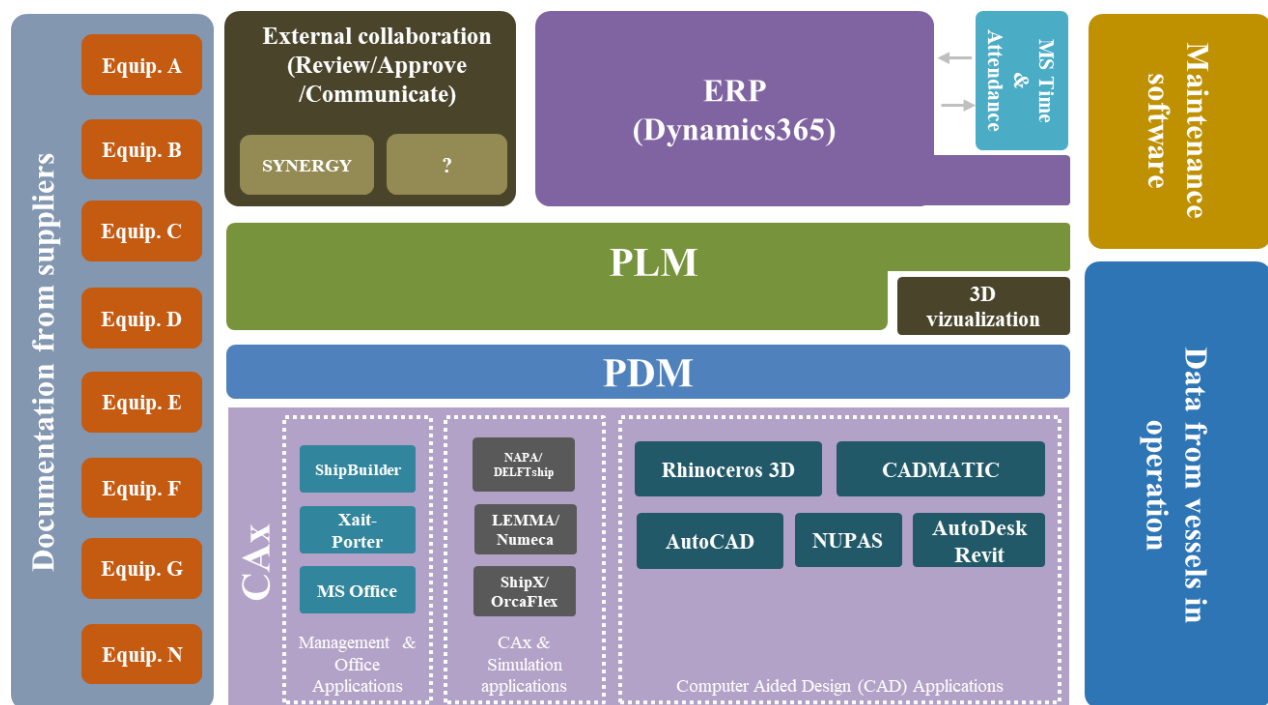

Figure 4. Software integration and complexity of shipbuilding projects.

The partners in the European-funded SEUS project are working on establishing this platform, integrating a well-established project and data management tool (Contact Software) into a well-established design tool (Cadmatic) (Gaspar et al., 2023). Connecting these two central elements of shipbuilding projects, the consortium targets 30%-time savings in engineering activities and 20% in production and assembly. Achieved by architecting and developing an integrated platform for a combined and open solution incorporating CAE, CAD, CAM, and PDM software and testing it at shipyards. The new platform solution will be built with the best European shipbuilding expertise provided by academic and industrial partners. Figure 5 organizes the value chain activities, indicates from estimates the savings potential in time saved, and suggests by what means these accomplishments will be achieved (Gaspar et al., 2023).

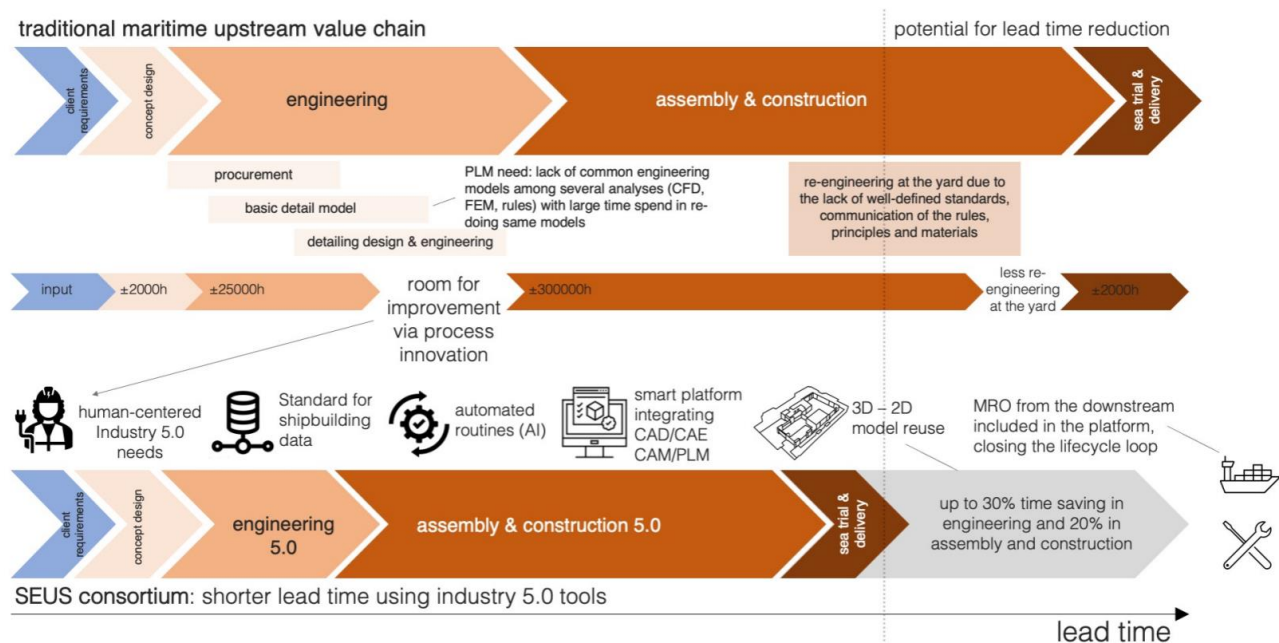

Figure 5. Potential for lead time reduction predicted by SEUS project (Gaspar et al., 2023).

But when all that data information has been generated, captured, structured, and stored during the design and building phases, is there any potential for further value creation during the operational and scrapping phases? What can be done with such information, and who will do it? It is argued in this article that such achievements can be obtained by carefully planning, developing, and stepwise implementing a digital business model for shipbuilding representing the digital thread or electronic communication structure necessary to integrate both upstream and downstream shipbuilding value chain activities.

## A DIGITAL BUSINESS MODEL FOR SHIPBUILDING

Business models describe the design or architecture of the value creation, in other words, describe how a firm plans to deliver value to its customers and be left in a position to perform such businesses sustainably, including, but not limited to economic and financial performance (Teece, 2010). The business model of ship design firms relies on the provision of ship design drawings and calculations (Lagemann et al., 2024), while the shipyard focuses on the construction of vessels and integration of vessel systems. As the ship owner takes control of a vessel after delivery, the state of the vessel traditionally transforms information-wise from "as built" to "as is". Thus, from the moment a change is made onboard when the ship is in operation – either by the crew, equipment supplier or by a third-party shipyard, the documentation of the vessel and its systems become quickly incorrect or at worst, obsolete. Hence, as the "ownership" of the "ship description"- specification, drawings and complementary vessel records/reports, changes hands in the value chain, the information and interrelationship interphases are challenged wrt what, when, and which formats shall be used and who is responsible for making the transactions take place. Who is responsible for the updates, collection, and safe and secure storage of this information? During the lifetime of the vessel, typically, this information transfer process can take place several times, when the ships are shifting ownership hands. Over time, it has been experienced that it is difficult if not impossible to start working on the upgrading of the vessels from a re-designing and refit standpoint without updated and "as is" past and present condition status documentation of the ship.

Traditionally, such downstream activities have been carried out by "any ship designer and shipyard" available with the capacity to handle such a particular vessel – not necessarily the ship designer and or shipyard that originally built the ship. Such situations represent very often a major hassle to the shipowner in terms of providing needed original – "as built" documentation of the vessel to be shared with the repair yard. Far too often has the vessel that has been subject to alterations underway – in some cases larger upgrades or conversions have taken place, in other circumstances has the vessel been subject to minor changes of which in many cases, the complementary documentation of these changes is non-existent or at best poorly described and supplied. No doubt, therefore, it is critical to the owner and repair yard that upgrading the information history of the vessel is well documented and preferably can be supplied electronically and efficiently shared with relevant stakeholders. To counteract this lack of "as is" information, many repair yards, and consultants have had to 3D scan the whole ship or relevant parts of it and reproduce 3D work drawings for progressing in the task at hand. Such expensive and time-consuming extra work would be unnecessary if proper digitalization of shipbuilding was in place.

Yet, these "anyone" shipbuilding outfits have no original deep understanding and appreciation as to how and why the vessel was designed, constructed, and equipped the way it was and what are the accompanying operational premisses or/and restrictions. The original ship design firms, designers, and shipyard building the ship, are, therefore, in a much better and partly unique position to take a central role in this integration exercise and required digitization development. They are the ones who know best the original vessels and most likely are best prepared to make changes to the vessel within recognized knowledge boundaries. They know what equipment is onboard, why, how, and where it is installed, and the performance expected of them. This alternative approach can contribute to the development of a successful digital business model (Teece, 2010, Lagemann et.al 2024), since only the designer and builder have this information in their possession, and thereby represent barriers to entry for other competitors. A change in the shipbuilding value chain as suggested, could, therefore, make life easier for most relevant stakeholders in the value chain. This does not mean that the ship owner has to re-position their ships to another place in the world to get the downstream repair work done, but using a properly planned administration of the lifelong maintenance of the vessels and a digital business model for shipbuilding in place, the owner should be able to trigger the original manufacturers of the design and ship, as they do with equipment suppliers today, set up a trusted digital communication and information channel among the original manufacturers and system suppliers, the chosen "any ship designer and shipyard", the classification society and other relevant stakeholders, if any, and the owner himself in a seamless way. Eventually, "everybody" will be a subscriber and supplier to a sort of a new "Open Vessel Description (OVD-DSP)" facilitating and encouraging an all-in-one open system approach. May be very optimistic, but an ideal goal to be reached, by the few or the many...

Ship owners and other value chain stakeholders are dramatically changing and increasing their expectations towards ship designers and shipbuilding companies, as they are required to operate in a more dynamic environment where information flows are increasing and operational information demands growing. Environmental regulations require shipping companies to report their emissions, to qualify the fuels and technologies they use. What is the vessel prepared for... and how future rule-proof is it? Investors require information regarding level 1, 2, and 3 emissions of the vessel – including its production, operation, and scrapping. Charterers demand real-time information on the operations of the vessel. Vessel managers need robust and reliable

information about the state of health of the vessel, its systems, and equipment. So, if all this information is required, who will enable it and who will take benefit of it and generate value out of it? Figure 6 depicts a conceptual idea of Ulstein when it comes to what an evolving digital business model for shipbuilding could look like.

**Figure 6: The conceptual idea of Ulstein's digital business model for shipbuilding.**

At present, it is experienced by many that there are expectations and deliverables gaps in the way we operate, communicate and exchange information with each other. Some of them are listed here for the sake of good order and make up a list of future "work orders" for the big OVD-DSP initiative – "be aware before you start factors": suppliers will not agree to a single delivery platform being the single source of information. Stakeholders are not able to agree upon an exchange format standard; interphase and systems' architecture standardization is going slow or not there in the first place, initiative-wise; ship design business and work process, as well as ship production workflows, are inherently complex, processes with intricate details, and very often varies depending upon the new building project at hand; different work processes require different software tools and application adaptations – and triggers the "chicken and egg" problem of what comes first – the established work process or the software application way of doing it; different operations have and require different set of tools, machines, facilities, amenities; location, people, knowledge, expertise and skills; domain logic, etc.

Digital shipbuilding is, therefore, all about connectivity – not just the physical and digital ship design and shipyard operations, but also with and among all relevant value chain stakeholders – the future interrelationship "spider-web".

In the following paragraphs, we have summarized and briefly described some of the downstream digital business model initiatives. In this article, we will not repeat some of the upstream digital business model initiatives relating to the existing vessel concept design phase challenges, because these have been revealed and discussed in previous IMDC papers to the extent thought necessary to capture the total digital idea (Brett et al., 2022; Brett et al., 2018; Keane et al., 2017; Ulstein & Brett, 2012, 2015). However, it is stressed that certainly do these upstream and downstream digital model initiatives belong together and should be considered as a whole – the overall digital thread of shipbuilding.

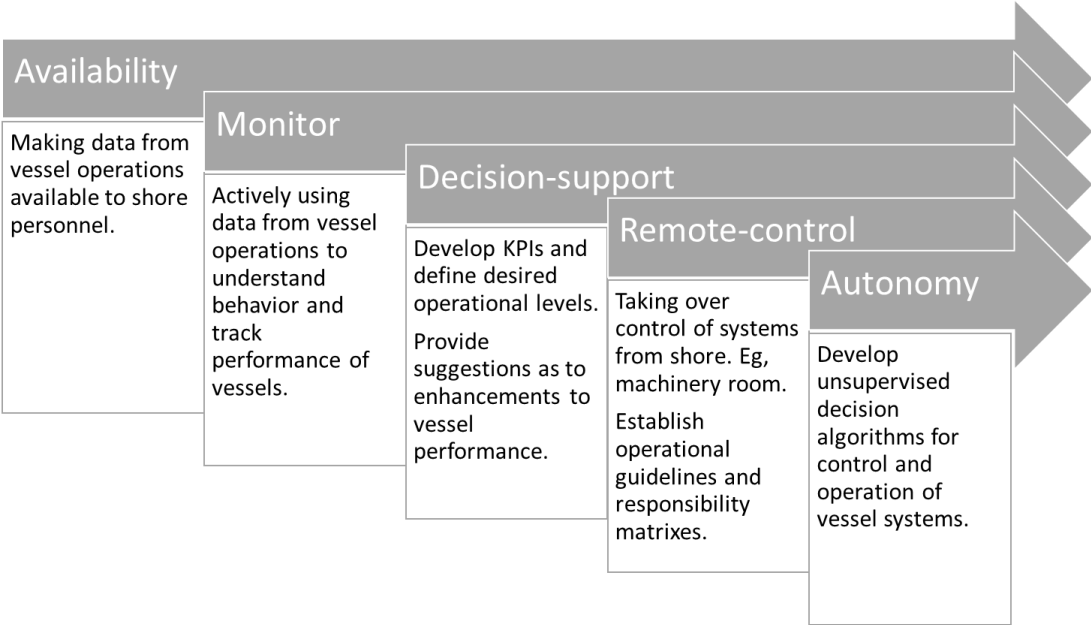

## **TYPICAL DOWNSTREAM DIGITAL BUSINESS MODEL DEVELOPMENT ACTIVITIES**

### **A: - Vessel support and control centre (VSCC)**

The focus on the development of autonomous vessels addresses aspects such as reducing operating costs – primarily linked to manning, but also maritime incidents linked to human error. Partly or fully autonomous ships have attracted a long debate across shipping, with several projects implemented recently to integrate them into commercial operations. However, the slow

regulatory framework will likely not allow fully autonomous ships to mature and be integrated into commercial maritime operations for at least another 10 years. Even if we are technology-wise there, we won't be there regulation-wise, as regulation needs to be harmonized all over the world.

Autonomy will follow a step-wise implementation in the shipping industry, and as such, the value chain needs to develop services that support such a development process. Figure 7 shows a plan for how vessel autonomy can be stepwise developed building on the foundations of vessel monitoring and remote control. Such a plan builds on IMO's four degrees of autonomy. Degree one represents the first three stages: availability, monitoring, and decision support, degrees two and three relate to remote control, and degree four for full autonomy. In other words, before we see fully autonomous vessels, we will see a wide range of vessel support and control centres.

**Figure 7. A stepwise implementation of remote-control and autonomy services.**

Remote support and control of ships (as a stage towards full autonomy) is growingly becoming a reality. Remote control technology is increasingly seen as a game changer for moving some crew onshore, rather than developing a completely unmanned ship, and at the same time, increasing the visibility of vessel operations. Intelligent software systems and enhanced ship-to-shore connectivity have laid the groundwork for the growth of remote solutions and autonomy in shipping. These control centers have as natural first step the machinery systems of the vessel. In other words, the establishment of the engine control room of a vessel ashore. This will require changes in maintenance procedures, as maintenance of systems might be performed only when the vessel is ashore.

**B: - Performance monitoring**

Vessel performance monitoring is the process of collecting and analyzing data related to the operation of a vessel. The data collected typically includes information on fuel consumption, engine performance, navigation, and other factors that affect the vessel's efficiency and environmental impact. The type of data and the factors that are relevant to monitor will change from case to case, strongly driven by the type of operation the vessel is designed to perform. For a work vessel, it will typically, include power generation, propulsion, environmental forces, and control system dynamics. With these insights, the performance monitoring system helps operators to achieve reductions in resources and materials consumption, fuel, emission, and maintenance costs, without compromising vessel redundancy margin or operating efficiency. Based on analyses, operational advice is provided to managers, and officers onboard and onshore on what work processes or machinery can be stopped to run the ship operations more efficiently. This type of advisory service is dynamic – if a change in the production level falls or weather conditions, power plant system, or DP system settings are detected, the performance monitoring system recommendations will change accordingly.

Performance monitoring involves the measurement of performance over time against index indicators of performance or key performance indicators (KPIs). Thus, it helps in identifying performance gaps and therefore be used to improve performance on a continual and or continuous basis. It provides an opportunity to exploit the full potential of optimizing the commercial,

and technical operation of and the navigation and control of the vessels when at sea. Monitoring the performance helps the organization and ship in providing accurate, objective, and balanced feedback to the ships, management and anyone involved with the upping of operational performance.

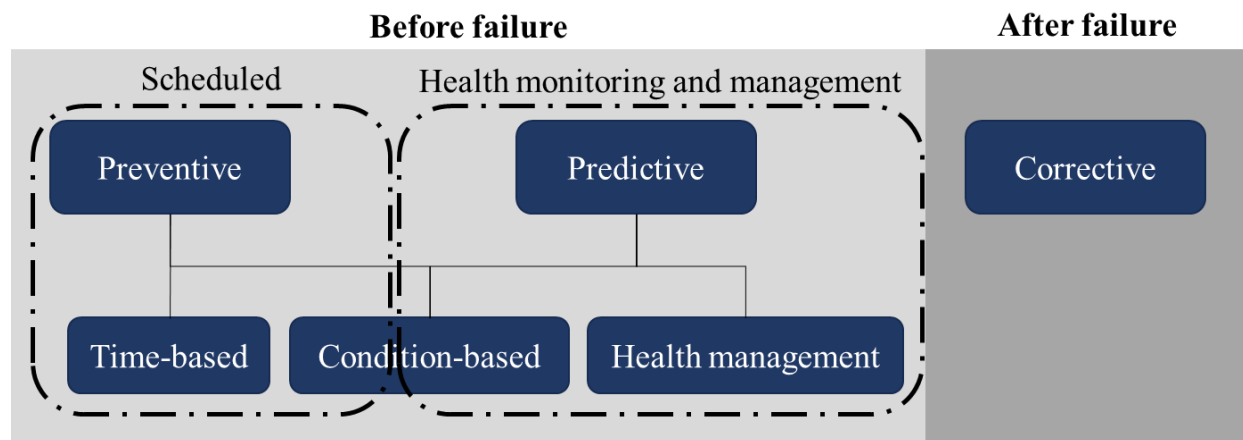

Performance monitoring is often broken down into five basic steps: i) Definition of performance objectives (or KPIs), ii) communication of objectives with vessel crew, iii) planning and defining operational guidelines, iv) monitoring operations and work progress, and v) correcting or rewarding performance.

### C: - Maintenance management

Vessel maintenance ensures the safety of the vessel, its crew, passengers, and cargo. Regular inspections and upkeep prevent accidents and mitigate risks at sea, minimizing the potential for undesirable events. Furthermore, vessel maintenance is vital for operational efficiency, but also the development of the 2<sup>nd</sup> hand value of the vessels in case a sales and purchase situation should pop up.

In the maritime world, a well-maintained ship is a happy ship - and a happy ship makes a successful business! Ensuring that vessels are in top condition isn't keeping them afloat; it's about safety, efficiency, and, of course, profitability. A well-maintained ship is a safe ship. Efficient ship operations depend on well-functioning systems and machinery. Routine maintenance checks and timely repairs help prevent breakdowns and reduce the risk of costly delays. After all, time is money in the maritime industry, and every day spent at the quayside or dock instead of at sea can have significant financial implications. With the growing emphasis on environmental sustainability, effective ship maintenance plays a crucial role in minimizing a vessel's ecological footprint. A well-maintained ship is a comfortable and enjoyable workplace for the crew. Good living and working conditions on board can boost morale, leading to better productivity and crew retention rates. A ship is a significant investment, and proper maintenance helps protect its value. So, how to ensure that a vessel is well maintained without overinvesting in preventive maintenance? How to ensure a homogeneous maintenance plan across a fleet of vessels? And how to evaluate what is good enough when considering a maintenance plan?

Preventive, predictive, and corrective maintenance are the 3 main forms of maintenance strategies of which time-based, condition-based, or health monitoring philosophies are derivatives of preventive or predictive maintenance. Time-based preventive maintenance is a method relying on fixed intervals maintenance intervals. This can either be related to time (days, months, or years), or cycles (system starts, running hours, accumulated cycles). Intervals are typically defined by the original equipment manufacturer (OEM), or defined in the guidelines of the shipping company. Most of these intervals are defined based on very risk-averse profiles. In other words, they suggest maintenance or replacement of components way before the system degradation would otherwise require. This approach is the most common in the industry. Condition-based maintenance is a further development of preventive approaches where maintenance periods are driven by the condition of a system. This requires the definition of performance factors and thresholds to which maintenance is required. An example is RAM and CPU utilization (%) for computers onboard.

**Figure 8. Classification of maintenance strategies. Adapted from (Montero Jimenez et al., 2020).**

Predictive maintenance is a further development of condition-based maintenance involving systematic measuring, monitoring, and evaluation of equipment conditions across time. The condition evaluation that results allows for the forecast of the remaining life for components. Predictive maintenance is applied when mechanics or software can be examined for the health of equipment before it breaks down, this is also called proactive maintenance. Health management is a variant of predictive approaches

focusing on the performance of the vessel and its systems as a totality, and not on single-equipment isolated. Corrective maintenance, on the other hand, is introduced when the upkeep is relatively straightforward. When anything goes wrong the mechanic, software or hardware needs to be repaired. Figure 8 describes the various maintenance strategies commonly practised in shipbuilding.

Real-time data available from vessel operations measuring events, such as running hours for engines, or start-ups for pumps, are a first step for health monitoring that can enable efficient predictive maintenance practices. Fatigue measurement is a natural next step, which involves the measurement of vibrations in critical components such as propulsion lines or electrical motors. Operational data from the vessel coupled with performance thresholds defined during the design or production phase (sea trials) are also meant to evaluate the health of components and to consider maintenance actions. In any case, health monitoring requires the definition of a threshold and the association of a vessel component or system. To monitor the health of a main engine, for example, it is required to have access to detailed data from the engine and to have a deep understanding of when a component of the engine starts deteriorating and risk increases for breakage. Such information needs to be identified and structured during the design and construction phase, so it can be used during the operational phase and the final recirculation of the vessel. Without a data structure of vessel components and their characteristics, the shipbuilding industry will not be able to go beyond traditional preventive or corrective maintenance.

#### **D: Spare parts handling**

Vessels need to replace some of their components over their lifecycle. This includes everything, from critical components such as electrical motors, anchors and chains, or switchboards, to minor components such as doors, tables, or TVs. What seems an easy task can become very complex when relevant information about the system to be replaced is not available or has become obsolete.

For shipping companies handling components that need to be replaced onboard can represent a significant load of work. Identifying the component and its characteristics, identifying and requesting quotations from relevant suppliers, evaluating quotations and technical feasibility, purchasing, coordinating shipping, reception and installation. It sounds like the day-to-day job of a purchasing department at a shipyard, rather than a shipping company. So, why aren't shipyards offering this service to their customers? Is it because they lack an information system to manage vessel components after the delivery of the vessel? Shipyards could make available a list of all the components installed on their vessels, with characteristics, and contact details to the supplier. Hence, when needed, a new component could be ordered "almost" automatically. And probably at a better price than what the ship owner could, as the yard will probably buy larger volumes.

#### **E: Life cycle assessment**

Life cycle assessment (LCA) is an approach and very often complementary analysis tool to assess potential environmental impacts throughout a product's life cycle, i.e., from natural resource acquisition, via production and use stage to waste management (including disposal and recycling). New national and international regulations require shipping companies a detailed report of emissions related to their operations. Investors and charterers go, in many cases, one step further, requiring Level 1, 2, and 3 emissions. In other words, emissions relating to the entire lifecycle of the vessel involve production, operation, and scrapping.

The emissions related to a vessel start with its production. The production of steel as raw material, its manipulation and integration in a complete hull. The production of pipes, cables, pumps, isolation, and other materials runs in parallel with the production of the hull. All need to be transported to the outfitting yard and integrated into the vessel. So sea trials and the operational life of the vessel start. Here is primarily energy consumption and the emissions related to it. Figure 9 showcases an LCA evaluation for a commissioning service operation vessel (CSOV).

Sooner than later, lifecycle emissions will impact the selection of a vessel design and the location where it will be built. For ship designers and builders, this means that LCA methodology needs to be integrated as part of their design decision-making toolbox. For us is still unclear how and when LCA should be integrated in the design process, but what is clear is that it needs to be integrated somehow.

Figure 9. Example of an LCA evaluation for a CSOV vessel.

## IMPLICATIONS TO MARINE SYSTEM DESIGN

For various reasons being addressed in this article, information, and data sharing from and between all these downstream services and their need to receive correct information from the upstream digital thread activities (ship design and ship production and equipment systems' integration) needs to be managed efficiently. It is obvious to the authors that all this intra- and inter-activity communication is simply not possible without a new overarching vessel digital business model for shipbuilding. Without it, necessary fidelity, and accuracy in providing better and robust management and operator support will suffer. It is, therefore, timely and important to address and start a sincere discussion as to how we can proceed from here.

The implementation of a digital business model like the one discussed and proposed in this paper has significant implications for the expertise, the processes, the tasks, and the activities carried out by ship design firms. Extracting the value of data and information collected during the design process, construction and operation of vessels will require a mix of mathematical and statistical knowledge, programming skills and ship design expertise. The latter is abundant in ship design firms, but the former are scarce and need to be recruited or trained. New processes need to be defined for the additional deliverables, and existing processes, related to traditional ship design and ship production activities, must be revised. As an example, the delivery of maintenance procedures – preventive or predictive – will require the definition of maintenance periods or performance levels. Today this information is not collected in design processes nor during the construction of the vessel. Rather, it is available on user manuals provided by equipment suppliers. Thus, new processes must reflect activities where such information is identified, collected from suppliers, and integrated into the PLM system. A similar example is the delivery of life cycle assessments for vessels, reflecting the emissions related to the design, production, operation and scrapping phase. Such deliverables, which are already being requested by shipping companies operating in the offshore wind market, will include an additional optimization goal, a Design-for-X (Papanikolaou et al., 2009). Targeting low emissions during the overall lifecycle of the vessel, as opposed to during the operational phase alone, will add a complexity layer for ship designers. But will also require the identification, capture and storage of emission information related to the production of equipment, systems, and vessels.

## CONCLUSION

This article argues that digitally linking data and processes streamlines shipbuilding activities, and can bring ship designers and shipyards back into a more central position in the coordination of the overall digitalization efforts of the marine industry. However, to take on such a challenging endeavour will require determination, financial strength, patience, expertise, collaboration and a bit of luck to become successful. Competition about the position-taking in the shipbuilding value chain is unavoidable, but, everyone can participate in contributing proportionally to the digital thread and establish themselves within the overall vessel digital business model for shipbuilding in an open and orderly fashion thereby creating a "win for all" situation ahead.

In this way, tedious and manual operations can be partly eliminated and sometimes minimized to those that add specific value. Business relationships can become more sustainable by removing ambiguity and misinterpretation, compliance assurance, and allowing controlled changes and better handling of business operation dynamics over time. Flexibility in digitalization systems' building is a must and should allow process variation, without having to use extra resources to manage and operate digital infrastructure. So far, the experience is that well documented, and controlled digitalization business processes are easier to sustain. It is expected that upstream digital twins of products, production, and downstream services will eventually lead to new value-creation opportunities. Digitalization efforts, so far, have shown potential for improving collaboration and innovation throughout the ship's lifecycle and should be further motivated. Fragmented and experimental digitalizing has anecdotally,

proven beneficial to ship designers, shipyards, suppliers, and owner/stakeholders and improving their overall chain value. Particularly digital twins and various integrated and partly disjointed digital thread elements in operation have been documented to positively impact ship-lifecycle performance. In Ulstein, we have also found increased digitalization to contribute to more sustainable product and service development and more transparent administration of shipbuilding projects. But, so far, not as a surprise to us, for uncertain reasons, more qualitative gains are registered, than quantitative ones, like for example economic results of our operation.

While agility and innovation are key to success in a rapidly changing business landscape, there is no excuse for not preparing your organization. Digitalization helps achieve agility, innovation, and new business developments. The march of technology, digitalization included, is widely recognized as unstoppable. Today we see only the beginnings of the connectivity that will be required and imposed by competitors. Digitalization is a journey – where to go and what roadmap to follow.

The marine industry is conservative – tend to be late followers in all things digital except for automation and navigation. The adoption of CAD has been focused on being followed by PDM and gradually PLM. Paper drawings do still have a central role – especially in production. Although urgency is written all over digital shipbuilding advancement, we expect this digitization transformation still to take years or decades before full adoption of evolving digital technology is in place and full competitiveness power benefits from it.

It is also concluded that a new effective digital business model for shipbuilding is strongly needed to more efficiently be able to administer the rapidly growing information exchange among stakeholders in the shipbuilding value chain. It is argued that an effective digital business model for shipbuilding development can only take place if all the prime actors in the value chain are participating in the development sufficient data handling rigour is secured, and at the same time, flexibility is allowed in the development process to include the existing, but only compatible myriad of applications, out there. Yet, it is important not to exclude new ship design, ship construction, vessel automation and control and logistics-related, and other business administration-oriented applications. Proper interfacing protocols must be developed internationally and discipline amongst the developers of useful applications must be motivated. At present, it is primarily, the larger ship equipment manufacturers and suppliers, and classification societies that have taken on the spearhead position for these developments. Many smaller and less powerful application outfits, like software provers of administrative software for shipping and independent consultancy firms, are also a part of the group of new business adventurers. So far, these small actors are struggling to establish a critical mass in the market and are notoriously searching for extra funding for their initiatives. Only to a small extent have ship design firms and shipyards seen their natural expanded value chain position opportunity and prioritized sufficient time, money, and expertise to support such a strategic initiative. Not, diminishing the importance of the efforts already realized in building up a full complete digital shipbuilding platform, that goes far beyond today's "ship twin" and "remote inspection" experiments, it is paramount to the authors and argued herein the need for a reorganization of who should take the lead for this development in the future. Although their stature (economics, expertise and recognition) is not an encouraging one, compared to the well-established large and rich equipment manufacturers and classification societies, still will, collaboration and smartness can get them there...

There might be natural and unfortunate reasons for this asymmetry in the lead position of the development and the very late involvement of shipbuilding. If we go back to Figure 2 of this article, it is a fact that shipbuilding is the value chain element actors that have over a long time, yielded the least performance, and thereby have put themselves in a bad position financially, geographically, and expertise-wise to take a lead position in the digitalization project. On the other hand, we can observe that the shipbuilding downstream actors –equipment manufacturers and suppliers have been and are in a different positive and more appropriate position to take on larger and demanding digitalization efforts...

The efficiency of the new "Open Vessel Description (OVD)" digital platform is secured if the ship owner and shipbuilder take the lead together in such a bold endeavour. We recommend that the ship designer – the new naval architect and marine engineer - the business developer, must lead such an effort with the firm and looser inclusion of all relevant suppliers and information takers (users). Since this means that much of the present initiatives and firms' involvement will be challenged a broader type of interest group must come together to coordinate both the standardization work and guidelines for the individual complementary partial software application work. The digitalization efforts will cost money and resources...

# Wither now the Design Building Block (DBB) Approach

Henrique M. Gaspar<sup>1</sup>, Ícaro A. Fonseca<sup>1</sup>, David Andrews<sup>2</sup>

## ABSTRACT

*A description of the Design Building Block approach (DBB) was first published at IMDC1997, followed by a practical realisation presented at IMDC2003, both emphasised 3D as a key element of dialogue and creativity in early ship design. The current article celebrates, at the 15<sup>th</sup> IMDC, this architecturally driven ship synthesis approach with an overview of its fundamentals, followed by a suggestion for an open, collaborative and web-based implementation, and then provides examples that can be used when teaching the approach in ship design. The paper's first part covers the basics of this UCL-developed method, with an overview of the processes, terminology, flow of ship design information, key analyses and key examples published in the literature. The second part focus on an initial attempt to compile a version of this method that can be adapted and implemented in other academic environments, outside the original scope, which was focused on the early stage design of a range of innovative naval vessels. This part of the paper includes an extension of the current taxonomy to commercial vessels, as well as an adapted approach that can be used for ship design teaching and research. Additionally, a compilation of open online stepwise examples is presented, using the NTNU-developed web-based library Vessel.js. These examples cover the basic steps to teach the use of and to readily modify DBB for environments outside the constraints more applicable to multirole naval vessels. The paper concludes with a summary of its main intentions, emphasising the current gap that it is seen to fulfil by compiling the key DBB derived information in a single document. This is then followed by open and online examples that can be readily accessed, modified and expanded.*

## A (NOT SO) SHORT STORY OF THE DESIGN BUILDING BLOCK METHOD – WHY IT FOSTERS INNOVATION

### Introduction

DBB has been explained in many previous papers, here at IMDC and pretty much most of other important maritime conferences and journals, by our preeminent co-author, David. J. Andrews, or by one of his colleagues and students. When the first author proposed the idea of this paper to the third, the core objective was to extract the key elements that makes the DBB one of the few ship design approaches able to produce real innovative designs from the start. DBB has at its core facilitating creative innovation in the *inside-out* conception and so was proposed with future CASD features in mind. In other words, DBB starts with a colour coded, visual and hands-on approach. It starts with the architectural mindset. Consequently, the validation and evaluation of the goodness of the design are part of the intent as was the fact that the ship model could be readily changed.

From the requirements elucidation, (Andrews, 2003a; 2011), overall sketches and formalisation of design margins via the, DBB approach pushes the designer to draw conceptual assemblies which, with modern 3D tools, can be *Lego-like* to

<sup>1</sup> Dept. of Ocean Operations and Civil Engineering – Norw. Univ. of Science and Technology (NTNU), Ålesund, Norway

<sup>2</sup> Dept of Mechanical Engineering – University College London (UCL), London, UK

explore the infinite space of ship arrangements. One may argue that this can be risky, as by stepping out of the traditional reliable evolutionary zone of designs, we are incorporating uncertainty and less knowledge, which may be true. But by having a new ship with at best incremental changes from previous designs, we also have made a stylistic choice in being constrained by the limitations from decisions made decades ago, and thus stagnating the field of ship design. Stagnation, imitation, replication thus oppose any possible Innovation.

It is thus a matter of style (5<sup>th</sup> of the S<sup>5</sup> the traditional focus of the naval architect on the aspects of Speed, Seakeeping, Stability, Strength and additionally that of Style - see Figure 1 and Table 1 in Andrews, 2017) in trading off innovation (and risk) against stagnation (and reliability) during ESSD. At one end of the spectrum, we can skip innovation and just copy the last ship, and we will possibly end up with a reliable, functional and cheap, and existing design. It might (if we are lucky) perform the mission, through the outdated solutions and limitations of the chosen previous design. This *shelf to order* (StO) solution is the bread and butter of ship design, since the majority of commercial ships are designed with functionality and reliability in mind, not innovation.

In this sense, most of the ship design methods taught need to cover the last approach, as starting from a Type Ship/reference ship and making incremental changes to it, which is a useful way to introduce the students to the terminology, trade-offs and challenges of the ship design task. This, however, hinders innovation and, in our personal opinion, removes also the joy of our craft. A young student that chooses naval architecture in her earlier years is attracted by the challenge of constructing large and unique artificial systems, including the freedom to draw, create and explore. We teachers, however, quite soon put aside all of it, pushing the students to rules, regressions, spreadsheets. In many cases the drawing, sometimes only a General Arrangements (GA), is done only at the end, only after all the tabular approach that is proposed in so many books and compendia is finished and approved. A ship design course may force a student to spend more time on complying with rules and criteria, typing these into a spreadsheet, than the real designs tasks involving decision making (see Figure 4, Andrews 2018).

The DBB approach does not jump into the design decomposition so rapidly, rather, it spends more time on providing the basis for elucidating the requirements and establishing limits for each requirement, in the shall / should manner. The functional decomposition, at first, is also less detailed than in traditional approaches (Rawson and Tupper, 2001), as it rarely covers more than twelve functions in the first approach. Each of these functions are indeed connected to Super Building Blocks (SBB), which, by adding a visual representation, improve on the tabular approach. It does, however, require the blocks, and moreover, it gets the designer to assign specific set colours (i.e. Blue, Red, Yellow and Green) to each of the four functional groups (i.e., Float, Move, Fight/Operation and Infrastructure - see Andrews 2018), thus bringing in the visual element right from the start. The design is then made by parsing these blocks into modern CASD software, connecting it to a certain space definition (e.g., taxonomy, such as cargo, weapons, etc.), geometric definition (main dimensions, decks, compartments, etc.), hullform (enveloping the blocks) and consequently the information consequently necessary for the initial naval architectural calculations, such as weights, centres and materials.

The approach to ship synthesis, prior to the use of computers in initial design, was initially continued using computers to speed up the iterative, weight and space, and (intact stability and power estimating) balancing process. This was followed by the computational facility, to explore a wider range of alternative design inputs and hull form relationships, which had been previously limited by manual methods. However, this early stage exploration was still one of a largely evolutionary nature, with weight group balancing by naval architects and draughtspersons drawing profiles and, occasionally, also deck plans. In 1980 the third author presented a paper to RINA entitled 'Creative Ship Design' (Andrews, 1981). The intention in choosing that title was not to imply that ship design as then practised was not capable of being innovative, but rather to make the point that, if naval architects were to fully utilise the benefits becoming available through the veritable explosion in design methods and creative techniques for dealing with complexity, they would then be better enabled to design even more creatively than hitherto. That early paper suggested that designers should focus more intensely, at the initial design stages, on ship architecture – both internally and on the topsides – than was possible before the advent of computer aids. Even that long ago rudimentary computerised graphics were becoming available to designers, and subsequently advances in computer graphics made such possibilities even more achievable, consequently a 2003 paper

entitled: *A Creative Approach to Ship Architecture*, presented a fully achievable architectural emphasis to early stage ship design (Andrews, 2003b).

## The Evolution of the Design Building Block approach

The arguments advanced in the 1981 paper led to a research programme into ship design methodology (Andrews, 1984; 1986; 1987; Andrews and Dicks, 1997) and naval ship design and acquisition (Andrews, 1993; 1994; 2013). It was perceived that the evolutionary approach to ship design, typified by so much of existing design approach and built into most design tools, has become progressively less appropriate. The latter aspect can be illustrated by the following observations made in the 2003 paper:

- a) Dependence on an evolutionary approach is less likely to lead to the production of designs responsive to the accelerating rate of change (Andrews, 2001a), whereas a creative design approach enables exploration of responsive and adaptable design options (Andrews, 2001b);
- b) Potentially better solutions, such as the Trimaran configuration (Andrews, 2004), are unlikely to be considered in an evolutionary approach, while many of the techniques now available are conducive to the search for and development of novel solutions;
- c) These new techniques, in conjunction with a creative approach, are practically indispensable for adequately coping with what has been termed the 'wicked problem' (Rittel and Webber, 1973). This arises in requirement elucidation when designing complex ships (i.e., requirement formulation and design responses are in a circular relationship).

While a research version of what was denoted as a 'Design Building Block' approach to the design of physically large and complex entities had been demonstrated in the 1998 paper, this was written (Andrews 1998) based on a breadboard demonstration using the developments in computer graphics when presented to the 1997 IMDC by Andrews and Dicks (1997). Already a working version had been produced in the form of a classified system, specifically for naval submarine concept design (SUBCON - Andrews et al., 1996), but it was not until 2001 with Andrews final return to UCL that a more general working system was produced and made openly available. It was then possible to demonstrate the approach could be applied to actual (rather than research) design problems (Andrews and Pawling, 2003, 2008). Since it has now become possible to demonstrate that the DBB approach has matured and can be applied to a large range of design studies *for real* (see Sections 6.2 and 6.3 in Andrews (2018) for outlines of published UCL studies). Moreover, regarding ship design as an example of Design on the Grand Scale, this graphical way of proceeding “inside-out” could provide insights relevant to a more general understanding of design philosophy and design methodology.

Before proceeding with the main body of the paper, it is appropriate to acknowledge that there has been a distinct bias towards naval ships in the examples used to illustrate the DBB based themes. This tendency arises from the third author's career as a naval architect working for the UK Ministry of Defence up to 2000, where he was largely engaged in the design of surface warships and submarines for the Royal Navy. We believe that warship design can be said to have made significant contributions to the discipline as a whole (see Andrews, 2010). This assertion is made even though the timescales and very significant resources, invested in the course of many warship designs, dwarf those invested in even the largest and most complex merchant ships.

While it could be argued that a design procedure capable of addressing such a level of complexity in the most complex of naval vessels should be scalable to suit less complex ship design processes, it is open to debate whether the naval ship design environment is disproportionately “over the top” and so makes the procedure – and the associated design philosophy – inappropriate for application to even the most sophisticated commercial vessels. On the contrary it is considered that all ship design is increasing in complexity and that there are growing synergies between naval and commercial ship design approaches, as instanced by the moves to apply naval ship rules and codes of engineering practice to be managed by the commercial classification societies (Gibbons, 1984). Therefore it has been argued that the creative ship design approach advocated, centred on an architectural schema, has a wider applicability to marine design in general.

As stated in the introduction, the 1980 paper concluded that creativity in ship design would be fostered by an approach to the initial ship synthesis which placed greater emphasis on the physical description of the ship's layout. A subsequent justification for this approach to initial ship sizing was reported in a 1986 RINA paper that followed the third author's PhD (Andrews, 1984), an early naval architecture thesis on ship design methodology.

In the 1984 PhD thesis, entitled "Synthesis in Ship Design", the third author contrasted the sequential process of gross ship sizing, followed by hull parameter determination and then architectural and engineering development with the *all in one* or integrated synthesis. This was subsequently confirmed by development of the Design Building Block approach, firstly in the UK MoD's developed SUBCON CASD tool (Andrews *et al.*, 1996) and then the UCL sponsored SURFCON module in the Paramarine CASD system (Munoz and Forrest, 2002). This combination of the ship architectural and naval architectural balanced numerical description served to provide an ability for the ship designer to develop *ab initio* design options, which could consider many of the main ship requirement drivers from the start of a new design study.

## FEATURES OF THE UCL DESIGN BUILDING BLOCK APPROACH

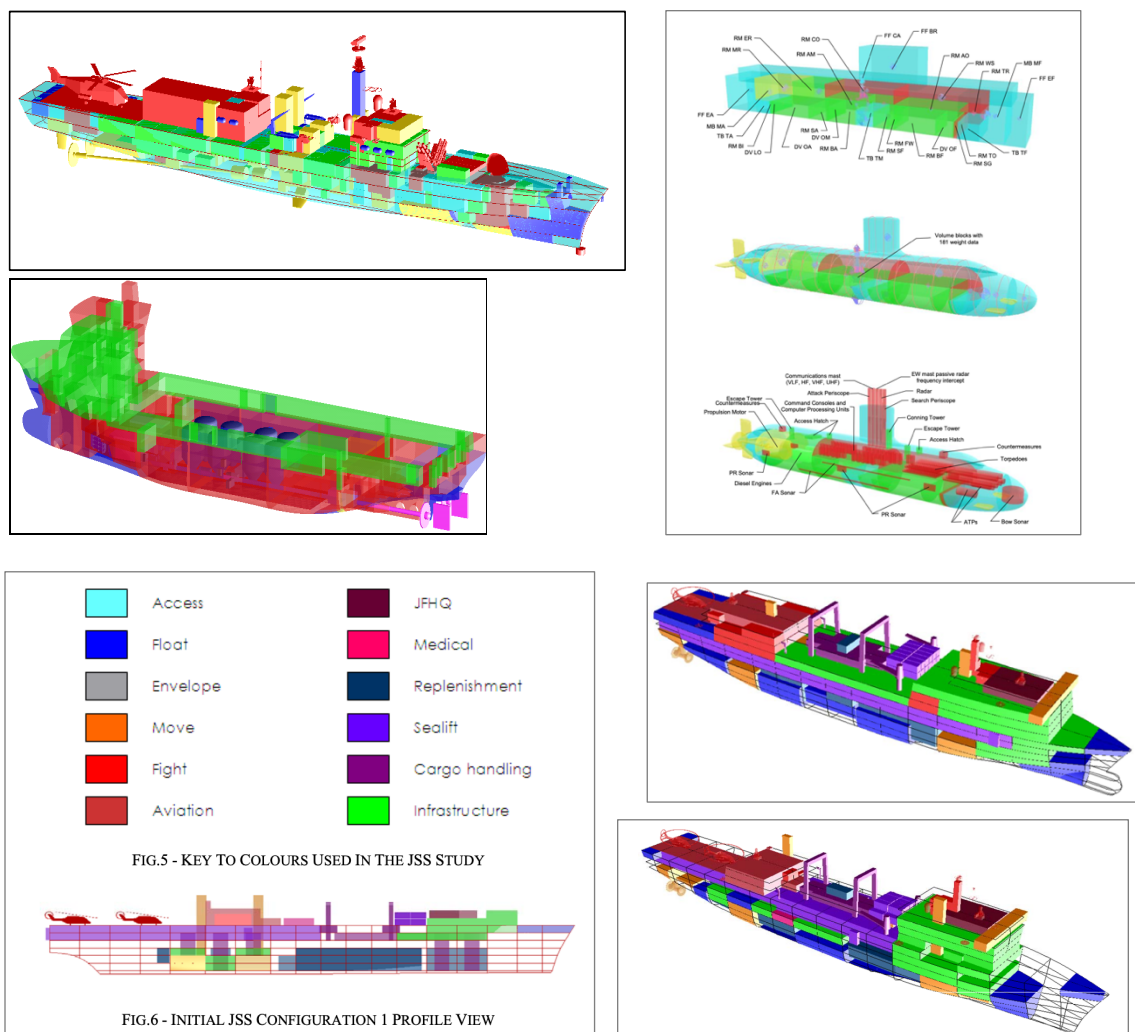

The manner in which the SURFCON tool is structured was described at the 7th IMDC following its beta testing by Andrews and Pawling (2003). Two features are considered worthy of note:

- a) A functional breakdown of the design building blocks adopted for ship description. The categories of the building blocks (i.e., float, move, fight/operational and infrastructure) can be distinguished by their four characteristic colours, plus purple for the main access routes (as a subset of the Float function, highlighted because it is seen as key to the ship's internal layout). This breakdown of the Design Building Blocks was introduced to foster the exploration of more innovative configurations as part of Requirements Elucidation (Andrews, 2003a, 2011), where choice of style is the key to synthesising a new ship option.
- b) Use of the term Master Building Block to indicate how the overall aggregated attributes of the DBBs would be brought together, to provide the numerical description of the resultant "appropriately balanced" ship design. The audited building block attributes assembled within the Master Building Block (constituting the top-level whole ship description) could be used directly by the Paramarine analytical modules, thereby enabling the necessary naval architectural calculations to be performed to ascertain the balance, or otherwise, of the whole ship configuration being derived by the designer.

Each design building block, as the fundamental component of the SURFCON approach, can be regarded as an object in the design space and as a "placeholder" or "folder" containing all the information relating to a particular function within the functional hierarchy. Importantly the "block definition" object permits the designer to add whole ship margins and characteristics, such as accommodation demands, once the "block summary" object has summarised all the information in the top-level block in the building block hierarchy – this is the Master Building Block object. The "design audit" object then allows the design description to be audited for any of the characteristics selected for monitoring, which typically will include style aspects alongside primary naval architectural capabilities. Results can be displayed using the functional group hierarchy; this "design audit" object is assessed for a range of design infringements, by other objects in the design space, and for the balance of the overall ship design from the whole ship characteristics listed in the Master Building Block.

After the SURFCON initiative finished, the exploration of ship internal configuration has been taken further by the Marine Group at UCL, specially the third author and his UCL colleague Dr. R. Pawling (see Section 6 in Andrews 2018). Firstly, in the exposition of the integration of configuration in ship design (Andrews, 2003b) and subsequently by expounding this approach to the design of ships (and other complex systems) to a wider scientific and technical audience (Andrews, 2012). This led to the realisation of the UCL Design Building Block approach, an integrated approach to ship synthesis, at the commencement of the design process, accomplished by using computer graphics to build up the ship's internal architecture, which can then be used to feed the traditional numerical sizing synthesis. Illustrations of the graphics output, linked to the PARAMARINE balanced numerical ship definition, exemplified the UCL DBB approach and taken from the extensive presentation of the architectural approach to early stage design of complex vessels (Andrews, 2018), are given in Figure 1.

**Figure 1 – Examples of Designs made by UCL using DBB method (compiled in Andrews, 2018)**

With an architecturally based description at the early stages of a design, it becomes possible to explore many of the issues which are of direct interest to the client/owner and stakeholders. Such issues - ranging from those concerned with naval vessel's fighting capabilities or the service ship's crew evolutions on board, to the sustainability and supportability of the vessel conducting tasks at sea - are best investigated for their impact on the overall design at the earliest exploratory stages of the design. Thus, for example, layout for weapons effectiveness is a function of topside disposition (Gharib, *et al.*, 2016) and also of internal arrangement and zone logic (Piperakis and Andrews, 2014), both of which are more readily explored through the ship's architecture. Zoning is also relevant to survivability concerns and to the logic adopted for routeing ship systems (Mukti, 2022), and these in turn interact with considerations on producibility and constructional building block arrangements. The initial design can also, with this approach, meet the aspirations of concurrent engineering (Keane, 2018) because the initial configuration is able to reflect not just the traditional focus of the naval architectural aspects of the S<sup>4</sup> as performance drivers but also producibility and even through life supportability considerations.

One clear reason why a 3D *inside-out* approach should be adopted in early stage ship design is that many issues that really ought to be addressed, early in design, can then be more easily considered. Given many of the practicalities of major interest to the client/stakeholders are best revealed by the upper decks/internal configuration definitions, then integrating the architecture into initial concepts must be preferable to the somewhat one-dimensional numeric exploration. However, this would counter the evolutionary set of steps in the initial design development and also the ability of the approach to produce, relatively quickly, an architecturally, numerically and analytically balanced design. Thus, an initial crude internal arrangement can be very useful in grasping the major "blocks" of operational, mobility and infrastructure categories and avoids being distracted by too much detail too early. With respect to the time taken to achieve design

balance appropriate to concept definition, Figure 1 shows four distinct configurations (plus three variants) for a heavy lift LCS Mothership concept, all with some 200 DBBs and balanced in space, weight, stability and powering (Andrews and Pawling, 2004).

We realise that the DBB approach can be used to discuss the *goodness* of a design in many ways, here summarized (from Andrews, 2022):

- a) **Cost.** By better understanding what is wanted and how it might be achieved, the partners in the process are more likely to understand, early in the process, where are the *knees in the cost-capability curves* and how they can be efficiently exploited, and how ships can be cheaper to construct and or operate in preference to adopting the *smallest* (less effective) design.
- b) **Sophistication.** A more sophisticated initial design approach would be able to both feed the marine design research and development and respond better to research innovation coming the other way, often hard to be revealed by tradition numeric concept design outputs. Quite unlike the aerospace industry, for too long the naval ship design community have accepted that it was possible, and therefore justifiable, to not adequately resource the R&D associated with ship design often reflecting commercial ship acquisition practice (Andrews, 2024). In the sophisticated offshore market (Ulstein and Brett, 2015) and cruise ship practice (Levander, 2015) this has become much more nuanced.
- c) **Holistic implications.** An enhanced DBB type of design approach might then help to recover the ship designer's role as *prime inter pares* in the ship design process. This is not trying to recover lost glory but recognition of the naval architect's inherent stance that *everyone else's problems are also the naval architect's, and they can best appreciate the whole ship implications* (Andrews, 2022).

## ADAPTING THE DBB APPROACH

As the DBB approach has been mostly taught at UCL, and most of the examples publicly available are naval service vessels, although these include not just combatants and carriers but also naval auxiliaries which are more like commercial tankers and cargo vessels, (e.g., Littoral mothership, Canadian Navy Joint Support Ship see Andrews, 2018), in the rest of this work we took on the challenge of adapting some its core elements to commercial ship design, both service and transportation vessels. In this context, traditional ship design disciplines like stability, resistance, strength and seakeeping ( $S^4$ ) can be taken out of the scope here, given that these calculations are necessary for any kind of ship, no matter the approach behind its design. Additionally, a better assessment of the ship's centroid, through a DBB description, should improve the initial stability assessment, as indeed would use of DBBs to allocate specific space and weight margins, furthermore, the DBB approach can be used to emphasise stylistic choices. The rest of this paper, thus, focuses on the use of design blocks, that is, this abstract and colourful construction that is the essence of the DBB approach.

We emphasize here some of the elements from the DBB approach that are connected to the fostering of innovative designs. It is important to note that this is a simplification, with the intention of identify the reasoning that leads towards achieving an innovative design culture. For a more detailed description, see references from the previous section.

Table 1 uses the terminology described in IMDC 1997 by Andrews and Dicks, adapted to a more generic description of the ship. In this case, phases like *Weapons and Sensor Placement* becomes *Task Related Equipment Placement*, and *Aircraft Systems Sizing & Placement* is changed to *Payload Systems Sizing and Placement*. Similarly, the block category FIGHT becomes OPERATE. This thus accommodates service vessels, such as Anchor Handling and Towing (winch) and heavy lift (crane), as well as cargo / transport vessel features, such as tanks and cargo areas. The explanation is based on the work of Pawling (2007) and Andrews (2012).

**Table 1 – Adapted DBB Stages to ship types beyond naval vessels (preliminary, first attempt)**

Adapted DBB Design Stages		Purpose	Output
1	<b>Design Preparation</b>		
1.1	Selection of Design Style and Capabilities	- Select type of design in terms of novelty, namely: second (stretched) batch, simple type ship,	Design Framework, containing sketches and sufficient data to start

		<p>evolutionary, simple (numerical) synthesis, architectural synthesis, radical configuration and radical technology (Andrews 2018, Table 3).</p> <ul style="list-style-type: none"> <li>- Select major style aspects, such as hullform topology and technical design standards.</li> <li>- Key design drivers (e.g. mission and operational profiles)</li> <li>- Identify capabilities required, such as speed, range (autonomy), tasks (mission), payload, crew.</li> </ul>	<p>the iterative design process, such as weight and space grouping systems, equipment and subsystems data and validate existing design data.</p> <p>Main design drivers and interactions.</p>
2	<b>Topside and Major Feature Design Phase</b>		
2.1	Design Space Creation	<ul style="list-style-type: none"> <li>- Populating the library of blocks, with geometry and volume definitions, that is, digitalizing the design framework.</li> <li>- Selection of the blocks taxonomy (e.g. FLOAT, MOVE, FIGHT /OPERATION, INFRASTRUCTURE)</li> <li>- Super Building Blocks (SBB) to develop overall layout and spatial style of the design.</li> <li>- Design margins and options</li> <li>- Study of alternative layout styles (parallel development)</li> </ul>	<p>Library of SBBS according to the taxonomy.</p> <p>First design definition (layout style)</p> <p>Shall / Should Requirements</p>
2.2	Task Related Equipment Placement	Estimation of size and weight of equipment related to key tasks of the ship (and support crew, if necessary)	SBB blocks for tasks (e.g. FIGHT, OPERATION)
2.3	Engine and Machinery Compartment Placement	Gross machinery size, based on style, type of fuel, estimated resistance and autonomy.	SBB blocks for machinery (e.g. MOVE, propulsion system)
2.4	Payload Systems Sizing and Placement	Gross estimation of payload, like tanks, cargo areas, deck areas	SBB blocks for payload (e.g. FLOAT)
2.5	Superstructure Sizing and Placement	Gross estimation of superstructure size (bridge, accommodation)	SBB for infrastructure and accommodation (e.g. INFRASTRUCTURE)
3	<b>Super Building Block Based Design Phase (10-20 SBBS)</b>		
3.1	Composition of Functional Super Building Blocks	Prepare an initial layout according to the taxonomy.	<p>Initial estimation of overall vessel size and displacement</p> <p>Initial hullform (topology) and resistance</p>
3.2	Selection of Design Algorithms	<p>Algorithms, constraints and criteria for preliminary analyses (S4 – stability, speed, strength and seakeeping)</p> <p>Scaling and morphing algorithms (hull)</p>	Models for assessment of S4 criteria
3.3	Assessment of Margin Requirements	Procedure to check if the design with SBBS is within the margin requirement (e.g. shall/should), criteria and constraints.	Procedure for evaluation / auditing
3.4	Placement of Super Building Blocks	<p>Placement of SBBS and creating a layout.</p> <p>Checking for necessary additional spaces (e.g. fuel tanks, auxiliary machinery, ballast tanks).</p> <p>Preliminary (parametric) hullform</p>	<p>Vessel estimation with improved topology, subdivision, and high-level functional zoning.</p> <p>Hullform aspect detailed.</p>
3.5	Design Balance & Audit	Iteration to numerical balance: adjusting current design iteration towards balance and evaluation of the requirements	Balanced design, assessed within the criteria, margins and constraints.
3.6	Initial Performance Analysis for Master B.B.	<p>Limited analyses of S4 performance indicator.</p> <p>Weight and volume demand trade-off and iteration.</p>	<p>Preliminary design, rough layout,</p> <p>Main design drivers revealed.</p> <p>Volume and weight estimated, iterated to satisfy gross margins.</p>
4	<b>Building Block Based Design Phase (100 - 500DBBs)</b>		

4.1	Decomposition of Super Building Blocks by function	Decomposition of SBBs into DBBs.  Refinement of design into a level of detail that satisfies the designer as to assess the performance within safe assumption of the margins.  Volume and/or weight definition and geometry	Design Building Blocks (volume, weight, description).
4.2	Selection of Design Algorithms	Approaches to detail the procedures, constraints and criteria for preliminary analyses (S4 – stability, speed, strength and seakeeping).  Algorithms for hullform tuning.	Models for analyse DBBs layout
4.3	Assessment of Margins and Access Policy	Procedure to check if the design with DBBs is within the margin requirement (e.g. shall/should), criteria and constraints.	Procedure for evaluation / auditing
4.4	Placement of Building Blocks	Iterative process of design development, manual and routines.  Detailed study of hullform shape.	Vessel estimation with subdivisions and spaces, and low-level functional zoning (pre-GA).  Hullform shape detailed
4.5	Design Balance & Audit	Iteration to numerical balance: adjusting current design iteration towards balance and evaluation of the requirements with DBBs	Iteration towards balanced design, with main and support related systems (spaces)
4.6	Further Performance Analysis for Master B.B.	Performance analyses according to the mission and taxonomy (e.g. FLOAT, MOVE, OPERATIONS, FIGHT, INFRA filtered systems)	Detailed analyses of the vessel systems and functions according to the requirements, margins, criteria and constraints.
5	<b>General Arrangement Phase</b>		
5.1	Drawing Preparation	Parsing DBB layout (3D) into traditional 2D GA and lines plan.  Detail of DBB into modern 3D GA software	GA, linesplan, 3D rendering

## DEVELOPING DBB IN AN OPEN AND COLLABORATIVE WEB-ENVIRONMENT

### 2D IMPLEMENTATION (2016 / 2019)

Since 2016 an online a simplified 2D design tool inspired by the DBB has been available as a joint collaboration from the first and third author. The first version of the tool was developed at UCL and can be accessed at <http://dbb.ucl.im/2016> (Figure 2a, Piperakis and Gaspar, 2016). An extended version was developed by Kramel in 2019 at NTNU, including a more comprehensive resistance analyses as well as closed-form functions for seakeeping (vertical movement, acceleration and roll), observed in Figure 2b (<http://dbb.ucl.im>, Kramel, 2019). This tool was based on an incipient work from 2015, published last IMDC, attempting to quantifying interfaces in general arrangements (Gaspar and Andrews, 2022).

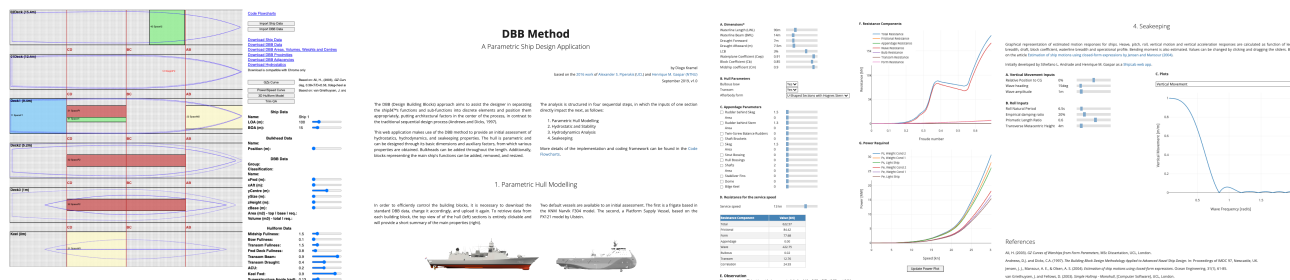

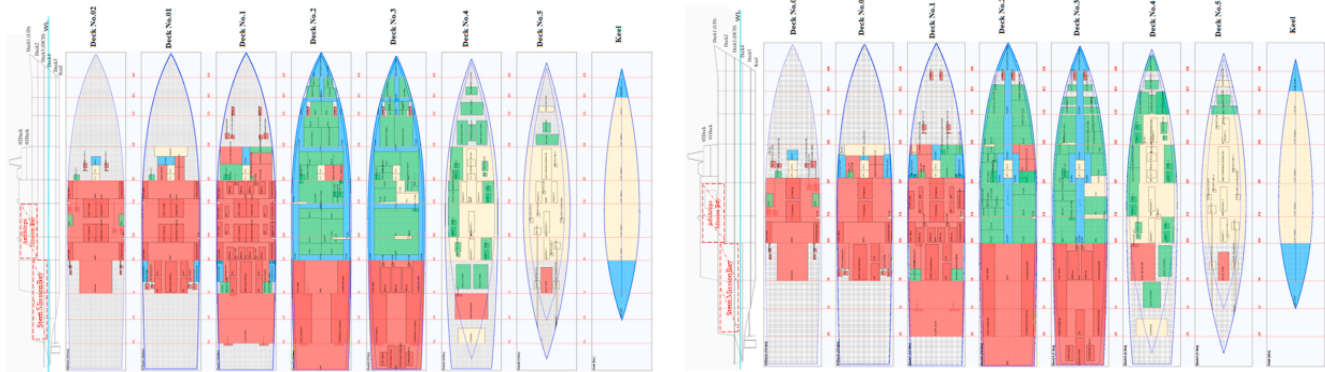

Figure 2 – 2D web-application of DBB by Piperakis and Gaspar (2016) and Kramel (2019)

Kouriampalis et al., (2021) uses this simple (and to be honest not user friendly) prototype DBB design tool to model the operational effects of deploying and retrieving a fleet of uninhabited vehicles (UXVs) in naval surface ships. The design revolves around the innovative idea of a mother vessel capable of transporting and deploying UXVs. The 2016 tool was

used to play around with the blocks, allowing the creation, visualisation and manipulation of the ship's GA. After a layout was preliminary established, the numerical sizing was made in Excel, with detail in traditional CAD software (e.g., Paramarine). Figure 3 exemplifies this work, depicting two different internal arrangements made with this simple and 2D ship layout design tool.

**Figure 3 – Internal arrangements for two design variants of motherships made by Kouriampalis *et al.*, (2021), using the 2D web-application of DBB from Piperakis and Gaspar (2016)**

### 3D IMPLEMENTATION – ADAPTING VESSEL.JS: OBJECTS AS BLOCKS

Vessel.js is an open-source library with tools and methods for Early-Stage Ship Design. The library has been described in more detail in previous IMDCs (Gaspar, 2018, 2022). In short, its main characteristics are being developed in JavaScript and employing an object-oriented approach to modelling of digital ship designs. In the same manner as the 2D DBB implementations, the choice for JavaScript stems from its usage in development of web-based applications and user interfaces. This makes it suitable for creation of interactive apps with graphics, such as charts and 3D rendering. All these come in handy when designing a ship, as they provide immediate understanding of architectural implications of a building block, such as its size relative to the other blocks and its interaction with the hull. Other advantages of web applications are their geographic availability with low threshold to use. Users can access apps on any web browsers installed on modern devices without additional installations. This allows students to promptly access developed examples and start playing with them in the classroom. As the source is open, they might eventually inspect the code to understand the logic underlying the analyses, modify it with different functionalities, or reuse it when creating new applications.

Vessel.js' object-orientation means it resorts to the computational concept of an “object” to represent vessel components and even modules used to run design analyses or render 3D visualisations. An object is a variable or data structure which contains values, functions, and methods, usually combined to encapsulate a significant aspect of computation in a single construct. Object-oriented paradigms support inheritance mechanisms, allowing the creation of several object instances, possibly containing different internal values, from a single blueprint, which might be defined as a “class” or “prototype”, depending on the implementation. Figure 4 shows Vessel.js' overall structure, containing ship-related objects in blue, design analyses in red, and supporting functionalities in white.

A ship model in Vessel.js comprises a hull, major structural elements, or dividers (decks and bulkheads), and internal systems placed into the ship. Those systems are represented with generic objects, named “base” and “derived” objects. These constructs were created to provide the flexibility when addressing different types of vessel components. A vessel object includes weight and spatial definition about an equipment or compartment, possibly with a 3D model to be loaded in its place (if no 3D model is provided, a bounding box is used instead). A derived object defines a specific placement of a base object, allowing its replication in multiple locations inside the vessel. Base and derived objects are not prescriptive as to whether the element being modelled is a tank, compartment, machinery, equipment, or other component. They simply provide a mechanism to define spatial and weight characteristics and replicate them with a 3D visualisation in the design. These functionalities yield an adequate framework to handle the DBB approach, as a base object might also be created to represent a Super Building Block or smaller Building Blocks, depending on the design stage.

Figure 4 – Vessel.JS structure, with core *classes*, *fileIO* and *math* (Gaspar 2018; 2022).

In addition, the web-based architecture allows the vessel as blocks to be combined with more realistic descriptions, such as 3D rendered models from gaming and animation. Such models do not incorporate the mathematical modelling but are important to communicate the idea that blocks (early design) and final drawings (with details, colours and texture) are part of the same process. Figure 5 presents cases with both representations. On the left, the blocks, during conceptual design, can be used for the evaluation of the S4 performance, while on the right is the artistic representation, from 3D art and based on sketches. Additional elements like sea or ocean can be added to aid the communication of the final product.

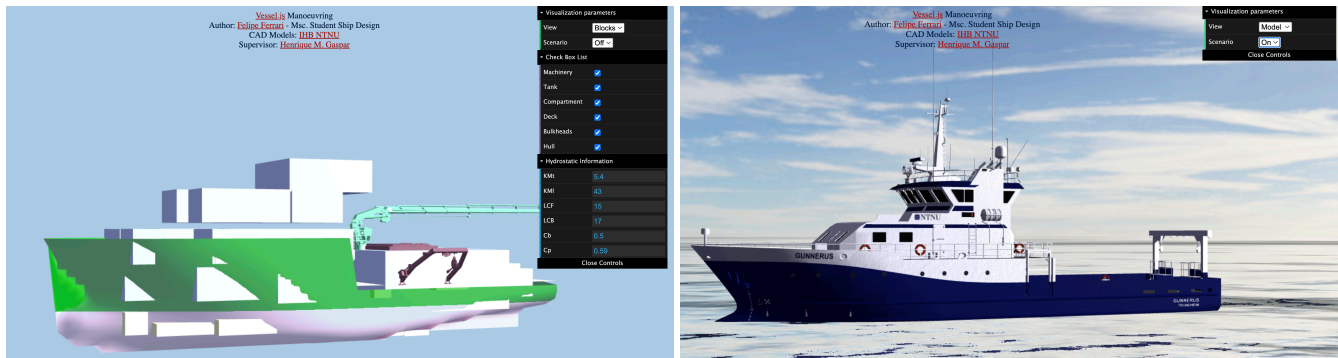

Figure 5 – Vessel.JS architecture blending early design, with blocks and a rough hull (left), used for calculating hydrostatic (right side menu) and the conceptual art in 3D of the same design, with a sea and sky scenario.

## A PLATFORM SUPPORT VESSEL (PSV) DBB CASE

### Design Preparation, Topsides and Major Feature Design Stage

A simplified case study is presented to illustrate the DBB approach using the 3D implementation. The design style was chosen to be that of a modern commercial PSV, an offshore support vessel aimed at transporting supplies between onshore and offshore installations. In that design style, superstructure and engines are placed forward on the vessel, leaving the midship and aft available for carrying cargo, either inside tanks (e.g., for drilling fluids), or on an extensive open deck. Propulsion usually supports Dynamic Positioning (DP) to allow for precise control of the vessel's position in relation to the installation being supplied, which is commonly an oil rig. The design in this case study is inspired by the PX121, a PSV designed and built by Ulstein (Ulstein, 2014).

The taxonomy of building blocks includes the functional group:

- FLOAT: trim and ballast tanks.
- MOVE: propulsion machinery, thrusters and containing spaces, fuel and lube oil tanks, exhaust openings, navigation rooms and equipment.
- FIGHT/OPERATE: cargo decks (open, covered) and tanks.

- **INFRASTRUCTURE:** accommodation, ship's stores and provisions, auxiliary machinery spaces and systems.

The functional groups are not prescriptive and can be chosen by the designer, to better support their activities. Additional categories such as ACCESS might be adopted in more detailed cases and are suppressed here for simplification.

The design characteristics are situated within a range delimited by a common list of equipment and minimum cargo runs and by mobile temporary storage capacity. Shall and Should requirements elucidation are adapted from the 2015 IMDC case (Gaspar *et al.*, 2015), transformed into feasible combinations. In this exercise, it was decided to constrain the overall size (GT) of the vessel, therefore assuming a new feature (e.g., Ice Class) would mean a smaller capability in another feature of the vessel (e.g., cargo size). Also, not all equipment is compatible, for instance *Towing and Salvage* equipment cannot be installed if a full *Fire-Fighting* capability is necessary, and vice-versa. At the end, Table 2 present the feasible combinations considered during the design preparation phase, with seven missions and five PX121 market options.

Table 2 - Missions, market options and compatibility for PX121

Vessel missions and use	PX121 Mrk1	PX121 Mrk2	PX121 Mrk3	PX121 Mrk4	PX121 Mrk5
Cargo Runs	V	V	V	V	V
Mobile Temporary Storage	V	V	V	V	V
Oil Recovery and Stand by			V	V	
Light Well and Extra Accomodation					V
Towing and Salvage		V	V		
Fire-Fighting				V	
Ice Class	*	*	*	*	*

\* - Optional at extra CAPEX

## Super Building Block Based Design Stage

The design was first modelled with “Super Blocks”, meaning major building blocks, which could have been further decomposed into more detailed Building Blocks. This reduced the threshold to modifying the early-stage design proposal and exploring alternative configurations by reducing the number of blocks to be arranged and provided a higher-level view of space utilisation inside the ship. Figure 6 shows the PSV early design modelled in superblocks. Green superblocks represent INFRASTRUCTURE, yellow superblocks are MOVE, and red superblocks are OPERATE.

Two algorithms for preliminary analyses were selected and applied to the design Constrained Linear Scaling (Figure 7) and Block Configuration Editor (Figure 8)

Figure 6 – PSV SBB Representation

**Constrained Linear Scaling.** The first algorithm allows changing blocks' dimensions while maintaining their sizes and positions in relation to each other constants. The algorithm constrains the total volume of blocks to a fixed number but allows the designer to “stretch” the design's main dimensions: Length, Beam, and Depth. This was developed with a web application where the user can use a slider to scale one of the linear dimensions. Say for instance, that increase Length is investigated, then Beam and Depth will then be automatically adjusted by the algorithm to keep overall volume constant. The user might also decide to lock one of the dimensions to a fixed value, say Depth. This will allow them to resize the Length while the Beam is automatically adjusted to compensate for the modification (and vice-versa). The changes in block and hull sizes are rendered in real time. This algorithm allows quick prototyping of design alternatives with different deck areas and identical volumetric capacities, while keeping an overall arrangement with the same relative positions among blocks.

For example: SBB1 must have 40m<sup>3</sup> (criteria x). It can be 2x4x5; 2x2x10. So for each arrangement, L/B/D could be varied, from the smallest L that is acceptable until the largest, seeing real time consequences in B and D. Same with B, and D, with six variations in total, each of them one maximum or minimum, for the same arrangement. One of the dimensions (e.g., L) could be fixed and the others played with (D and B). Each option will then have different tank and deck sizes. If design speed is changed, then the whole design is adapted to it (e.g., larger or smaller propulsion), then the process starts over again.

Figure 7 – Variations pf the SBB PSV design by *stretching* and *squeezing* blocks, maintaining the volume SBBs criteria, while *playing* with  $L \times B \times D$

**Block Configuration Editor.** An alternative algorithm within the DBB approach, involves changing relative placement of the blocks by manipulating them akin to *Lego pieces*. This allows the designer to obtain and evaluate multiple arrangements before further detailing any of such alternatives. Vessel.js' “3D block editor” application allow users to modify design configurations with intuitive manual controls like drag and drop. This expedient can of course be interchanged with the previous one, so that first the designer defines block placement, then adjust dimensions, or vice-versa.

Figure 8 – Preliminary block-editor, able to decompose SBBs into DBBs

### Building Block Based Design Stage

Once design balance is reached, the design is refined by decomposing the Super Building Blocks into smaller building blocks corresponding to the position of specific vessel systems. Figure 9 illustrates the PSV design after being refined with 106 building blocks. Similar *stretching* and *squeezing* was performed, to test 441 different variations of the design according to the criteria.

Figure 9 – 441 solutions were developed, with 106 DBBs, maintaining the fixed GT constraint.

At this stage, a more refined evaluation of design weight, hydrostatics and stability balance is carried. An existing Vessel.js app receives the digital ship definition in JSON format and plots a report containing the list of blocks, with positions and weights, and a summary of hydrostatic parameters for that design (Figure 10).

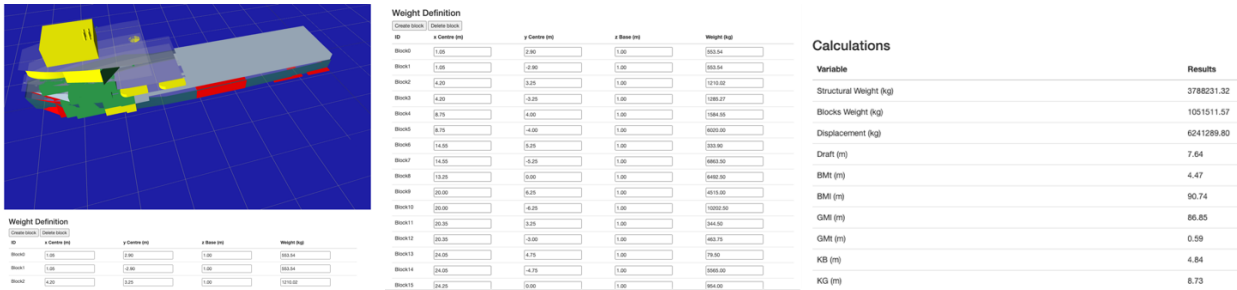

Figure 10 – PSV DBB hydrostatic data using vessel.js library.

### General Arrangement Stage

Resorting to a combination of a 3D-first design approach and tools allows a simple General Arrangement to be automatically generated as a by-product of the 3D visualisation created during the previous steps, instead of having it being drawn manually as a separate document. A specific Vessel.js web app renders top views of the ship model on each deck, resulting in the General Arrangement depicted in Figure 11 As the PSV design was detailed, building blocks were gradually substituted by 3D models of parts and equipment. The GA was consequently updated toward a detailed version adequate to upcoming design stages.

Figure 11 – Simple GA from blocks, adjusting the camera from the web-based render.

## DBB USE IN BSc STUDIES – INNOVATION IN THE SPECTRUM OF SHIP DESIGN METHODS

Since 2017 the second author has attempted to introduce the DBB method in his *SKID2300 Ship Design III - Design Methods* in combination with other methods, in his NTNU modules (Gaspar, 2023). The course is offered in the 5th semester of the BSc in Naval Architecture (Ship Design Course), in Ålesund, Norway. The students at that stage have already learnt the fundamentals of S4 (Andrews, 2018), so they are sure that they can calculate stability, resistance, design a safe hull, comply with regulations and classification, and understanding a (basic) dynamic response of the vessel (seakeeping / dynamic stability). It is one of the objectives of this last course, thus, to present to the students a compilation of more modern and realistic ship design methods. This is given theoretically by the second author, and in practice, by Øyvind Kamsvåg, Head of Design at Ulstein Group (Kamsvåg, 2018). Importantly, this course was designed with the intention of rekindling the students' desire to be creative, that the two previous years of analyses had suppressed. The logic of the course is the following:

**1) Self-evaluation from the previous design exercises:** The student has to explain their previous designs, and is challenged with critical thinking questions, specially connected to *Why X and not Y*. It is no surprise that the usual answer is *because I copied from Z, and they used it*. It is also in this phase that the student realise that their previous attempts are addressing the learning of an analytical skill (e.g. *stability or resistance*) rather than designing skills.

**2) Mission Matrix and Requirements Elucidation:** This phase presents two basic taxonomies to the students. First, that vessels operate in a spectrum of *Service and Transport*, and that they can be designed to maximise *Weight or Volume*. This is a starting point to point to expose the limitations of the basic design spiral, as well as that their previous attempts, which addressed analytic skills, can now reveal that to produce a new design requires a stylistic choice on their part (Andrews, 2018). In other words, it's a stylistic decision from the designer to place the design more towards one or other side of this *spectrum*. Requirements Elucidation are tackled with the *Shall / Should* approach, and so communicate expectations. Figure 12 presents a collage from student's reports: in the left the *Mission Matrix* and in the right a *Shall / Should* example for a PSV.

**3) Top-Down Methods (Reference Ship / Catalogue / StO):** Top-Down is here used to describe ship design methods that have a starting point data from formulas, regressions, previous designs and parametric studies based on existing solutions, such as the one commented in Parsons (2011), most of Watson and Gilfillan (1976) and Roh and Lee (2018). Such top-down approaches to collecting data, usually find a practical and consensual solution in a short time and cost but lacks innovation and carries on the bias and out of date insights from previous designs. At this step is important to go into the detail of the design of a reference ship, understanding the design and stylistic choices that the designer of that ship has

made. In this stage the Systems Based Ship Design (SBSD) Taxonomy from Levander (2006) is also introduced, asking as a core exercise that the student decompose the ship into a functional breakdown, such as *Ship Systems* and *Payload Systems*.

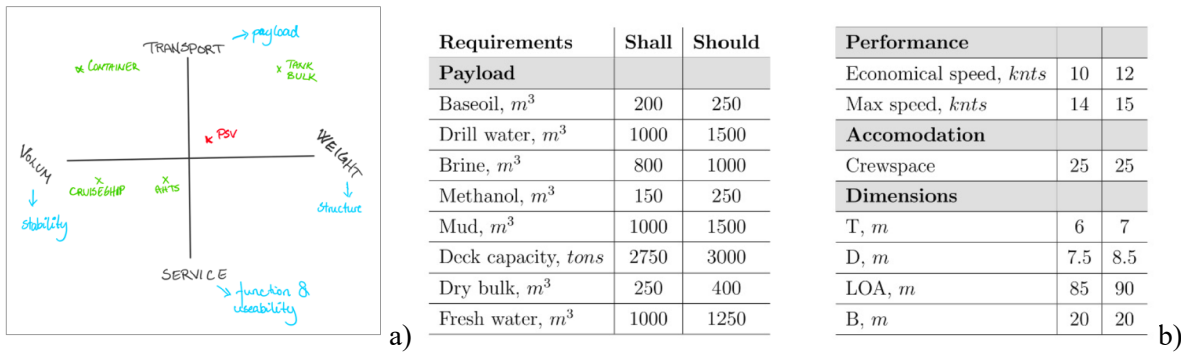

Figure 12 – a) Mission Domain Matrix (*Service x Transport / Volume x Weight*); b) *Shall / Should* description of requirements

**4) Bottom-Up (Design Inside Out, SBSDB+, proto-DBB):** Bottom-up methods are here understood as starting the design from specific key elements and subsystems that directly affect the mission of the ship. Bottom-up data presents different taxonomies or different vessel descriptions and understanding them, such as in SBSDB and DBB. Bottom-up data is the starting point for innovative and technological break-through designs, but may suffer from the lack of knowledge connected to the uncertainty of one-of-a-kind projects. A key change to the traditional SBSDB method, is to introduce the concept of DBBs, with the addition of distinct colours to identify the functional breakdown. Figure 13 presents this exercise made for a RoPax Ferry (left, in Norwegian) and a Factory stern trawler (right).

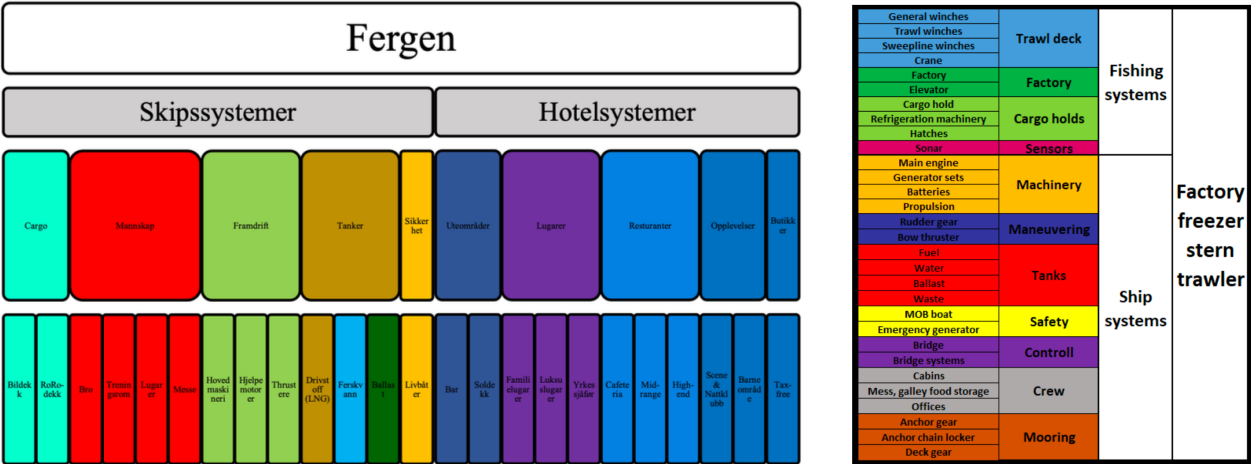

Figure 13 – From functionalities break-down to colours - initial step to connect SBSDB and DBB

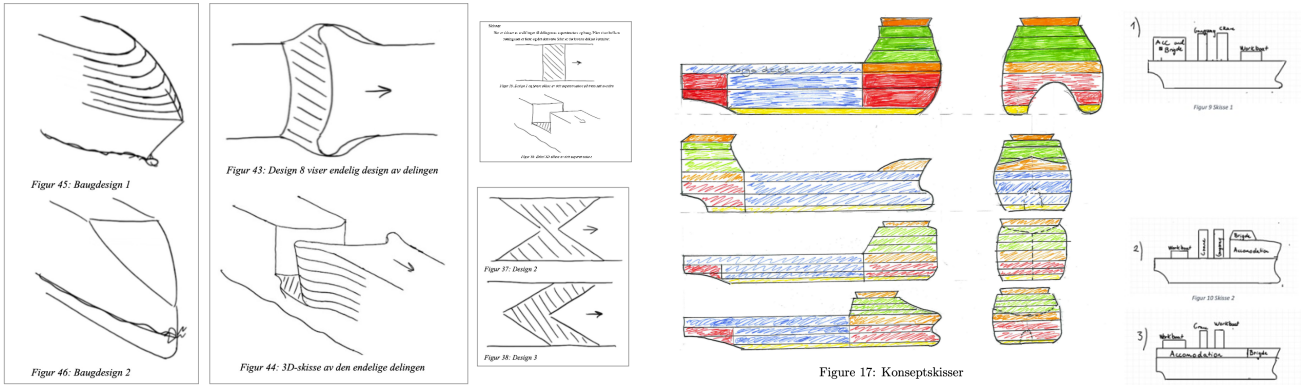

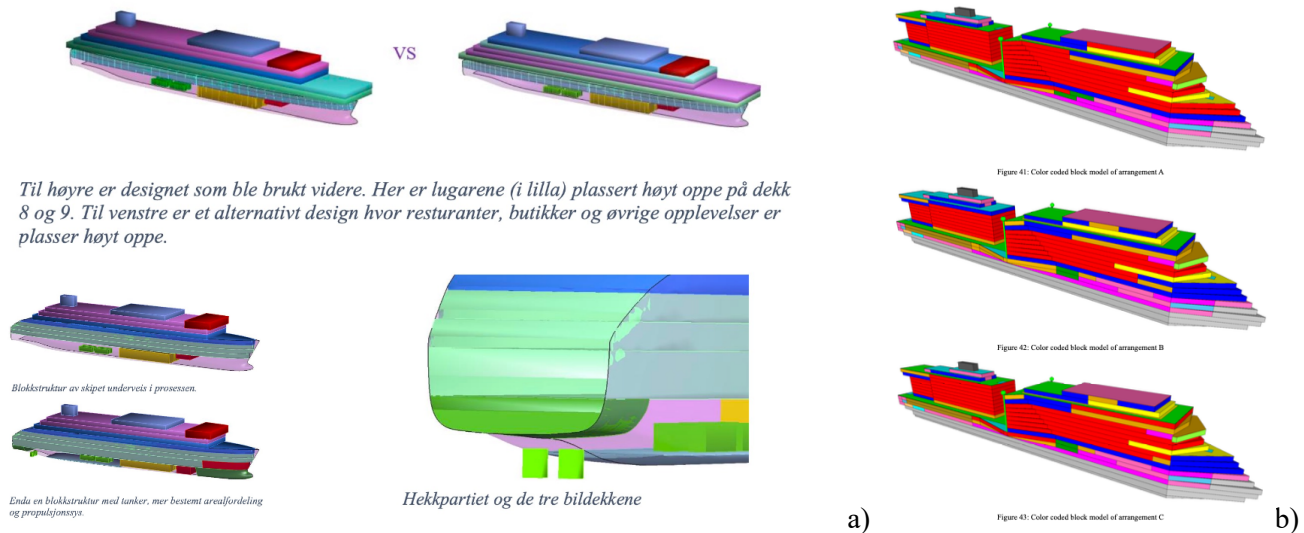

Figure 14 – Sketches to foster innovative solution in BSc student designs.

**5) Sketching and design space exploration:** This step is crucial, as the students have a class in the middle of the course to pause the dense theoretical approach and sketch, freehand, the innovative and key elements that are the core of its mission. Is it emphasised that artistic qualities are not being judged, but this is rather an exercise to explore solutions out of the box. Figure 14 presents a collage of sketches from the students.

**6) Proto-DBB Exercise:** This stage gets the students to implement some of the DBBs methods to explore their innovative ideas. The functional breakdown from Step 3 is used to create a simple library of SBBs, mostly visual, that is, not necessarily provided in ship design software. The core of this phases is not the comprehensive validation of a concept, but the use of 2D and 3D tools to *play around* with the newly sketched ideas. That said, the *weapon of choice* is for the student to select. Some use traditional naval architecture software, like Maxsurf (Passenger Ferry Design, Figure 15a), others use drawing tools like AutoCad or Sketch-Up (Cruise Ship, Figure 15b). The important thing is for them to explore the design space.

**Figure 15 – proto-DBB exploration of a passenger Ferry (a) and Cruise Ship (b)**

**7) Tabular Summary and GA:** Parsing the blocks and assembly into useful information is the next step. The student thus converts the blocks into volumes, areas, weights and centres, in a way to quickly input the data in the existing  $S^4$  tools. A GA is also created, documenting the innovative design in the proper manner. Figure 16 exemplifies this step.

## WITHER NOW THE DBB: ADVANTAGES, LIMITATIONS AND PROMISES WHEN BORDERS ARE EXTENDED

The first two authors share similar experiences from the ship design approach taught during their graduation years. It was aimed at vessels for commodity transports and relied on methods heavily reliant on previous designs, such as use of regressions and of previous general arrangements for vessels of comparable size and capacity. From the commercial

perspective, this might be a suitable combination for transport vessels as they are often designed to similar (if not identical) requirements and might as well be standardised for reproducible manufacturing in shipyards. From the educational perspective, it might be useful to have students have their first design experience with that a non-original set ups for two good reasons. First, it gives them some confidence that their design decisions are at least plausible, by providing external references. Second, it provides them with the opportunity to practice basic design analyses (e.g., stability assessment, propulsion sizing, structural dimensioning) in an exercise environment where the solution is roughly known beforehand. This means propulsion will be comparable to that of other Suezmax vessels and so will adopt the same compartmentation and similar aspects.

The disadvantage of such regression-based methods is that once students and practitioners are familiar with the knowledge needed for addressing common design aspects, the process tends to become mechanistic and repetitive, as a direct consequence of design reuse. In that sense, the DBB approach puts higher emphasis on holistic and architectural design concerns. It assumes the ship designer already has sound knowledge (and maybe even intuition) of fundamental trade-offs incurred by key design decisions and, for that reason, is able to focus on space use and arrangement without losing sight of the ship as a whole system. As already pointed, this gives the designer greater autonomy to explore design alternatives (and thus innovate) by not resorting to prescribed templates. It also reduces the threshold to iteration in early design by giving a set of elements (building blocks) that can be directly manipulated to consider and evaluate different alternatives without committing to any in detail. As a result, it can be said that the overall process becomes more engaging as it gives the naval architect space to explore the design problem with a creative mindset, instead of being limited to being the professional who ensures a previously chosen design sticks (without questioning) to applicable rules and standards by class, IMO, or others.

The attempts to extend the boundaries of the DBB discussed here are far from finalised, and many shortcuts were taken. The 2D and 3D online tools are in an incipient stage of development, given the lack of commercial support. The example from the BSc course is limited by the scope of the course, as well as the strong connection that the campus from NTNU in Ålesund has with the local ship design companies. In this sense, elements from DBB are adapted and merged with other methods. It is important to reiterate, however, that the proto-DBB exercise is one of the highlights of the course, resulting in engaged and motivated students. We invite the readers, naval architects working for the industry or academia, to dig into the references and adapt for their cases, DBB elements, especially if the aim is to explore innovative designs.

Given that, before the research and teaching at NTNU described in the latter part of this paper, the only research and educational use of the UCL Design Building Block approach to synthesising complete descriptions of ESSD were those in the Design Research Group team under the third author at UCL, it is worth ending this *Whither* paper by considering whether the DBB approach in an age of “advanced CASD”, with AI and ML implications, can be adopted more widely. This needs to be considered from both a teaching/academic research perspective and actual ESSD “in the real world”. It is the case that the specific Paramarine applications of the UCL DBB approach (facilitated by the SURFCON module incorporated in the Paramarine suite (Monez and Forrest, 2002)) have been used “for real ship design” by ship design agencies, including non-naval ship designers ([www.paramarine.qinetiq.com](http://www.paramarine.qinetiq.com)).

It is hoped this academic and wider usage will be undertaken in a manner consistent with the intent that the current paper’s introductory remarks re-iterated. As part of considering how this might be taken forward the following remarks are offered:

- There are clear different types of ship design approaches due to its very diverse nature. Andrews (2018) spelt this out in Table 3 and Section 5, covering the range of design novelty undertaken with specific extra sections: Sections 8.1 (configurationally driven designs); 8.2 & 8.3 (examples of unconventional hullforms) and “the very special case of submarine design (Section 8.4). All of the latter can only be sensibly synthesised by a DBB like architectural approach, while the conventional monohull also ought (especially if “novel” to any noticeable degree) to be designed “inside-out” (i.e., a DBB like approach).
- Accepting a requirements elucidation approach (see Section 3 of Andrews, 2018) even the conventional monohulled service vessel when synthesised “inside-out”, can (and normally should) be explored for different

internal configurations to see what is “best” as part of requirements elucidation. (A quite old but very comprehensive presentation of different configurations explored as part of the design of a major new class of combatant was provided by Leopold and Reuter (1971) - see Figure 7.) The message of a DBB type approach is that different internal configurations can be readily explored and tied to the numerical balance (through the Paramarine NA suite) so that the whole outer hull (and the superstructure) can be readily adjusted to accommodate “better” internal (DBB) configurations. This is creative ship design.

- A final set of SD educational remarks: Teaching ship design, both progressively to undergrads and to more general engineering graduate entrants (at NA masters level) can be done in steps and using an architectural/sketching approach (see Pawling and Andrews, 2011); the higher level of PhD and post-doctoral SD research is best fostered by a DBB type approach (see Andrews (2018) Sections 6.2 and 6.3 for UCL examples of new ship designs and researching specific ship design issues for whole ship implications); Sketching needs to be fostered as part of inside-out/architectural/DBB exploitation – to both encourage creativity and to not be limited by specific tools. This further encourages innovation and the necessary dialogue with design stakeholders (especially requirements owners/operators/funding bodies).

## CONTRIBUTION STATEMENT

**All Authors Equally:** Conceptualization; data curation, methodology; writing.

## ACKNOWLEDGEMENTS

To Dr. Pawling (UCL), who did the bulk of the Beta Test of the Paramarine realisation of the DBB approach and subsequent research students that used the approach to design innovative vessels and wider aspects of ship design behaviour; To the former NTNU students, and now naval architects, Magnus Weidemann, Hans Jørgen Sveen, Lars Vestnes and Sivert Rosø for sharing part of their exercises. The online tools presented in this work are available at <https://vesseljs.org/>. This research is part of the Ship Design and Operation Lab at NTNU (<https://www.ntnu.edu/ihb/ship-lab>) and UCL Marine Research Group (<https://www.ucl.ac.uk/mechanical-engineering/research/marine>) ongoing collaboration since 2016.

# Seeing a Sea of Ships - Exploring the Ship Design Space in the Digital Domain

Henrique M. Gaspar<sup>1\*</sup>, Yasuo Ichinose<sup>2</sup> and Kazuo Nishimoto<sup>3</sup>

## ABSTRACT

*We tackle in this work aspects of the ship design space in the digital domain, with an overview of the current status and opportunities to shift from fixed arrangements towards open technologies, proposing a mix of open and proprietary databases. The discussion is focused on the visual domain and digital thread in ship design. Literature examples from the Brazilian case and the visualization of the ocean space are presented (Numerical Offshore Tank - TPN), followed by the Japanese services to design and optimize hull for specific missions (NMRI), and lastly the current open ship design library developed in Norway (Vessel.js, NTNU). We present the argument that seeing a sea of ships, that is, visualizing the behavior of many options is already a reality, accessible from a portable device, without the need a large cluster as in the past, exemplified by web-based cases. Our conclusion is that computer graphics approaches to Ship Design should be considered open and exchangeable. Naval architects should focus on what they do best: creating, analyzing, refining, storing and populating the database of the know-how from the institution (e.g. university, research institute or company).*

## KEY WORDS

Virtual Prototype; Web-based simulation; Hull simulation; Digitalization.

## SEEING THE DESIGN OF A SHIP

### The Visual Domain in Maritime – Towards a Coherent Digital Thread

Bertram (2023) uses an analogy with DNA and its four simple elements to express the ship design process when highlighted by computer. His CAVE acronym stands for Creation, Analyses, Visualization and Enlightenment, and the use of these terms are used to remind us that creation remains in the realm of the human (centric or driven), but that the computer (created by us) accelerates and improves the final result of the design, that is, the ship. We explore in the rest of this work this idea, that the *tool* computer, when properly used, is essential to CAVE, and exploring the ship design space is, in essence, exploring the opportunities that the computer gives us to CAVE when the abstract idea and physical existence of a ship are parsed to the digital domain.

A great practical example of this whole loop is presented by Ulstein Group in a 3m11s video about the vessel SX121 Island Performer, a subsea (RLWI/IMR) vessel delivered in 2015 (<https://www.youtube.com/watch?v=I9YGfM2AzTo>). This short piece of visual information can cover in its small duration the power of the CAVE analogy. The hundreds of thousands of hours that humans used to design, analyze, and construct that vessel are summarized in this brilliant piece of advertise. Figure 1 presents a collage of this vide, highlighting the human activities in the design, engineering,

construction and sea trial of the ship. Such video enlightens us on the nature of the ship upstream value chain (Brett and Ulstein, 2012).

**Figure 1: Ship design as a human-centric and human driven activity – collage from Ulstein Island Performer video**

The one of a kind nature of the maritime domain, thus, bring two additional assumptions when watching the video: i) innumerable designs and analyses were explored and discarded for Island Performer exists as it is; and ii) the ship existed first in the digital world, decomposed in thousands of files, bits and bytes of text, drawings, functions and tables.

The older generation of ship designers is still proud to remember how the maritime industry was pioneer in adopting CAD (or computer aided ship design, CASD) in the 70s and 80s (Gaspar, 2019). CASD thus appeared as the future step to document, copy, reuse and detail the design, a digital alternative for the blueprint firstly, and a drastic way to change the engineering and yard offices lately. The equivalent process of doing each of the parts, assemblies, blocks and other drawings were firstly mimicked in the new CAD systems, one digital file for each required drawing, and multiple copies of parts due to individual storage of each drawing in a unique.

The old school may argue (with reason) that the high dependency on CASD for all the calculations may remove the student from the tactile knowledge of a ship, since the abstraction required for a 3D drawing of a hull is different than decomposing it on the 2D surfaces that are cut to physically assemble the hull from frames and plates. But undoubtedly the screens, computers, keyboards and mouse are responsible for:

- 2D/3D design processes quicker; designers can create new concepts in short time.
- Reliable documentation of the whole ship design process, from early design to construction and maintenance.
- Exploration of a large number of options during early stages, smartly copying, pasting and adapting past design into new ones
- Exchange and exporting drawings and descriptions between formats, as well as filtering level of detailing.
- Connect design (creation) with performance (analysis), and visually understanding cause and consequence of changes in internal (e.g. geometry) and external (e.g. environment) parameters, enlightening the decision-making process.

Not all promises from the last decades, however, are fully concretized. Take the hype idea of *integrated model*, and *3D as basis* for all models. Ideally, the 3D concept developed during the tender package could be the start point to feed the next phases, like 2D general arrangements, and detailed engineering. Very little, however, of the original 3D file is really used in the next phases of engineering analysis and detailing, with each of the design groups, such as hydrodynamic, structures and cargo systems to name few, redoing and redrawing the hull and GA over and over again in each of their specific software – a task *fancily* called *manual flow* in the flowcharts.

Additionally, traceability is not a strong point when multiple software is used, and usually a major change in the design implies a large time of re-work and precious engineering time in correcting each of the non-connected engineering models.

The same lack of integration is observed in the subsequent phases, with multiple proprietary databases, sometimes inside the same company. Observing the development of the systems from the past, five reasons can be commented, namely: proprietary formats, lack of integration, licensing and profitability of the tool, high cost to training and a deviation from the principle of parsimony (Gaspar, 2018).

The commercial aspect of modern CASD software also keeps an unnecessary level of paperwork and licensing *contortionism* with outdated technology from the 90s, a political approach that yet requires a dedicated server which checks a license for each of the computers that are using the software. While this seemed a good solution to avoid piracy and gain control from the side of the creators on the past, this looks extremely counter-productive in face of the modern online tools, apps and pay per use technologies that we have available in non CASD computer software. On the top of it, count the hours that IT technicians use to install the software in each machine, a long process configuring client and server due to antiquate anti-piracy policies. We dare to speculate that the ship design developers would benefit of providing as open as possible solutions to install and use their software in order to gain terrain in the market share (Fonseca *et al.*, 2023).

We present in the rest of this paper three developments towards a coherent digital thread, shifting from fixed and closed platforms towards open technologies and the choice of open and/or proprietary databases. The next section presents an example from University of São Paulo (USP, Brazil) developed more than two decades ago, which still holds valid and feels *modern*. This is followed by the developments at the National Maritime Research Institute (NMRI – Japan), in hydrodynamic simulation, combining processing demanding CFD of a hull with efficient machine learning (ML) techniques to quickly obtain the hydrodynamic response of a set of hulls, developed by the Japanese in the last decade. Lastly, it gives an update on the open ship design library developed at the Norwegian University of Science and Technology (NTNU-Norway), with a web-based proof of concept able to generate and simulate 10 000 designs in time-domain analyses in real time, using validated surrogate models.

## SPACE AND BEHAVIOR - VIRTUAL TOWING TANK

The numerical offshore model basin, TPN-USP (Nishimoto *et al.*, 2003, Gaspar *et al.*, 2009), is a 20+ year old ongoing initiative between a collaboration of Brazilian universities, research institute, and the oil company PETROBRAS. Its utilization was initially focused on analyses and verification of the design of complex offshore systems that normally requires even more complex tests in physical model basins. Today, it also included a physical basin calibrator and simulators for crew training and operational assessment.

TPN was created as a time domain simulator that encompasses several methods and algorithms in a single tool. The main characteristic of the simulator was the possibility of carrying out a coupled analysis of the lines with the bodies. The lines are modeled with Finite Element Method that demanded great computational power two decades ago. Its procedure followed the trend of the time, with pre and pos processing or the analyses in separate instants (Figure 2).

Parallelization of the code was the key innovation at the time (Luz *et al.*, 2009). The distribution of process was linear among processors. First the cases processes were processed and in sequence the bodies and lines processes. The communication among the processes occurred as: 1) Before initializing the simulation, main process import the data file and distributes it among other processes. 2) In each time step of simulation, the body process receives the force that each line process computes, sums the other loads and computes the acceleration, velocity and position of body, sending this data to the case process that it belongs. The case process replenishes its body's processes whit this data and the line forces that attach the bodies (linking lines) for the calculus of next time step. Simultaneously, it gives directly to the lines processes the position of corresponding body, since the calculation of force acting in the line depends only upon its upper ending coordinates. A common bottleneck was the the number of processes being superior than available CPUs, which required some sort of multiprocessing parallel Interface to distribute automatically the extra load homogeneously among CPUs.

TPN had its architecture based mostly in open software (e.g. Linux, OpenFOAM), and used proprietary commercial program when necessary (e.g. WAMIT). The same idea was applied to its database of solutions. Some of them were based on open data, from non-proprietary calibration and simulation, which could be shared; others, were based on analyses developed for its main partner (PETROBRAS), and were proprietary, not to be shared outside the laboratory, but nevertheless contributing to increase the expertise of the team.

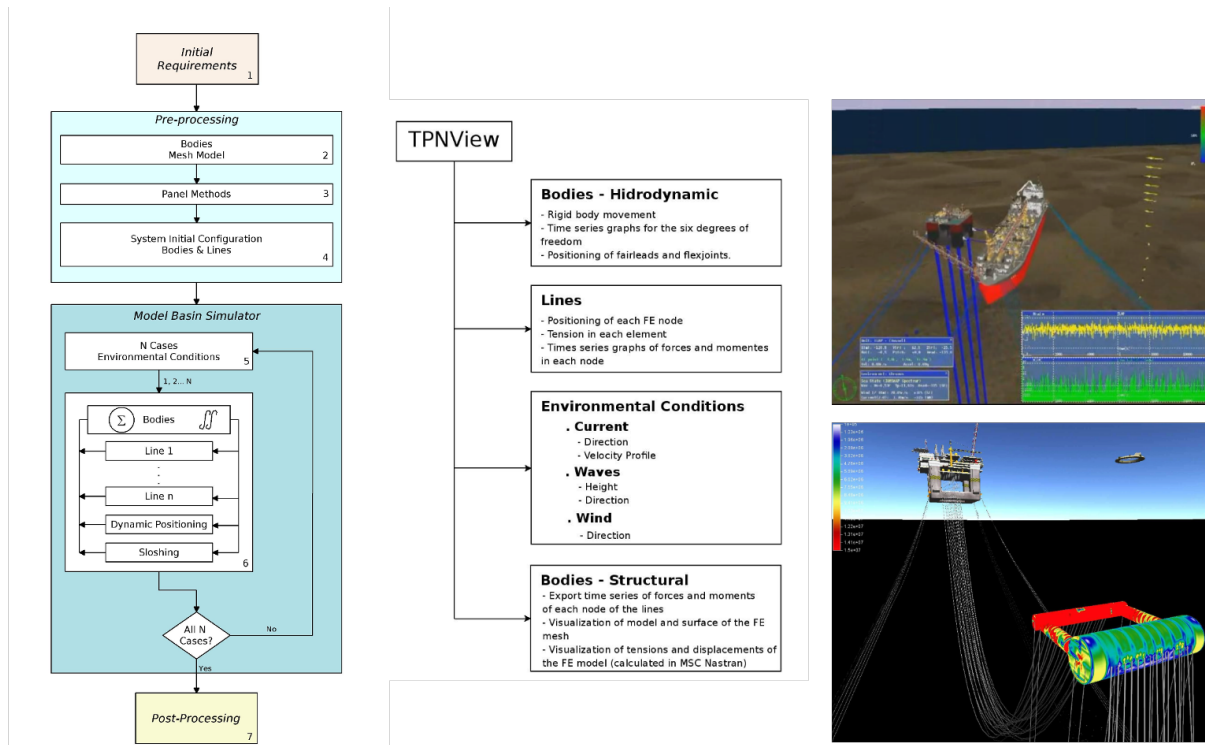

Figure 2: A time domain simulator encompasses several method and algorithms in a single tools in TPN

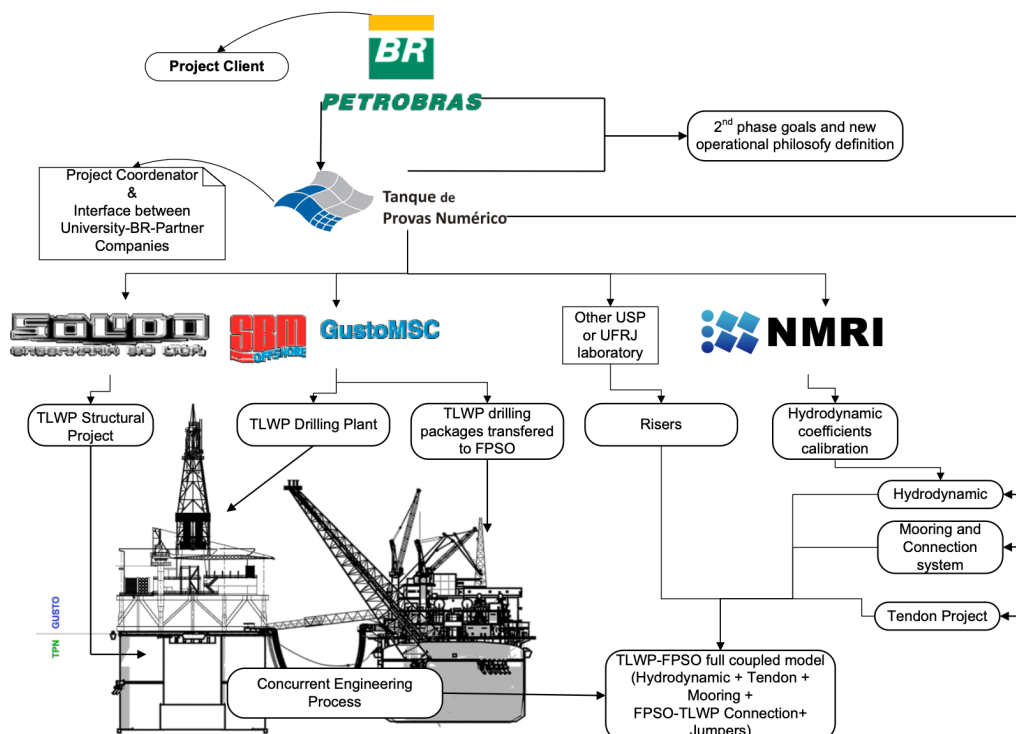

Figure 3: System Dimensioning Integration of TPN Simulator (Rampazzo et al., 2010)

The initiative was very successful, both national, boosting the offshore innovation in Brazil, and international, placing TPN as a key provider of simulation and visualization solutions for evaluation the design of vessels and multi-bodies operations. Other research institutes, such as Marin (NL), Marintek (NO) and NMRI (JP) developed at the same time complementary initiatives, and in few years the new ideas from early 2000s, like realistic graphics and hybrid methods combining physics based with surrogate models were implemented in most maritime research institutes. Figure 3 exemplify this synergy, in a collaboration from 2010 between TPN, Petrobras, engineering companies and the NMRI, for the development of a conceptual design of a FPSO + TLWP coupled system.

## HULL AND SEA - SIMULATION AND OPTIMIZATION

In certain Ship Design *niches*, especially the ones connected to the high-sea transport of heavy cargo, the field of simulation-based design has become a prominent approach for shaping hull forms since the early 2000s, with the promise that CFD could *scrap* few percentages in efficiency, which could materialize in huge fuel savings over long trip. Such specialized analyses become thus a service offered by few, firstly in research institutes, and later by (some) software companies (Bertram, 2014).

Even with many advancements, ensuring design optimality under diverse operational scenarios yet remains a challenge. Researchers have explored stochastic shape optimization and visualizing design space to enhance robustness. Stochastic optimization studies have focused on minimizing total resistance and improving operability across different ship speeds. Visualizing the design space aids decision-making by elucidating effective parameter limits (Ichinose, 2022). Recent research has delved into using machine learning (ML) methods to analyze propulsive performance. Artificial neural network (ANN) models have been developed to estimate total resistance, trim conditions, and added resistance. Despite their efficacy, these automated design methods often lack transparency, posing challenges for designers. Efforts to develop explainable artificial intelligence or organizing hull-form databases for deeper understanding are underway.

Integrating visualization methods into machine learning-based hull design methodologies can be useful for effective decision-making and consensus-building among stakeholders involved in ship design. Visualizing and analyzing hull form performance requires a structured approach to organize and parameterize their database. Unlike propellers, which can be defined through factors like pitch and skew, hull forms present a challenge due to their complex 3D shapes. While various parameterization methods have been explored, no single standard has been universally adopted.

**Figure 4: Distribution of admiralty coefficient ( $C_{ADM}$ ) isolating the fineness factor in the aft part ( $Hr/B$ ) (Ichinose, 2022).**

In recent years, computer graphics techniques have been integrated into hull form deformation processes (Ichinose, 2022). Concurrently, shape morphing, originally developed for satellite image transformation, has found utility in ship design, preserving detailed shape information and facilitating better understanding of results. However, the practical application of shape morphing is hindered by its limited degrees of deformation, typically restricted to mixing two or three hull forms due to visualization challenges. Addressing this limitation, Ichinose has extended the morphing method into a multi-

dimensional context and proposed a Hull-form coordinate system that defines each ship type. Figure 4 is an example of visualizing the design space of ship forms using the Hull-form coordinate system. Here, the admiralty coefficient ( $C_{ADM}$ ) in the figure is a performance coefficient representing transport efficiency, which is widely prevalent in the naval architecture field. Observing this performance distribution, it is evident that there are areas where performance remains stable despite slight changes in shape parameters and areas where performance is unstable in response to shape deformation.

In designing within the Digital Domain, particular attention must be paid to simulation errors and variance. That is, the optimal point obtained in numerous optimization simulations may not necessarily be the shape to be adopted in an actual construction project. We require a iteration of CAVE, from creation to enlightenment. Therefore, instead of a single optimal shape in the domain, it is necessary to adopt a group of candidate shapes, including the second and third viable options, in the design. Visualizing thus a design space that indicates a stable performance domain is a crucial technological element in engineering projects.

Furthermore, in engineering projects, efforts to improve physical interpretability through visualization are also essential for consensus formation and decision-making among designers and stakeholders in the Digital Domain. Figure 5 illustrates another example of visualizing a large set of simulations at once, presenting how the distribution of waves changes with the deformation of the hull form. We observe that, when the forepart becomes a full body, the generated wave height increases sharply (Figure 5, red perimeter). Thus, by optimizing the design space with physical interpretability, it is possible to achieve designs with high robustness.

**Figure 5: Listed figures of wave patterns in fore parts isolated by breadth-to-depth ratio ( $B/d$ ) (Ichinose, 2022).**

A bottleneck in adopting design methodologies that explore and visualize the entire design space is the time-consuming nature of simulations. Especially since the Navier-Stokes equations, which are the governing equations of fluid dynamics, are nonlinear and require numerical discretization to be solved, numerical analysis demands extensive time for grid generation. As an alternative to such numerical calculations, design charts have traditionally been used. However, there is a recent trend towards replacing design charts with machine learning methods. For this, a database with a large number of validated hydrodynamic simulations is needed. This database does not need necessarily to be open. The methods, however, need (and are), given that merging ML and surrogate models is a task beyond the ship design domain. In response to this, research is being conducted in ship design to visualize pressure distributions on hull surfaces and flow fields using machine learning surrogate models, traditionally performed with CFD simulations (Ichinose & Gaspar, 2023). Utilizing such surrogate models for CFD, it is possible to visualize thousands of cases in a matter of seconds as shown in Figure 6. This represents an evolution in the application of machine learning in ship design that goes beyond merely replacing

traditional design charts and highlights the anticipated growth in design development through using the existing validated databases.

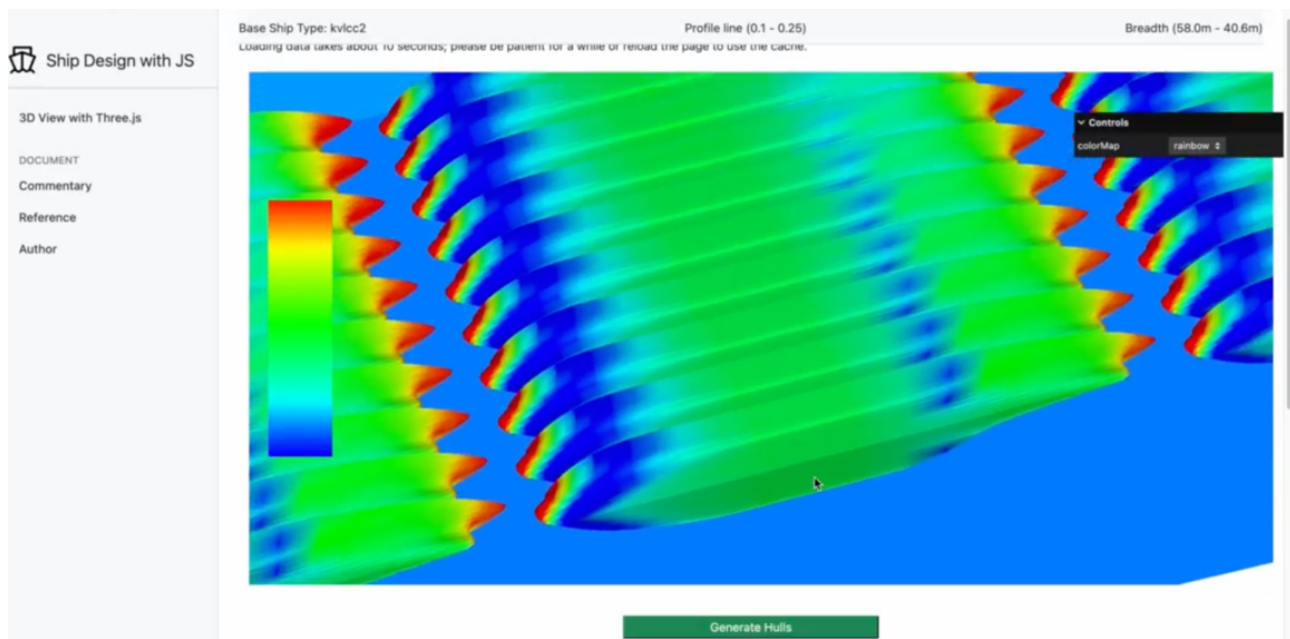

Figure 6: Example of Visualizing Pressure Distribution Across Thousands of Cases in Seconds Using a Machine Learning Surrogate Model for CFD, extended from Ichinose and Gaspar (2023)

## A (DIGITAL) SEA OF SHIPS - THE ARGUMENT FOR WEB-BASED TECHNOLOGIES

Open digital methods allow us today to simulate and visualize in real-time 100s, 1 000s or even 10 000s of hull designs using a laptop. Actually, as the technology is web-based, probably with a modern mobile or tablet, using as example the open Vessel.js (<https://vesseljs.org/>) library. As introduced in earlier IMDCs (Gaspar 2018; 2022), this open ship design development is aimed at the design and simulation of maritime entities, combining ship design thinking within a JavaScript-based object-oriented approach. As the library is web-based, all examples and codes discussed there are available to be accessed, modified, and re-used by a community. The data and methods there are therefore transparent and can be tested and scrutinized.

Figure 7: Visualization of 1, 100, 1000 and 10 000 hull in a fixed 4km x 4km virtual square.

Figure 7 presents the *Sea of Ships* currently implemented in the examples sections of the library (Ferrari and Gaspar, 2024). It presents a proof of concept able to load a database of many hulls, varying in real time from 1 to 10 000. As this was tested using a normal personal computer, we believe that a gamer PC, aimed at fast 3D rendering could jump this number to even one order of magnitude higher.

To exemplify open simulation, the described static representation is then connected to the seakeeping simulator described in Chaves and Gaspar (2016). It uses validated closed-form expressions from Jensen *et al.* (2004) to estimate wave-induced motion for mono-hull vessels. These expressions require only vessel main dimensions and basic hull form coefficients, being especially relevant for conceptual design, where little information about the hull form is available. The approach allows the designer to vary amplitude (A), period (T), direction ( $\theta$ ), phase ( $\phi$ ), and quickly assess their influence on the wave-induced motion. The case from 2016 was the first to present in an open web-based version the response of a vessel. Now, we implement it to the *Sea of Ships*, simulating seakeeping for 1, 100, 1 000 and 3 000 hulls in the same environment, in real time (Figure 8).

**Figure 8: Simulating the seakeeping behavior of 1, 100, 1000 and 3 000 hulls using closed-form functions, in a virtual 4km x 4km ocean with virtual waves.**

Compared to traditional engineering programming environments, web technologies provide more options and freedom for the creation of sophisticated user interfaces. The developer of a web application may use sliders, text fields and buttons to gather inputs from the user – exemplified in Figure 8 by the sliders to modify the simulation parameters. Results can be presented as formatted text, tables, plots or interactive visualizations, either 2D or 3D. Multiple textual and graphic elements can be combined in dashboards to present a cohesive experience to the user, allowing them to vary inputs and observe the effects of the variation on the results in real-time.

It is important to note that the possibility of assessing in real time such sea of ships is not a common feature in the majority of commercial software. The usability of this exercise is being tested also outside the boundaries of NTNU. Similar to the case discussed at TPN, collaboration between research institutes to check the validation and usability of open web-based technologies is increasing (Q.E.D. this article). The attempt made by NTNU seem in Figure 8 inspired a Japanese version,

result from the recent MoU signed between NTNU and NMRI. Diverse implementations of the method were combined with existing initiatives at NMRI (Figure 9).

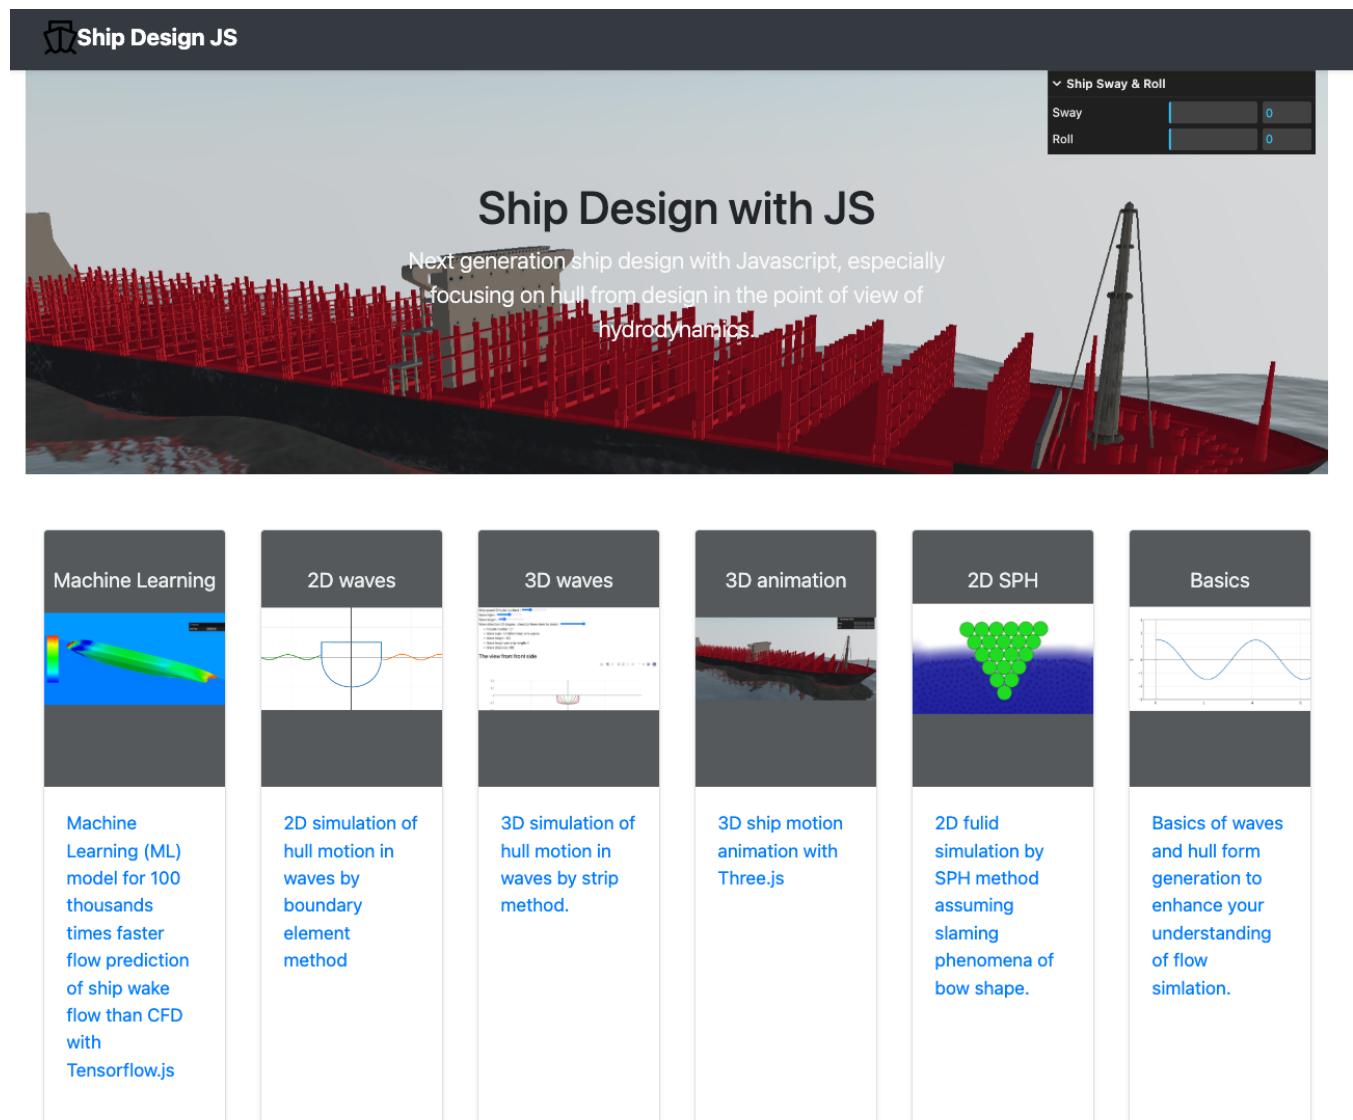

Figure 9: NMRI Research on Web-based Hydrodynamics, based on a joint initiative with NTNU from 2023.

## FINAL NOTES: THE OPEN AND COLLABORATIVE APPROACH

We close this paper with a call for colleagues and students to consider trying develop their own version of a *A Sea of Ships*. The code and examples to replicate the examples in Figure 8 are open and available. We believe that by implementing open and collaborative methods in the everyday design tasks, both at academic and industrial environments, will foster innovation. Simple practices for versioning, tagging and library concepts are recommended (Gaspar, 2018). A Github page for a project – either public or private (paid) is also an experience highly recommended. As this is used to manage large software projects, it has functions like allocating tasks, discussions a traceability in pair (or even better) than most of PDM/PLM solutions. Giving up proprietary data-files in exchange of a standard among all tools seems to be a feasible (and lucrative) path.

The open initiatives here discussed are a working in process, and much of the libraries and methods intends to be improved in the years to come. The main point defended in this paper is that technology is not a bottleneck any longer, and a development that in 2003 would require a cluster of computers and proprietary software, can be done nowadays using a

laptop and downloading from an open repository. The real value lies in the humans working with ship design, and their ability to access and filter the open and proprietary databases. In other words, how efficient ship design data is able to be transferred from books and experience to useful reusable models. As for the development of real ship design engineering in an open library, we recognize the value of current engineering tools and PLM suites; no doubt, they are responsive for the visible gain in productivity that the maritime industry faced in the last decade. Industry 5.0, with an open digital thread that all actors may follow is thus the next step (Sepalla *et al.*, 2023).

As a final call, we believe that a large part of the digital tools for Ship Design should be considered open and exchangeable. Naval architects should focus on what they do best: creating, analyzing, refining, storing and populating the database of the know-how from the institution (e.g. university, research institute or company). Learning from modern software companies shows that the gain nowadays, both technological and commercial, seems to be in efficiently handling digitally the intrinsic ship design knowledge (databases), providing services from the know-how rather than a more powerful computer, a mesh more refined or a cluster with  $n+1$  CPUs. Seeing is a reality one click away.

## ACKNOWLEDGEMENTS

To Olivia Chaves, Elias Hasle and Felipe Ferrari (NTNU). The first two, for developing the first version of the *sea of ships* at the Ship Design and Operations Lab at NTNU, back in 2016. The second, to improve and build on this version years later, creating the recent online interactive version presented in Figures 7 and 8 and available online for scrutiny at [vesseljs.org](https://vesseljs.org).

# On empirical methods to predict the rolling period of ships

Rob Grin<sup>1,\*</sup>

## ABSTRACT

*A reliable prediction of the roll period is crucial, as it forms the basis of the calculation of the roll motion and transverse accelerations. Both are extremely important for the comfort and safety of passengers and crew as well as the loads on the cargo and their lashings. At present, some prediction methods are quite unreliable, with sometimes errors in the predicted roll period of 5 to 10 s. This paper describes and compares eight methods. It shows that the four best performing methods have a mean absolute error of less than 1.4 s for the three validation cases evaluated, making them considerably more reliable than some of the other methods used in the industry.*

## KEY WORDS

Rolling period; Radii of inertia; Stability; Seakeeping; Ship motions

## NOMENCLATURE

$A_{\text{lateral}}$	[m <sup>2</sup> ]	Projected side area of ship	$H$	[m]	Effective depth of ship

$\delta I_{xx}$	[ton·m <sup>2</sup> ]	Roll added mass inertia	$T$	[m]	Draft at midship
$FSC$	[m]	Free surface correction	$T_a, T_f$	[m]	Draft at stern and bow
$g$	[m·s <sup>-2</sup> ]	Gravitational acceleration (9.81 m/s <sup>2</sup> )	$T_\phi$	[s]	Natural period of roll
$GM_t$	[m]	Transverse metacentric height	$VCG$	[m]	Vertical centre of gravity

## INTRODUCTION

The rolling period has a large influence on the ship roll motion and accelerations of ships, not only for resonant roll but also for parametric roll. Both are extremely important for the comfort and safety of passengers and crew as well as the loads on the cargo and their lashings. As part of the design verification, seakeeping assessments (either numerical or experimental) are performed. However, when the real roll period is not known, incorrect estimates are made, and the predicted ship

<sup>1</sup> Maritime Research Institute Netherlands (MARIN), The Netherlands

\* r.grin@marin.nl

performance might be misleading. This is also the case when applied to vulnerability criteria within the second generation of intact stability code. At present, many prediction methods are quite unreliable, with errors in the predicted roll period of more than 10% regularly occurring. This paper will give guidelines for the required accuracy that will ensure that the changes in roll behaviour are marginal. Various estimation methods are compared for a range of illustrative ship types. For each of the methods, advantages and disadvantages will be discussed and a practical estimation method will be proposed that can be used both in the ship design phase and in operation.

## ROLL PERIOD AND UNCERTAINTY

The natural frequency ( $\omega_0$ ) of an undamped mass spring system is given by equation 1, where  $k_{spring}$  is the spring stiffness and  $m$  the mass. Assuming that the roll is lightly damped this equation can be used to calculate the roll natural period, see equation 2, in which the roll inertia  $I_{44}$  consists of the total roll inertia including added mass and the spring term  $C_{44}$  is the roll restoring coefficient. This can be rewritten and further simplified to equation 3 as  $\pi/\sqrt{g}$  is around one. In this equation  $k_{xx}$  is the roll radius of inertia,  $a_{xx}$  the roll added mass radius of gyration and  $GM_t$  the transverse stability (see also the chapter on transverse stability if that should be the dry or wet  $GM_t$ ).

$$\omega_0 = \sqrt{\frac{k_{spring}}{m}} \quad [1]$$

$$T_\phi = 2\pi \sqrt{\frac{I_{44}}{C_{44}}} = 2\pi \sqrt{\frac{I_{xx} + \delta I_{xx}}{g\Delta GM_t}} \quad [2]$$

$$T_\phi = 2\pi \sqrt{\frac{\Delta k_{xx}^2 + \Delta a_{xx}^2}{g\Delta GM_t}} \approx 2 \sqrt{\frac{k_{xx}^2 + a_{xx}^2}{GM_t}} \quad [3]$$

$$\text{with } k_{xx} = \sqrt{\frac{I_{xx}}{\Delta}} \quad \text{and} \quad a_{xx} = \sqrt{\frac{\delta I_{xx}}{\Delta}} \quad [4]$$

The uncertainty (error) in the rolling period can be estimated if the uncertainties  $\delta k_{xx}$ ,  $\delta a_{xx}$  and  $\delta GM_t$  are known and have a normal distribution (Coleman and Steele, 1999). From equation 3 and after some math, equation 5 gives the total uncertainty in the rolling period. It shows that the  $\delta k_{xx}$  and  $\delta a_{xx}$  make a bigger contribution than the  $\delta GM_t$ , as the uncertainty in  $GM_t$  has a cube root of the  $GM_t$  in the denominator. As the  $k_{xx}$  is typically about twice as large as the  $a_{xx}$  the  $\delta k_{xx}$  is typically bigger than the  $\delta a_{xx}$ . It can therefore be argued that for a small uncertainty in the rolling period ( $\delta T_\phi$ ), the uncertainty in the  $k_{xx}$  prediction should be reduced as much as possible. This can be illustrated by taking the 77,500 DWT bulk carrier loaded with grain as example (see Appendix A, ship ④). When an uncertainty of 10% is assumed for all 3 input parameters, the roll period is  $16.0 \pm 1.8$  s. If the  $\delta k_{xx}$  is reduced to 5% the uncertainty in the rolling period reduces to 1.3 s, whereas it only reduces to 1.7 s or 1.6 s when the uncertainty of the  $a_{xx}$  or  $GM_t$  reduces to 5%. It is therefore important to get a good prediction of  $k_{xx}$  as it makes the biggest contribution to the rolling period.

$$\delta T_\phi = \sqrt{\frac{4}{GM_t} (\delta k_{xx}^2 + \delta a_{xx}^2) + \frac{k_{xx}^2 + a_{xx}^2}{\sqrt[3]{GM_t}} \delta GM_t} \quad [5]$$

## EXISTING APPROXIMATION METHODS

Many of the existing methods for monohull vessels use equation 3 as starting point but do not split the roll radius of inertia and the roll added mass. They typically provide the total roll radius inertia as a fraction of the beam of the vessel  $B$  (see equation 6). This factor is called the roll factor  $k$ . Note that in most formulations the factor 2 is contained in the roll factor, causing twice as large a roll factor. Some other formulations use a constant bigger than 2, accounting for the roll added mass. For comparison reasons these variations are not applied in the present work.

$$T_\phi = 2 \frac{kB}{\sqrt{GM_t}} \quad [6]$$

Some examples for the roll factor are given in Table 1. It is shown that it ranges from 0.33 up to 0.52 and on average 0.42. There seems to be no clear trend; for instance, bulk carriers can be both well below average (BV) or well above (IACS).

**Table 1: List of roll factors**

Source	Ship type	Roll factor k	Remarks
LR, 2022	Container	0.41	
DNV, 2023	All	0.45	Except bulk and ore carriers
	Tanker, ballast	0.40	
ABS, 2019	Container	0.40	
ClassNK, 2023	All	0.40	
BV, 2014	All	0.39	
	Bulk carriers	0.33	Ore carrier
Lewis, 1989	All	0.36	Range: 0.29 – 0.43
IACS , 2012	Bulk carriers	0.40	Homogeneous full load
		0.48	Steel coil
		0.52	Ballast
		0.46	Heavy ballast

Instead of a fixed value, a slightly more complicated estimation of roll factor was proposed by the Shipbuilding Research Association of Japan, JSRA (1982) and IMO (2024). This method is adopted within several IMO documents, for instance the intact stability code (IMO, 2008) and the interim guidelines on second generation intact stability criteria code (IMO, 2020). As shown in equation 7, it increases with the beam over depth ratio ( $B/D$ ) and decreases with ship length. For small vessels this gave satisfactory results, however for large vessels it gives a considerable underestimation of the roll period. For this reason, JSRA made an alternative fit only depending on  $B/D$ -ratio (equation 8). Figure 1 shows the reproduced cross plots of JSRA, with on the x-axis the k-factor recalculated from the measured rolling period of in total 70 vessels and on the y-axis the estimated k-factor according equation 7 and 8. Both fits give fairly equal but considerable scatter, with an  $r^2$  of 0.59 versus 0.43 without ship length dependency.

$$k = 0.373 + 0.023 \frac{B}{D} - 0.043 \frac{L_{wl}}{100} \quad [7]$$

$$k = 0.3437 + 0.024 \frac{B}{D} \quad [8]$$

**Figure 1: Reproduced scatter plots according to Shipbuilding Research Association of Japan (1982)**

Much longer ago, Doyere (1927) proposed equation 9 with a ship dependent  $c$ -factor. The formula shows that the rolling period increases with increasing beam and vertical centre of gravity (VCG). According to Doyere, the average  $c$ -factor is 0.29. Doyere provided a table with five naval vessels with multiple loading conditions where  $c$  varied between 0.26 and 0.32.

$$T_{\phi} = c \sqrt{\frac{B^2 + 4VCG^2}{GM_t}} \quad [9]$$

Kato, 1956 proposed equation 10 in which  $T$  is the draft of the vessel,  $C_u$  is the waterline coefficient of the main deck and  $H$  the effective depth (defined as the lateral area divided by the ship length). The factor 0.125 is valid for passenger and cargo vessels. For tankers a value 0.133 was suggested and for navy ships 0.172. It shows that larger  $C_b$  and larger  $H/B$  ratio give a larger roll factor. The  $C_u$  is often close to 1.0 for modern ships; for this reason the middle term is in most cases small compared to the  $C_b C_u$  term and the  $(H/B)^2$  term. It can even become slightly negative.

$$k = \sqrt{0.125 \left( C_b C_u + 1.10 C_u (1 - C_u) \left( \frac{H}{T} - 2.20 \right) + \frac{H^2}{B^2} \right)} \quad [10]$$

Lehmann, 1940, Laurenson, 1949 and Vossers, 1962 assumed that  $k_{xx}$  should be between a solid homogeneous rectangular beam (equation 12) and a rectangular tube with wall thickness of  $0.025B$ . The second is practically identical to a rectangular tube with infinitely thin walls (equation 13). By combining equation 4 and equation 12 and replacing the term  $\sqrt{1/12}$  by coefficient  $c$ , equation 11 is obtained. It results in a  $c$ -value of 0.289 ( $\sqrt{1/12}$ ) and 0.397, respectively. These factors only include the roll mass inertia and not the roll added mass. Laurenson proposed a  $c$  ranging between 0.33 and 0.39, which is very similar to Peach, 1987 suggesting a factor  $c$  of 0.30. Both include the roll added mass. It has to be noted that for ships with heavy cargo concentrated around the centre of gravity (like loaded bulk carriers and tankers),  $c$ -values of less than 0.289 are possible.

Figure 2 shows the resulting curves for Lehmann and Vossers (blue lines), Laurenson (red lines) and the homogeneous rectangular beam and the tube with infinitely thin walls (black lines). Note that for Vossers and Lehmann the line for the empty ship ① is equal to the rectangular tube.

$$kB = c\sqrt{B^2 + D^2} \quad [11]$$

$$\text{Homogeneous rectangular beam: } I_{xx} = \frac{1}{12} m(b^2 + h^2) \quad [12]$$

$$\text{Rectangular tube with infinitely thin walls: } I_{xx} = \frac{1}{12} m(b + h)^2 \quad [13]$$

Figure 2:  $c$ -factors as function of  $B/D$  ratio

## ROLL RADIUS OF INERTIA

The aforementioned methods estimate the roll factor, which combines the roll radius of inertia and the roll added mass. As there are methods to calculate or estimate the roll added mass (see next section), it would be good to separately calculate or estimate the roll radius of inertia. Preferably, detailed weight calculations are used; however, they are often not available, despite all state of the art CAD tools and software to calculate stability.

Estimation of the  $k_{xx}$  can be done for instance with ITTC, 2017. In equation 14 it is shown that the ITTC formula weights the rectangular tube (first term in the equation) and the solid beam (second term). The last term is a measure for the vertical offset for a half-submerged homogeneous beam (in that case the last term is zero).

$$k_{xx} = \sqrt{\frac{1}{12} \left( 0.4(B + D)^2 + 0.6(B^2 + D^2) - \left( 2T - \frac{D}{2} - VCG \right)^2 \right)} \quad [14]$$

Another estimation method was proposed by Grin et al., 2016, shown in equation 15. This method is based on detailed weight calculations for 9 vessels and in total 16 loading conditions. It also consists of 3 terms. The first term is solid beam with factor  $\beta$  being ship type and loading condition dependent (and 12 for a solid beam, see also equation 12). The second term is accounting for the offset between the real VCG and the VCG for a solid beam ( $H/2$ ). The last term gives a correction in case of fluid cargo. In this case part of the roll inertia of the fluid should be subtracted from  $k_{xx}$ . This is done by the  $c_{fluid}$  factor, which varies between 1 for solid cargo and 0 for fluid cargo in a cylindrical tank (Grin et al, 2016). The suggested  $\beta$ -factors are 9.8 for ships in (near) ballast condition, 11 for ships in loaded condition with a more or less homogeneous mass distribution and relatively high stowage factors and 14.7 for ships carrying cargos with low stowage factor or a large portion of the mass close to centre of gravity.

$$k_{xx} = \sqrt{\frac{B^2 + H^2}{\beta} + \left( \frac{H}{2} - VCG \right)^2 + (c_{fluid} - 1) \frac{I_{fluid}}{\Delta}} \quad [15]$$

## ROLL ADDED MASS

It is recommended to calculate the roll added mass  $a_{xx}$  by means of potential flow strip-theory or panel codes. This gives the most reliable estimate accounting for the hull shape, speed of the vessel and roll period. Note that the roll added mass is also dependent on water depth and presence of side walls (e.g. the quay). In the case of restricted water, the  $a_{xx}$  increases and thereby the rolling period.

In the case of deep water, a first rough estimate can be made using equation 16. This is based on the recalculated  $a_{xx}$  from MARIN model tests of 228 different monohull vessels, varying from small patrol boats to large tankers and container vessels. This estimate assumes that the  $a_{xx}/B$  increases linearly with the  $B/T$  ratio. Figure 3 shows a cross plot of the measured and predicted roll added mass. It shows that correlation is fair, with an  $r^2$  of 0.46.

Figure 3: Predicted against measured roll added mass

$$a_{xx} = 0.05 \frac{B^2}{T} \quad [16]$$

## TRANSVERSE STABILITY

The transverse stability is in the denominator of the rolling period equation: the higher the transverse stability ( $GM_t$ ) the lower the rolling period of the vessel (a stiff ship). In most publications it is not clearly stated if the dry  $GM_t$  or the wet  $GM_t$  (including the free surface correction, FSC) should be taken. In IMO, 2020 (SGISC) it is recommended to use the dry  $GM_t$  for excessive accelerations and for the other modes the wet  $GM_t$ . This is considered a conservative estimate by IMO.

Using the wet  $GM_t$  assumes that the fluid in the tanks is always in phase with the roll motion and consequently always at the lee side. For many tank geometries this is indeed true. With equation 17 the natural period of a rectangular tank can be predicted. This further simplifies to equation 18 in shallow water. In this equation  $b_{tank}$  is the width of the tank and  $h_{tank}$  the water level.

$$T_{tank} = \frac{2\pi}{\sqrt{\frac{\pi g}{b_{tank}} \tanh\left(\frac{\pi h_{tank}}{b_{tank}}\right)}} \quad [17]$$

$$T_{tank} = \frac{2b_{tank}}{\sqrt{gh_{tank}}} \quad [18]$$

For example, the natural period is only 1.6 s for a side tank of 2.0 m wide and 7.5 m height and 20% filled with water. Assuming a rectangular double bottom tank with a width of 12.5 m, a height of 2.0 m and also 20% full, this increases to 12.6 s. However, that assumes that there are no obstructions in the tank. In reality, a double bottom tank has many obstructions like longitudinal frames and girders. In Figure 4 an example is shown of the typical double bottom construction of a large container ship. These ships have a girder for each stack of containers, leading to a girder spacing of around 2.5 m. These girders have typically only a few manholes, for instance every 3.5 m one manhole of 700x500 mm and only a few small discharge holes at the bottom of the girders. In the case of a static heel angle the water (or fuel) eventually flows to the lee side. This is why the free surface correction of a double bottom tank is significantly larger than for a side tank. However, in the case of a rolling motion of say 20 to 30 s, the water does not have sufficient time to flow to the lee side and will move mostly in between two girders, and at low water levels maybe even in between two longitudinal frames. It is therefore not realistic to account for the full FSC of these double bottom tanks for the calculation of the roll period. In the previous example of the 12.5 m wide double bottom tank the FSC decreases by a factor 25 if the water moves between girders. In practice this means that for many ships the FSC can be disregarded and the dry  $GM_t$  can be taken in the calculation of the rolling period. However, caution should be taken in the case of for instance large fluid cargo tanks, LNG fuel tanks and other tanks with only few internal obstructions. For these cases the FSC should be included in the calculation of the rolling period. A special case are anti-rolling tanks; these tanks are designed to reduce the roll motion and therefore the water is moving in counterphase of roll motion. For this reason, the FSC of these tanks should be disregarded.

Note that the  $GM_t$  could also be speed dependent. When ships with a flat transom sail at forward speed, the steady wave pattern, trim and sinkage typically increase the waterline area at the stern. This increases the  $BM$  and thereby the  $GM_t$ . As a result, the roll period could decrease somewhat at forward speed.

Figure 4: Typical cross section of double bottom tank of a large container ship

## VALIDATION

Two statistical quantities are used for the three validation cases mentioned below: the well-known correlation coefficient ( $r^2$ ) and the mean absolute error (MAE). The first one is a good measure for the scatter but does not show bias, whereas the second one also accounts for bias. Cross plots are presented in which the measured or calculated values are shown on the x-

axis and the predicted values on the  $y$ -axis. With a perfect correlation (an  $r^2$  of 1 and an MAE of 0) all points will be on the diagonal.

### Case 1, detailed weight calculations

For the first validation case, detailed weight calculations were done for 9 ships and 16 loading conditions (Grin et al., 2015 and Grin et al., 2016). A variety of ship types were used: 2 general cargo vessels, 2 tankers (LNG and LPG), 2 bulk carriers, a container vessel, a cruise ship and a frigate. The main particulars, stability data and roll coefficients are given in Appendix A. The previous publications focused on the detailed weight calculation and the prediction of the roll, pitch and yaw radius of gyration. For this work, strip-theory calculations were done to predict the roll added mass  $a_{xx}$  and on the basis of the given dry  $GM_t$  and the  $k_{xx}$  from the weight calculations, the roll period was calculated.

The cross plots in Figure 5 shows the eight different prediction methods. It is shown that most methods give a fair to good prediction. Even a straightforward method like the roll coefficient method with a fixed value of 0.40 has an  $r^2$  of 0.96 and an MAE of 2.0 s. JSRA (as used by IS2008 and SGICS), Kato and ITTC and are the methods that have the smallest  $r^2$  and highest MAE. On the other hand, the JSRA without the ship length in the empiric formula performs quite well (3<sup>rd</sup> place) with an  $r^2$  of 0.98 and an MAE of 1.4 s. The roll coefficient method (with  $k=0.40$ ), Doyere (with  $c=0.34$ ) and the beam method (with  $c=0.36$ ) fall in the middle. Grin has the best performance, with an  $r^2$  of 0.998 and an MAE of only 0.7 s. It has to be noted that this is logical as the method is based on these ships.

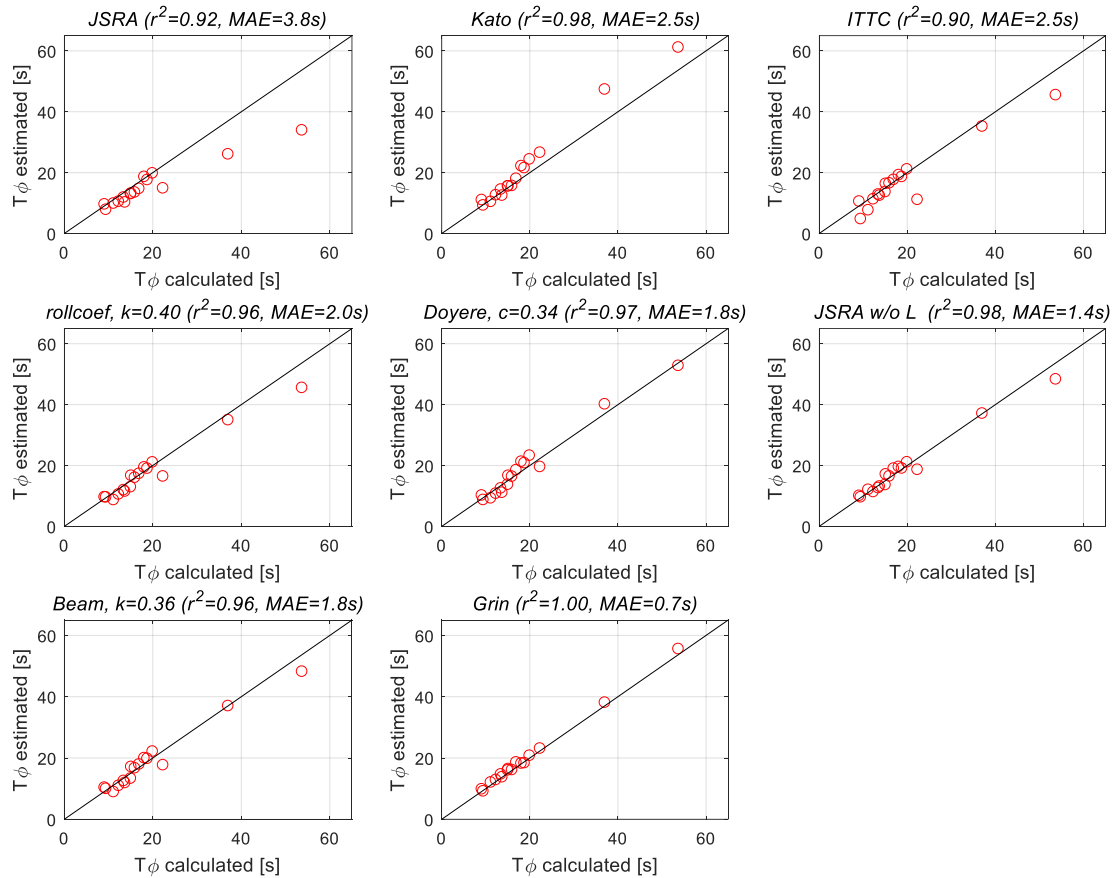

Figure 5: Cross plots of calculated and estimated rolling period of 9 vessels (16 loading conditions)

### Case 2, full scale measurement data on a 9200 TEU container vessel

Full scale measurements on a 9200 TEU container vessel were re-analysed within the TopTier joint industry project. This project aims at a significant reduction of containers lost at sea (Koning et al, 2022). A proper estimation of the roll period is very important as it is used in the lashing software to determine if lashing loads are within limits as well as for determining the risk of large roll motions during the voyage. The main dimensions of the vessel are given in Table 2 and Figure 6 shows the side view for one of the voyages including the calculation of the effective depth  $H$  (total lateral area divided by  $L_{pp}$ ).

The measurements were done for a long period of time and for part of this period also the loading conditions for each voyage were stored. In total 114 voyages contained both measurements as well as the loading condition. As shown in Table 2, the variation in loading conditions is large, ranging from (near) ballast conditions to full load condition at almost scantling draft. Also, the GM range was large, from relatively low stability of 1.2 m up to 13.2 m in very light load coastal voyages in Asia. Note that the effective depth is dependent on the arrangement of deck containers and is variable as well.

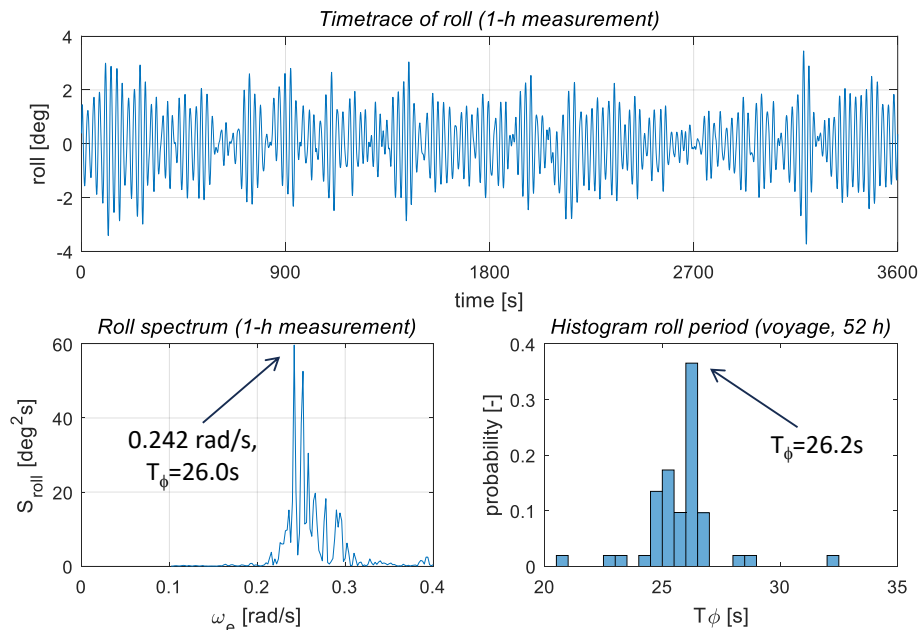

**Table 2: Main dimensions of the 9200 TEU container vessel**

		min	max
$L_{pp}$	[m]	333.0	
$B$	[m]	42.8	
$D$	[m]	27.3	
$H$	[m]	30.2	49.6
$T_a$	[m]	7.3	14.8
$T_f$	[m]	4.9	14.7
$\Delta$	[ton]	47,000	143,000
VCG	[m]	13.3	19.4
GM	[m]	1.2	13.2
FSC	[m]	0.1	1.2
$T\phi$	[s]	11	34.5
$\beta$	[-]	14.7	
$C_u$	[-]	0.89	

**Figure 6: Side view of the 9200 TEU container vessel**

From all the measurements only the roll motion is used. The sample rate was 20 Hz and data was stored in 1-hour datafiles. The roll period was obtained by a spectral analysis (Welch method) of these 1-hour measurements. A small frequency step of 0.002 rad/s was used to get enough resolution. The drawback is that the spectrum is quite spiky. The peak frequency of the spectrum was stored and if the same peak frequency is measured 10 times, it is considered to be the roll natural period. This procedure is needed as a ship is not necessarily rolling at its natural roll period: this could be easily 5% longer or shorter. This is clearly illustrated in Figure 7. The upper plot shows one 1-hour timestep of the roll motion within one of the voyages. The accompanying roll spectrum is shown in the lower left plot with the largest peak at 0.242 rad/s, resulting in a roll period of 26.0 s in that timestep. After 52 timesteps, the same roll period was found 10 times, being 26.2 s. The histogram shows all 52 roll periods found; they show a considerable spread, from 20.9 s to 32.1 s. It is probably possible to find a more efficient procedure to accurately measure the roll period, but these results illustrate that simply timing 10 roll oscillations is not sufficient for an accurate assessment.

**Figure 7: Example of 1-h time trace, roll spectrum and resulting roll period for the complete voyage**

Similar to the previous case, cross plots are made with the measured roll period against the estimated roll period, see Figure 8. The score is more or less the same, with JSRA and Kato being the worst. The ITTC and the roll coefficient method are in the middle. The top 4 consists of Doyere, JSRA without the length, Grin and the beam method. All 4 methods perform equally well with an MAE of around 0.9 s. Note that the scatter in these plots comes not only from an imperfect fit, but also from uncertainty in  $GM_t$ , as the actual weight and position of the stowed containers might be different from the provided one.

**Figure 8: Cross plots of measured and estimated roll period of 114 voyages of a 9300 TEU container vessel**

### Case 3, full scale measurement data of a 14,000 TEU container vessel

Within the Toptier joint industry project, full scale measurements are ongoing on 3 large container vessels. For the 14,000 TEU vessel part of the measurements are already analysed, resulting in the roll period for 45 voyages. Table 3 shows the main particulars and loading conditions of the vessel. In this case the stow positions of the deck containers was not available. Consequently, the effective depth ( $D$ ) was not calculated per voyage, but an average was taken assuming an average of five high cube containers stowed on deck. As shown in the previous benchmark case the effective depth could vary considerably and this affects to some extend the results of Kato and Grin as both use the effective depth. The roll period is determined using the same analysis procedure as for validation case 2.

Figure 9 shows the resulting cross plots. It is shown that the correlation coefficient is somewhat lower than previous two benchmark cases, mainly caused by a few outliers (whereas the MAE is comparable). After checking these outliers, no reason was found to disregard these voyages. The prediction methods give again similar results, with JSRA and Kato having the largest MAE, ITTC, JSRA without length and the roll coefficient method ending in the middle and Doyere, Grin and the beam method as 3 best performing methods.

## CONCLUSIONS

A reliable prediction of the roll period is crucial, as it forms the basis of the calculation of the roll motion and transverse accelerations. If the roll period and underlying parameters  $k_{xx}$ ,  $a_{xx}$  and  $GM_t$  are wrong all subsequent calculations are wrong as well. This could have large consequences and might even affect safety when passenger, crew and cargo are exposed to large, unexpected roll motion e.g. due to parametric roll. Within this paper eight methods are evaluated and compared. Based on the present work, the following conclusions can be drawn:

- The uncertainty in roll period comes in large part from the uncertainty in  $k_{xx}$ . The uncertainty in  $a_{xx}$  and  $GM_t$  have roughly equal contribution. In order to reduce the uncertainty in roll period it is best to reduce the uncertainty in  $k_{xx}$ . The difficulty is that  $k_{xx}$  is not as readily available as for instance the  $GM_t$ .
- The  $a_{xx}$  can easily and reliably be calculated with any frequency domain seakeeping code. The  $a_{xx}$  is dependent on hull shape, roll period and water depth. In shallow water the  $a_{xx}$  increases and thereby the roll period. For this reason, onboard measurement of the roll period should take place in deep water. As the  $a_{xx}$  dependency is not very sensitive to loading condition, a fairly small  $a_{xx}$  database with as variables draft and  $GM_t$  would be sufficient and intermediate values can be interpolated from this database. If direct calculation or interpolation from a database is not possible, a rough estimate can be made with equation 16.
- For the prediction of the roll period, the dry  $GM_t$  (without FSC) is typically the best choice. This is because for many ships the FSC mainly originates from the double bottom tanks in which the water ballast or fuel cannot move freely when exposed to rolling because of the internal structure. Also, for anti-rolling tanks the FSC should not be included. The remaining tanks typically have a small FSC which can be included in the rolling period calculation, but if disregarded the error is fairly small. Only in the case of wide tanks without a lot of internal structure like e.g. cargo tanks and LNG fuel tanks, should the FSC be accounted for.
- Eight roll period prediction methods were evaluated. All of them essentially predict the  $k_{xx}$  and except two (ITTC and Grin), all of them include the  $a_{xx}$ . These methods have been compared to three validation cases: 1) detailed weight calculations and strip-theory calculations of 9 different ships with 16 loading conditions in total; 2) full-scale

measurements on a 9200 TEU container vessel consisting of 114 voyages and 3) full-scale measurements on a 14,000 TEU container vessel consisting of 45 voyages.

- Based on these 3 cases it is shown that JSRA (as used in IS2008 and SGICS) and Kato have relatively large errors, with a MAE of 2.5 s up to 5.3 s. All other methods give a fair to good estimate with a MAE of 0.7 s to 2.5 s. The four best performing methods are listed in the table below.

**Table 4: Best performing methods to predict roll period**

Method	$r^2$ , case			MAE [s], case			Pro (+) / cons (-)
	1	2	3	1	2	3	
Doyere, $c=0.34$	0.97	0.96	0.86	1.4	0.9	0.9	Only B and VCG needed (+), physics based (+), added mass in c-factor (-)
JSRA w/o L	0.98	0.96	0.84	1.4	0.9	1.2	Only B and D needed (+), not based on physics (-), added mass in c-factor (-)
Beam, $k=0.36$	0.96	0.96	0.87	1.2	0.8	0.9	Only B and D needed (+), physics based (+), added mass in k-factor (-)
Grin	1.00*	0.96	0.85	0.7*	0.9	0.9	Require effective depth H (-), physics based (+), added mass separated (+)

\* It has to be noted that the first validation case is also used within the development of Grin, it is therefore logical that it performs best there.

## FURTHER WORK

Ship stability software has potentially the capability and information (weight, position and geometry of all deadweight mass) to accurately calculate the  $k_{xx}$ . It only requires the radii of inertia of the light ship. This would make estimation methods obsolete; only roll added mass needs to be calculated or predicted.

It is advised to do onboard measurement of the rolling period. This can be used for onboard advice to reduce the risk of large roll motions but also to tune roll factors for the specific ship, and if needed, loading conditions. It is however not straightforward to accurately derive the rolling period from measurements. Guidelines on how to do this should be developed.

The three validation cases showed almost the same four best performing roll period predictors. Within TopTier full scale measurement campaigns on another 2 large containers vessels are ongoing. These will be used to further validate these methods for container vessels. It is recommended to do some further validation work for other ship types as well. After validation, it is suggested to update the roll period formulas in IMO, ITTC and Class to (one of) these four methods.

## ACKNOWLEDGEMENTS

The author would like to acknowledge the participants of the TopTier joint industry project who made this research possible. A second acknowledge goes to the Shipbuilding Research Association of Japan who supplied background information on the alternative JSRA fit without length.

# An Automated Method for Pipe Routing in Ship Unit Modules

Jisang Ha<sup>1</sup>, Myung-II Roh<sup>2,\*</sup>, Min-Chul Kong<sup>3</sup>, Mijin Kim<sup>4</sup>, Jeoungyoun Kim<sup>3,4</sup>, Nam-Kug Ku<sup>5</sup>

## ABSTRACT

*This study addresses challenges in ship arrangement design by proposing an automated pipe routing method in ship unit modules. Currently, designers rely on experience, lacking quantitative assessments and causing difficulties for non-experts. The proposed method incorporates expert knowledge and design rules into an expert system, evaluating expertise and adherence to rules. The system's evaluation result was used as the objective function of an optimization problem formulated for pipe routing in conjunction with metrics such as total pipe length, the number of bends, and space availability. Through validation by comparing actual unit module designs, it is demonstrated that the proposed method suggested improved pipe routing design while adhering to expert knowledge.*

## KEY WORDS

Ship Unit Module; Pipe Routing; Expert System; Arrangement Design; Optimization

## INTRODUCTION

The equipment in the ship is installed by connecting a ship's unit modules, each individually manufactured. These unit modules consist of the equipment with similar functions and pipes connecting them. This is a frequently used method because it can reduce production and installation costs by considering the similarity of the equipment or piping systems that comprise the modules and performing the arrangement through modularization (Gunawan et al., 2021). However, when doing the design for these modules, designers must consider the locations of the installed equipment and pipes when they perform pipe routing. However, the current approach to pipe routing in unit modules relies heavily on the designers' experience and lacks quantitative assessments. Consequently, non-experts have difficulty understanding the characteristics of unit modules and performing pipe routing. Moreover, the design review of pipe routing is time-consuming and challenging due to intricate pipe patterns and the absence of quantitative evaluation. To address these issues, this study proposed a method that analyzes pipe patterns and automates pipe routing in unit modules while incorporating expert knowledge and design rules. For this, an expert system was developed to assess the expertise of pipe routing experts and their adherence to design rules. The result of evaluating the system, the feasibility index, was used as one of the objective functions of an optimization problem formulated for pipe routing in conjunction with metrics such as total pipe length, the number of bends, and space availability. An effective pathfinding algorithm was used to solve the optimization problem. The designs of actual unit modules were compared to the results obtained using the proposed method to validate its effectiveness. The comparative analysis with manual designs demonstrated that the proposed method finds better alternatives for pipe routing while adhering to expert knowledge.

## Related Works

Since automating pipe routing in ships has the benefit of reducing design and review costs, there have been several studies on automated pipe routing and optimal pipe routing to achieve better results. Kimura and Ikehira (2009) and Furuholmen et al. (2010) tried to optimize piping cost by using optimization algorithms such as genetic algorithm and ant colony algorithm to optimize pipe routing. Ando and Kimura (2011), Lee et al. (2019), and Gunawan et al. (2022) utilized pathfinding algorithms to perform automated pipe routing. Also, research has been done in the form of using a combination of pathfinding and optimization algorithms, such as the work of Dong and Bian (2020). More recently, research has been conducted on pipe routing using reinforcement learning (Shin et al., 2020; Y. Kim, Lee, Nam, & Han, 2023). In this study, one of the heuristic pathfinding algorithms was chosen to perform automated pipe routing for faster route finding. A summary of studies related to pipe routing and this study is in Table 1.

**Table 1. A summary of related studies on pipe routing and this study**

## THEORETICAL BACKGROUND

The pipe routing target of this study, the ship unit module, refers to a set of equipment, piping, etc., that are typically grouped together within a particular system. Each piece of equipment and pipe that constitutes a module has input and output points, and they are complexly connected. Therefore, a detailed analysis of the characteristics of the connection relationship between equipment and pipes is required, and this study performs pipe routing of existing or new equipment based on the patterns already analyzed. The information analyzed includes the equipment's location, orientation, and bounding box information. Nozzle information was obtained by considering the pipes at the point of contact with the bounding box as the input/output point. We also utilized the pipes and equipment information, which includes pipe type, diameter, length, and coordinates.

### Expert System for Pipe Routing in Ship Unit Modules

Many parts of pipe routing design are based on the data of previous ships or the know-how of experts. In order to apply the data of previous ships or the know-how of experts, this study uses an expert system to evaluate the results of pipe routing design and utilize them as objective functions or constraints (Kendal & Creen, 2007; Kim et al., 2015; Kim and Roh, 2016; Kim et al., 2017; Jung et al., 2018). The expert system utilized in this study consists of an Arrangement Template Model and an Arrangement Evaluation Model. They are described in the following sub-sections.

#### *Arrangement Template Model*

An Arrangement Template Model is a data structure for storing information about an arrangement target. The main value of the information of each "Node" that constitutes the "Pipe" that is most utilized in this study is stored in the "Pipe." For example, the "Max. Serial straight nodes" property value (maximum intuition length) is utilized in the Arrangement Evaluation Model by selecting the largest value among the "Serial straight nodes" values for each "Node."

## Arrangement Evaluation Model

An Arrangement Evaluation Model consists of an ID, a target object, an attribute, and a target value (K. S. Kim et al., 2015). A target object and a subjective object are the objects that specify information. An attribute means the attribute of the object, such as the distance between objects whether they are connected. A target value is a value that the attribute should have. Object information refers to expert knowledge about the requirements related to the properties of a particular object, and relationship information refers to expert knowledge about the relationships between objects.

The American Bureau of Shipping (ABS) recommended arranging items that need to be precise, frequently used, or used for emergency purposes at a height of 860 to 1,350 mm from the floor (American Bureau of Shipping, 2018) as shown in Figure 1.

**Figure 1: Recommended height for standing personnel**

Expert knowledge can be expressed in the IF/THEN rule and used in the Arrangement Evaluation Model (rule-based expert system). If the corresponding expert knowledge is not essential, a continuous feasibility index can be calculated. An example of this categorized expert knowledge is shown in Table 2.

**Table 2: Examples of expert knowledge in the Arrangement Evaluation Model**

ID	Target object	Attribute	Target value	Knowledge expression	Priority
A001	All nodes	Node z coordinate	860_MIN_mm	IF node z coordinate $\geq$ 860 mm THEN 100 ELSE 0	3
A002	All nodes	Node z coordinate	1350_MAX_mm	IF Node z coordinate < 1350 mm THEN 100 ELSE 0	3

In Table 1, ID refers to the ID that classifies the relevant expert knowledge. The target object refers to the target to which the expert knowledge is applied. Attribute refers to the property of an object to which expert knowledge is applied. Target value refers to the value that an attribute must achieve to satisfy expert knowledge. Knowledge expression is content expressing the relevant expert knowledge using IF/THEN rules. If expert knowledge is satisfied, a feasibility index of 100 is obtained; otherwise, a feasibility index of 0 is obtained. The total feasibility index is used as the third objective function. Priority refers to the level of priority of that expert's knowledge. This is determined through interviews with experts and is an integer between 0 and 3. 0 is the most essential expert knowledge that must be satisfied, and 3 is the least important.

## Pipe Routing for Ship Unit Modules

### Design Variables

For design variables, we set the positions of nodes constituting each pipe as design variables. For objective functions in pipe routing, we calculate values based on the information of each node constituting the pipe  $p_i$ . Figure 2 shows an example of a pipe with nodes. For example, the pipe  $p_1$  in Figure 2 consists of four nodes ( $n_1, n_2, n_3, n_4$ ).

Figure 2: An example of nodes of the pipe  $p_1$

### Objective Functions

The 1<sup>st</sup> objective function  $F_1 = L(p_i)$  is calculated as the sum of the distances between nodes constituting  $p_i$ . In Figure 2, the sum of the length between nodes ( $n_1, n_2, n_3, n_4$ ) is  $L(p_1)$ . In the 2<sup>nd</sup> objective function, the total number of bends  $F_2$  is calculated by the number of bends in pipe  $B(p_i)$ . In Figure 2, the number of bends  $B(p_1) = 1$  can be calculated from the information of nodes ( $n_1, n_2, n_3, n_4$ ). To consider the workability and cost of pipe installation and maintenance, The smaller the total length of pipes ( $F_1$ ) and the number of bends ( $F_2$ ), the better the pipe routing.  $F_1$  and  $F_2$  were commonly utilized as objective functions for pipe routing in various related works, including Furuholmen et al. (2010), Ando and Kimura (2011), and Lee et al. (2019). For the 3<sup>rd</sup> objective function, the space availability of pipes  $F_3$  is used. It is a value of how efficiently the pipe is utilizing the space. In this study, space availability is a measurement of how efficiently the piping is arranged in a given design space. When piping is co-located with other equipment, the arrangement of supports and space availability should be considered. While there are previous studies that have considered space availability, this study used the space availability metric of the study of Lee et al. (2019). They calculated the distance from the wall or obstacle to where the piping is installed and used this as an indicator of space availability. The lower this value is, the closer the piping is located to the wall and the better the space is utilized. Minimizing this value was defined as the 3<sup>rd</sup> objective function  $F_3$ . As the final objective function  $F_4$ , we used the sum of the feasibility index, the output of the Arrangement Evaluation Model.

### Constraints

For constraints, we check pipe routing to prevent collisions with obstacles and deviations from the pipe installation area.

### Pipe Routing Method

For generating routes for pipes, the Jump Point Search (Harabor & Grastien, 2011; Min, Ruy, & Park, 2020) algorithm is used. To improve the computational speed of pipe routing, we utilized a grid with a dynamic size. By defining a grid that changes dynamically according to the complexity around the grid space, it is designed to use a grid of a different size depending on the situation (Ha, Roh, Kim, & Kim, 2023). Let  $d$  be the distance from where the node is located to the closest obstacle, and if  $d \leq \text{grid space}$ , smaller grid spaces are created for considering the distance to the nearest obstacle/ bulkhead. In this study, the maximum grid space is 200 mm, and the minimum grid space is 10 mm.

## APPLICATIONS

In this study, pipe routing was performed using the proposed method for a ship's on-deck unit modules. A comparison of the objective function with the results of a manual design is shown in the following figures and tables. In this study, manual design refers to pipe routing results that are designed by experts according to design rules and manuals. Figure 3 and Table 3 show the pipe routing results for the first module.

Figure 3: The result of pipe routing for Module 1

Table 3: The objective functions of pipe routing for Module 1

Case	Total length of pipes ( $F_1$ , Min) [m]	Total number of bends ( $F_2$ , Min)	Avg. space availability of pipes ( $F_3$ , Max)	Feasibility index of pipes ( $F_4$ , Max)	Calc. time [Sec]
Module 1 (Manual)	74.87 (100%)	183 (100%)	8,166.5 (100%)	483 (100%)	-
<b>Module 1 (Proposed)</b>	<b>58.50 (78.1%)</b>	<b>112 (61.2%)</b>	<b>10,274.4 (125.8%)</b>	<b>483 (100%)</b>	<b>64.21</b>

For Module 1, the total length of pipes ( $F_1$ ) was reduced by 21.9%, and the total number of bends ( $F_2$ ) was reduced by 38.8%. The space availability of pipes ( $F_3$ ) improved by 25.8%, and the routing results satisfied all expert knowledge ( $F_4$ ). The pipe routing results for Module 2 are shown in Figure 4 and Table 4.

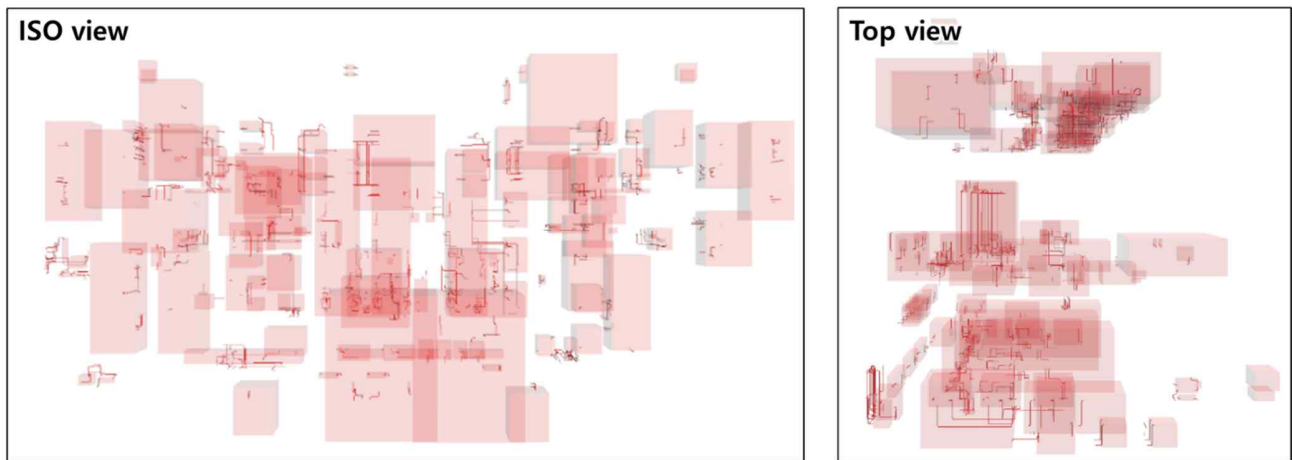

Figure 4: The result of pipe routing for Module 2

Table 4: The objective functions of pipe routing for Module 2

Case	Total length of pipes ( $F_1$ , Min) [m]	Total number of bends ( $F_2$ , Min)	Avg. space availability of pipes ( $F_3$ , Max)	Feasibility index of pipes ( $F_4$ , Max)	Calc. time [Sec]
Module 2 (Manual)	111.89 (100%)	204 (100%)	8,255 (100%)	952 (100%)	-
<b>Module 2 (Proposed)</b>	<b>97.20 (86.9%)</b>	<b>185 (90.7%)</b>	<b>10,022.6 (121.4%)</b>	<b>952 (100%)</b>	<b>89.7</b>

For Module 2, the total length of pipes ( $F_1$ ) was reduced by 13.1%, and the total number of bends ( $F_2$ ) was reduced by 9.3%. Space availability of pipes ( $F_3$ ) improved by 21.4%, and the routing results satisfied all expert knowledge ( $F_4$ ). The pipe routing results for all on-deck modules are shown in Figure 5 and Table 5.

**Figure 5: The result of pipe routing for all on-deck modules**

**Table 5: The objective functions of pipe routing for all on-deck modules**

Case	Total length of pipes ( $F_1$ , Min) [m]	Total number of bends ( $F_2$ , Min)	Avg. space availability of pipes ( $F_3$ , Max)	Feasibility index of pipes ( $F_4$ , Max)
All on-deck modules (Manual)	4,887 (100%)	1,439 (100%)	10,640.2 (100%)	15,006 (100%)
All on-deck modules (Manual)	4,843 (99.1%)	1,236 (85.9%)	11,778.2 (110.7%)	15,006 (100%)

After performing pipe routing, we can see that all the objective functions improved compared to the original results of the manual design.  $F_1$  improved by 0.9%,  $F_2$  by 14.1%, and  $F_3$  by 10.7%, and the feasibility index for expert knowledge was the same as the manual design given by the expert. The routing results satisfied every expert knowledge.

## CONCLUSIONS

This study performs successful pipe routing by utilizing the given information about the unit modules of a ship and the interrelations between pipes. The pipe routing results obtained in this study show a significant improvement over manual designs, achieving a reduction of up to 21.9% in the total length of pipes ( $F_1$ ) and up to 38.8% in the number of bends ( $F_2$ ). Space availability in the piping was improved by up to 25.8%, and the feasibility index for expert knowledge was evaluated, and all expert knowledge was satisfied. Leveraging the method proposed in this research, we developed a prototype for an automated program dedicated to the pipe routing of ship unit modules.

The accurate start and end points of the pipes are defined based on the connection information of the pipes, ensuring precision in the pipe routing process. Since the pipe routing in this study is targeted at the initial design stage, there is a limitation that prior research is needed to extract the information required for pipe routing from P&IDs at this stage. Additionally, we will include a review of potential improvements in pipe routing to meet the requirements of additional expert knowledge in this field.

## ACKNOWLEDGEMENTS

# Defining a Framework for Implementing the Circular Economy Principles into Ship Design

Elise Hoffmann<sup>1,\*</sup> and Jeroen Pruyn<sup>2</sup>

## ABSTRACT

*This research addresses the importance of sustainability in shipping beyond fuel selection, stressing the need for responsible material usage in vessel construction and maintenance. Transitioning to a circular economy is crucial for sustainable waste management in the industry, yet current ship design neglects circularity considerations, prioritising functionality and cost. The research evaluates frameworks such as the butterfly diagram, Cradle-to-Cradle, 10R, and ReSOLVE to integrate circularity into ship design. Combining the 10R framework with the Material Circularity Indicator method, this study offers practical insights for circularity in ship design. Challenges include integrating these methods into standard design processes, which are mitigated by fusing 10R strategies with systems engineering. A case study on wheelhouse redesign demonstrates the effects of this approach, highlighting the importance of supplier collaboration for circularity enhancement.*

## KEY WORDS

Circular Economy, Systems Engineering, Ship Design, Sustainability

## INTRODUCTION

In 2015, 193 world leaders have agreed to 17 global goals to end extreme poverty, inequality and climate change by 2030. Goal number 12 states: "Responsible consumption and production" (The Global Goals, 2015). The aim of this goal is to ensure sustainable consumption and production patterns. To achieve this goal eleven targets have been set to create action. One of them also being: "Substantially reduce waste generation". By 2030, the aim is to substantially reduce waste generation through prevention, reduction, recycling and reuse.

In the maritime sector, currently virgin materials are used for the construction of vessels which all have to be taken care of again at the end of a ship's life. Ships are broken down at ship recycling yards, where steel is recycled, but often with disregard for the environment (Mikelis, 2019). In 2018, 90.4% of the ships (measured in the gross tonnage) were recycled by shipbreaking and recycling industries in Bangladesh, India, and Pakistan. These are popular countries because of the absence of strict environmental regulations (Alam et al., 2019). Also, recycling is a valid option but when looking at retaining value, recycling is not the best way and other methods such as reuse or refurbishment are preferred (Cramer, 2020). Not only at the end of a ship's life, during demolition, the materials need to be processed but also during the ship's lifetime of approximately 25 years, components on board are replaced, creating a lot of waste. Additionally, little is known about how all other parts except for the steel of the hull are handled, such as electronic systems or furniture.

At the moment shipbuilding is not considering the reuse of materials at the input and output side of the process. As a result, circular economy would offer many opportunities for improvement and could increase the sustainability of this key sector. In a circular economy there is no waste since waste is seen as a raw material for new products (Stahel, 2016). Currently, vessels are designed with a focus on functionality, cost and operability. Next to that, designers mainly reuse existing knowledge to establish assumptions and probability to deal with uncertainty. This makes it difficult to take higher levels of uncertainty into account, whilst due to the ongoing energy transition there is uncertainty about the required refits and updates of systems in the future (Zwaginga and Pruyn, 2022). Taking into account the circularity of products when designing a vessel could reduce waste and improve the sustainability of vessels since up to 80% of a product's environmental impact is determined already in the design phase (European Commission, 2020a). The circular economy principles, also known as cradle-to-cradle, are therefore seen as a sustainable strategy.

This paper explores a method of implementing the circular economy principles into the ship design approach. Where circularity is considered to be any process that improves the reuse of equipment, components, parts and materials, where the maintenance of value is a key priority. This is achieved by first assessing the current state of circularity in the shipping industry. Next, there is a selection of a definition of circularity and a way to measure it. After that, the goal is to identify important system properties that enable identifying the level of circularity that is currently prioritised in the design of the system by looking at these system properties. Combining these topics, a framework will be drafted to guide future ship designers in also taking circularity into account alongside the current design drivers such as functionality, cost and operability. As a case study, the framework will be tested on the wheelhouse of a Damen RSD2513 tug. In the case study, different system levels will be examined on their current circularity level and improvements to increase the circularity level will be proposed.

## THEORY

In this section, the current state of circularity in the shipping industry is researched to determine the potential of applying (more) circularity in the sector. After that, the theory behind the circular economy will be elaborated upon. Lastly, approaches for both circular design and ship design will be discussed to look for opportunities of combining these two approaches.

### Circularity in Shipping

Literature research on the topic of circularity in the shipping industry was done by the use of the databases of Scopus, WorldCat, the TU Delft repository and Google Scholar. To achieve relevant results, search terms were determined in advance. The keywords such as "Circular\*", "Ship Design", "Ship recycling", "Ship repair", "Systems Engineering", and any combination of these words were used. This research revealed no scientific resources on the topic and by use of Google and the same keywords, an understanding of the circularity in shipbuilding was obtained.

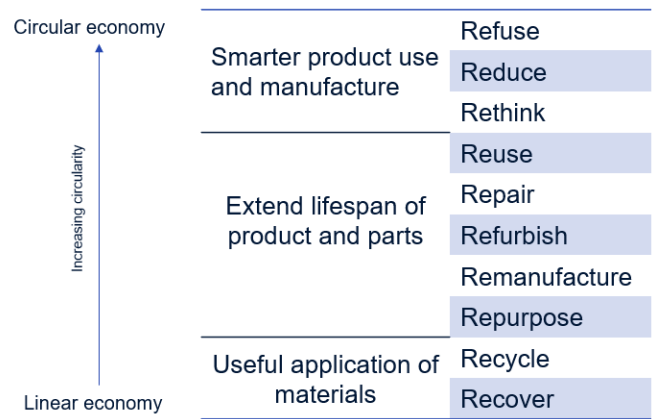

Sustainable Shipping Initiative and 2BHonest (2021) state that the shipping industry is already applying reuse, repair and recycling, which are all circular principles. However, the circular economy is more than those three principles and the current practice is primarily cost-driven, so other principles of the circular economy have great potential to be implemented in the shipping industry as well. To ensure this, more and more rules and regulations such as the Hong Kong Convention (IMO, 2015), EU Ship Recycling Regulation (European Commission, 2020b), the Circular Economy Action Plan, The European Sustainability Reporting Standard (EFRAG, 2022) and ISO standards are put into place (Balder, 2021). During the process of this research, the requirements to put the Hong Kong Convention into force were met and on June 26th 2025, the convention will enter into force (IMO, 2023). However, the fact that the HKC took almost 14 years to be signed by enough states, shows that many states are not very eager to comply with the regulations that would improve circularity, most likely because of the cost and extra work that will come with it. If the maritime sector wishes to become more circular and more sustainable, all stakeholders in a vessel's lifetime need to be on board. How circularity can be achieved will be researched in the next section.

## The Theory of the Circular Economy

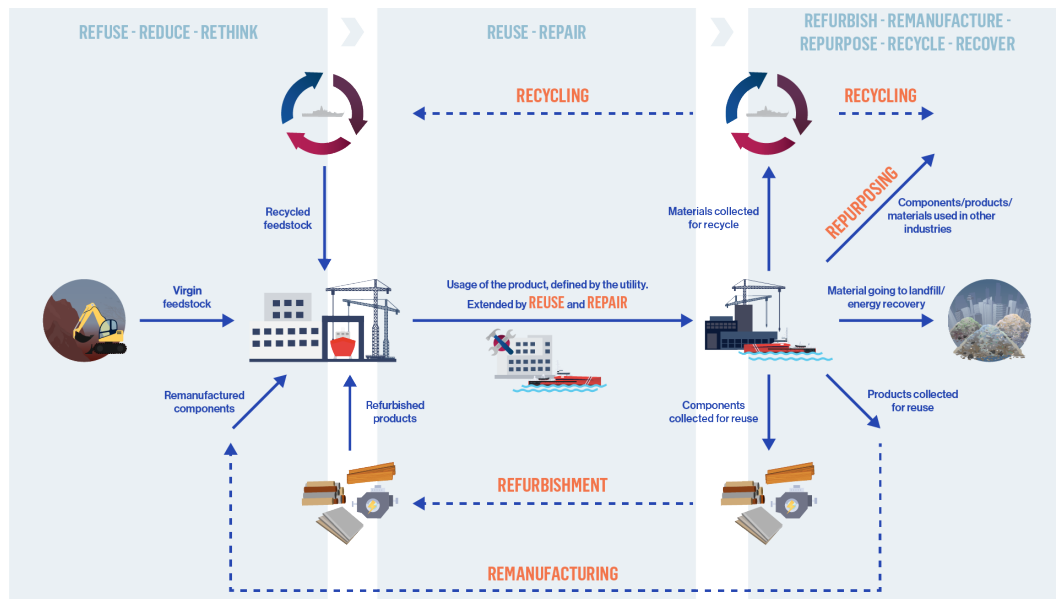

The current 'take-make-dispose' economy is called a linear model (Di Maio and Rem, 2015) (Bocken et al., 2016). Di Maio and Rem (2015) state that in Circular Economy (CE) models, products maintain their added value for as long as possible and minimise waste. The aim is to keep resources within the economy when products no longer serve their functions so that materials can be used again and therefore generate more value. Thus circular business models create more value from each unit of resource than traditional linear models. Stahel (2016) describes the linear economy as a flowing river, whilst the circular economy can be seen as a lake, where the goods and materials are reprocessed.

The World Business Council for Sustainable Development (WBCSD) concludes that the concept of the circular economy is relatively vague and amorphous, resulting in companies moulding and defining circularity in ways that are most relevant to their core business (wbcscd, 2018). As a result of this, most companies have their own approaches for the implementation of the circular economy. Popular approaches are Cradle-to-Cradle, 10R, the butterfly diagram and ReSOLVE. Even though the frameworks differ in name and exact approach, there are many overlapping principles. First of all the main takeaway for every circular framework is to have as little waste as possible and ideally never throw any materials away by closing the loop. But also the way materials are kept in the loop shows some overlapping principles within the frameworks; words such as reuse, refurbish, recycle etc are in the butterfly diagram of the Ellen McArthur Foundation (2019) but also in the 10R framework. The environmental impact besides material circularity is not part of these frameworks. This was also defined in the scope, to not look at other environmental impacts but purely circularity in terms of material reuse and using as little material as possible. The 10R framework is widely cited and shows clear steps for the circularity level of a product/material in every stage of the life cycle of a product; from design until the end of life (in its current function). The different R-levels are Refuse, Reduce, Rethink, Reuse, Repair, Refurbish, Remanufacture, Repurpose, Recycle and Recover. Additionally, even though R0 until R8 can all be seen as circular, it is important to make a clear distinction between the levels of circularity, something that other frameworks have a less clear definition of. Therefore, to continue this project, the 10R framework will be chosen to work with (Cramer, 2020). In Figure 1 the order of the 10R's is shown together with their applicability in the lifetime of a system.

**Figure 1:** The 10R framework from Refuse (R0) to Recover (R9) based on Cramer (2020)

This framework does not have a clear way of measuring on which step of the circularity ladder a system is currently functioning, but to measure how circular products are, again multiple frameworks and methods exist. To measure circularity, the Material Circularity Indicator (MCI) method is selected (Goddin et al., 2019). This is because it makes a clear distinction between the different circularity levels of the 10R method, the formulas are clear and open access, and the focus is on the product level. The method calculates circularity by taking the average of the circular inflow, which can be a combination of recycled, refurbished or remanufactured materials flows, and the circular outflow, which can be a combination of recycling, refurbishing, remanufacturing or repurposing, measured in percentage of mass. During the lifetime, the utility is calculated based on the lifetime and intensity of use of the system compared to the industry averages of similar systems. The different material flows are visualised in Figure 2.

**Figure 2:** Visual of the material flows when combining the 10R framework with the MCI tool

## Design Approaches

Looking at design approaches, two types of design approaches will be discussed in this section; Ship design approaches and circular design approaches.

### Ship Design

In ship design, four classes of high-level design strategies are often distinguished; Point-based design, Set-based design, System-based design and Optimisation-based design. Of the four presented design approaches, system-based design, also known as systems engineering, is the preferred method for this research because it defines the customer needs and required functionality early in the development cycle, focuses on documenting requirements and after that proceeds with design synthesis and system validation while considering the complete problem. Kossiakoff et al. (2011) states that "The function of systems engineering is to guide the engineering of complex systems". Where a system is seen as "a set of interrelated components working together toward some common objective" ((Kossiakoff et al., 2011)). In systems engineering, a system can be broken down into systems, sub-systems, components, sub-components, and parts (Hopman, 2021). Systems engineering solves some of the problems that occur in the other methods such as the point-based design where the design spiral is often used and the starting point is so important that it is hard to implement innovations. Next to that, the method considers both business and technical needs of all customers in order to provide a quality product that meets the user's needs. The fact that the system is broken down in a modular way also helps in including circularity, where modularity plays a big role in the circularity of a system. Modular products can be divided into different modules and each module can be repaired/replaced separately ((Kimura et al., 2001)). The determination of size and content of each module is complicated to decide and are determined by multiple factors such as cost, functional independence, standardisation, ease of maintenance, etc.

Within systems engineering, an application of the theory is the Requirement-Functional-Logical-Physical model (RFLP). The complexity of systems is not only determined by the amount of connected physical components, but also the functional interdependencies play a huge role (Li et al., 2020). By working together, various systems can achieve one function. This so-called functional integration is associated with the different power sources and information flow between the systems. The requirements need to be validated against the higher level of requirements and user needs, therefore there are horizontal validation rules.

None of the four design approaches for ship design takes circularity into account. This can be because circularity is hard to express in terms of an optimisation code or functional requirement. Therefore there is a need to explore design approaches for a circular product since circular design is already quite common for consumer goods.

### ***Circular Design***

For circular design, there is no step-by-step guide on how to apply the circular economy principles to the design process. However, for every R-value, one or multiple design focuses can be identified. Many of the current circular design strategies are focused on consumer goods and are not yet applied in technical fields. The first three; refuse, reduce and reuse, focus on the cut down on raw material usage by use of design for reduction of resource consumption (Cramer, 2020)(Bocken et al., 2016). The design focus for the strategies Reuse, Repair, Refurbish, Remanufacture and Repurpose focuses on product life extension. For Recycle and Recover, the focus is mostly on designing for resource recovery or using materials for multiple cycles.

### ***Combining the Approaches into Circular Ship Design***

According to Ashby and Johnson (2003), there is a difference between engineering design, under which the art of ship design could be seen, and industrial design which involves the design of consumer goods. First of all, engineering is systematic; it follows well-established and commonly accepted procedures, whilst industrial design does not. Industrial design is strongly influenced by fashion and advertising. Industrial design is less about functionality and efficiency, but the focus is more on qualities such as form, style, and texture; the ones that cannot be measured. Engineering designers often use formal guidelines such as ISO standards whilst industrial designers have representations which are imprecise, ill-defined and less established (Pei et al., 2011). Pei et al. (2011) also states that engineering design is more about associating models with engineering principles, production issues, and functional mechanisms, whilst appearance and usability are the most important focus points for industrial design. The need for clear guidelines and standards is also bigger when looking at ship design since a vessel is way larger and more complex than consumer goods. Inside a ship, many systems, sub-systems, components and parts are present, whilst consumer goods such as chairs and tables, often consist of significantly fewer parts and components.

To include circularity, the systems engineering method has to be combined with the ten design methods complying with the 10R framework. Because systems engineering follows a clear step-by-step approach, circular design principles are best to be included in the steps of systems engineering. To include these principles, the differences between the design methods should be kept in mind and where possible the circular principles should be added in every step of systems engineering.

## **METHOD**

Now that the definition of circularity is clear, the circularity measurement method is chosen and the different design approaches have been reviewed, the next step of combining all this into a framework on how to design a vessel whilst applying the circular economy principles can be made. The framework consists of six steps that will all be separately elaborated upon in this section. The framework is visualised in Figure 3. The first step is to identify an overall goal the system needs to achieve, after which the system is broken down using the RFLP-approach in step 2. After this, in step 3, the MCI score of a comparable, existing design will be determined. After this, the system's life cycle and associated stakeholders will be identified. Finally, in step 5 the system is (re)designed by use of the RFLP approach and the use of circular principles, after which the new design will be validated in step 6. Looking at the method and comparing it to the "classic" V-diagram which is often used to visualise the RFLP approach, it becomes clear that the new method adds a few steps. The steps that differ from the classic approach are highlighted by the orange blocks.

**Figure 3:** Visual of the framework for including the circular economy principles the classical V-diagram visualisation of the RFLP approach

### Step 1: Identify the Goal and Overall Mission

In systems engineering, the first step is a needs analysis. During the needs analysis, the goal is to show clearly and convincingly that there is a valid operational need for a new system or an update of an existing design. To do this, it needs to be assessed whether or not a system already exists that is meeting the needs or whether a (re)new(ed) system is required. The general or main requirements are often dominated by three main parties; customers, production and regulations (B. Vink, Personal Communication, June 28, 2023). Where, in identifying the high-over mission, the customer often has the biggest say. Requirements are, in non-circular design strategies, often operational and functional requirements. However, when looking at the circular design, there should also be a circular goal from the start. Not only do circular aspects have to be a part of the performance and physical requirements, but also general things such as the quality of the product can be performance and physical requirements. Ideally, the goal might be to have one hundred per cent circular systems, but this might not always be achievable. For the general circular requirements, it would be wise to specify this wish into different material streams. Examples of this would be to set a requirement that ninety per cent of the inflow of materials needs to be non-virgin, or at least ten per cent of the outflow of materials should be used in remanufacturing.

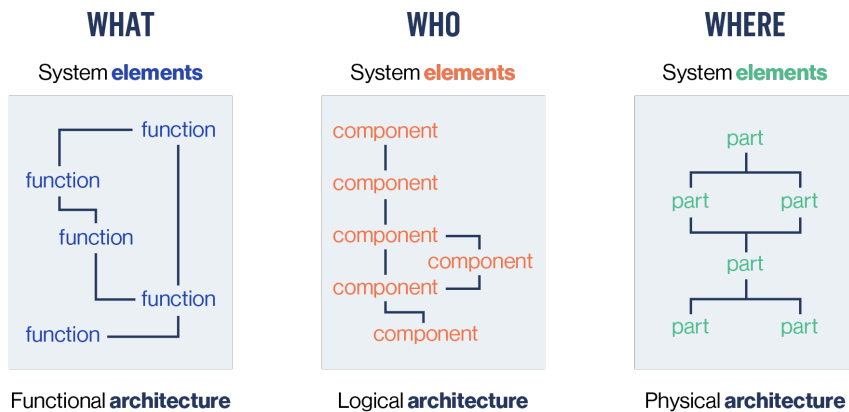

Based on the set requirements there are three possible scenarios:

- 1) A system exists that fulfils the high over requirements
- 2) A system exists that fulfils the operational requirements but not the circularity requirements
- 3) No system at all exists that fulfils the operational nor circular requirements

In case a system already exists that fulfils all requirements (scenario 1), no need exists to design a (re)new(ed) system. In case a system exists that fulfils the operational requirements but not the circularity requirements (scenario 2), step two of the framework should be carried out. In case no system at all exists that can fulfil any requirements (scenario 3), steps two and three of the framework can be skipped and step four of the framework should be carried out.

## Step 2: Identify and Breakdown System, Sub-System, Components, Sub-Components, and Parts

As mentioned before, the theory of systems engineering divides systems into sub-systems, components, sub-components and parts. According to Kossiakoff et al. (2011), the term "system" should only be used "for entities that 1) possess the properties of an engineered system, and 2) perform a significant useful service only with the aid of human operators and standard infrastructures" (Kossiakoff et al., 2011). How far a system can be broken down for analysis is very dependent on the information provided; if no information is there on the structure of the system because, for example, the system is designed by a separate company, this is hard to break down further. Next to breaking the system down, it is also important to identify the boundaries of a system to define what is inside the system, and what is outside. Several criteria can be used to help determine whether an entity is part of a system or not; Development control, operational control, functional control and unity of purpose. For every criterion, questions can be asked such as; "Does the system developer have control over the entity's development?" and "In the functional definition of the system, is the systems engineer "allowed" to allocate functions to the entity?" (Kossiakoff et al., 2011). Additionally, entities that are not part of the system, will still interact with it. Once the boundaries have been set and the system has been broken down, the connections within the system can be analysed. The interactions on multiple levels of a system can be evaluated by the use of architectures. Architectures help to capture the relationship between the different elements of a system. There are functional, logical and physical architectures, all visualised in Figure 4.

**Figure 4:** Visualisation of a functional, logical and physical architecture, based on The Mathworks (2020)

After all these theoretical boundaries and frameworks on how to identify the system, practice might prove to be different. In reality, one needs to work with the information available. This information could be retrieved from drawings of systems, material lists or other documentation. The level of detail per system might differ since some systems might be designed and built by the company performing the analysis whilst others might be designed and built by suppliers. Since the circularity of the systems is measured based on weight, resulting in the heaviest components or parts having the biggest influence on the total circularity level of a system. Thus selecting a heavy system when having the choice between multiple systems to assess is an effective way to increase the circularity level.

## Step 3: Determine the Current Level of Circularity of Existing Design

To have a baseline and be able to measure improvement in terms of circularity after redesigning it, the previously selected MCI method will be applied. During the assessment of a system on its current level of circularity, mostly material choice, modularity, reliability and cost play an important role. For the outflow, the material should allow for a certain level of circularity, the modularity should be high enough to allow for easy dismantling and the cost of the value retaining steps should not too high, otherwise system will be disposed of.

For the determination of the input and output values of the MCI method, the key indicators identified can be used. For every input, multiple questions can be asked in order to determine the contribution of the input. For the inflow of materials, the key indicator of material choice is the most important. The most important question here is; have non-virgin materials been used, and are these materials reused or recycled materials? The inflow is often controlled by designers and suppliers. Therefore this is where this research can have the most impact. A very important aspect here is good communication with suppliers to get information about used materials, but also to ensure the reuse of non-virgin materials in the future.

The same type of questions can be asked about the utility and end-of-life of the product: Is the product reliable enough to reuse? Is the product built modular so it can be dismantled into different materials? Does the material choice allow for recycling? Since the MCI calculation is based on weight, the mass of the product also needs to be determined, preferably split out all the way to the part level. To acquire all this information, contact with the supplier of the system and its materials needs to be established. If the resource of the materials is unknown, industry averages can be used based on a material database such as Ansys Granta Edupack (Ansys Granta Edupack, 2006).

Based on the circularity calculation, it needs to be verified that a valid need exists to (re)design a system that fulfils the overall goal and mission.

#### **Step 4: Map the System's life cycle and Associated Stakeholders**

To know which stakeholders need to be involved in the (re)design process, the life cycle of the system and its associated stakeholders need to be mapped. The first step is to map the life cycle, which encompasses all the necessary steps involved in taking a product in service from its initial idea stage through the various stages of production (including physical transformation and the involvement of different producer services), delivery to end consumers, and ultimate disposal after use (Kaplinsky and Morris, 2000). General example life cycle steps for a vessel are engineering, manufacturing, commissioning, operation and decommissioning. To help guide a designer in mapping the life cycle, Kossiakoff et al. (2011) suggests mapping or modelling at least the following circumstances:

1. storage of the system and/or its components,
2. transportation of the system to its operational site,
3. assembly and readying the system for operation,
4. extended deployment in the field,
5. operation of the system,
6. routine and emergency maintenance,
7. system modification and upgrading, and
8. system disposition.

Once the life cycle has been mapped, stakeholders in each step of the life cycle can be identified. For the mapping of the stakeholders, not every stakeholder is of equal importance. Additionally, often the needs that different stakeholders have are in conflict. Stakeholders can be divided into the direct beneficiary and several indirect beneficiaries (Erikstad, 2018). When looking at stakeholders and their needs with regard to circularity, often an outside incentive is required. Here, the regulations that were mentioned in the theory section can be the main driver. For every stakeholder, a different regulation will be of the appliance. A strategy to reach more circularity within companies is to set goals on company-wide goals that are measured by indicators; Key Performance Indicators (KPIs) (Coalition circular accounting, 2023). These indicators can help stakeholders in guiding them in defining requirements they have with regard to circularity. In case a company does not have KPIs on circularity yet, it is recommended to first draft these before setting needs for a specific system.

## Step 5: (Re)design the System by use of the RFLP method, Applying Circularity Principles

The selected RFLP method uses requirements to define functions, which are connected by logic and then put into a physical form. It is essential for every step that the level of detail of the previous step is sufficient to make the next step.

The first step of creating a (re)new(ed) system is to set up the requirements the system has to comply with. These requirements are determined by the stakeholders as identified in Step 4. There are different types of requirements; operational, functional, performance and physical requirements (Kossiakoff et al., 2011). To check requirements, a requirements analysis can be executed. Requirements need to have certain characteristics; they should for example be feasible and verifiable. In addition to the currently common practice of operational and performance requirement defining, circular requirements should be defined. These can be seen as operational, performance and physical requirements. For circular design, there is a higher urge to reach a higher level of detail in the requirements. During "normal" design it might be enough to specify the need for, for example, a pipe with a certain length and diameter. In the case of circular design, it is important to also specify the material the pipe needs to consist of and in which way it should be attached to other parts of the system.

Once the requirements have been identified, the next step in defining the system is to define the functions. A function often consists of a verb and a noun/object (The Mathworks, 2020) and the in and outflow of a function is information, energy and/or material (Hopman, 2021). So it is a task or activity that must be performed to achieve a desired outcome. Functions are mostly the result of operational requirements. Because functions describe an action that needs to be performed, circularity is hard to capture in terms of functions. This means, that the influence of the circular requirements is minimised in this step of the systems engineering because the operational requirements, such as "lift objects and materials" say nothing about circularity.

Once the requirements and functions have become clear, logic comes into place to see where logical connections can be made. However, this is also a step that needs feedback, because in the next step, the physical components will be defined based on requirements and functions. When multiple components can be combined into a logical module, this step needs to be repeated to enable that. Applying logic to the design is something that comes back in the key indicator of modularity; if systems or parts are connected in a certain way, they will be or not be suitable for repair, remanufacturing, recycling, etc. This means that in the phase where the components, which then again consist of parts, are identified, these components need to be connected in a modular way that allows for these actions.

By use of the identified requirements, functions and logical connections, physical elements for the system can be selected. There is no clear step-by-step process on how to do this, but it is an iterative process where the level of detail gets more and more clear with every step. A way to explore the options and make a decision between different possibilities is a morphological chart as presented by Zwicky (1969). The goal of the Morphological chart is to provide a structured approach to concept generation to widen the area of search for solutions to a defined design problem (University of Cambridge, 2016). To visualise this, the functions are listed in the first column, and the possible solutions are listed in the rows.

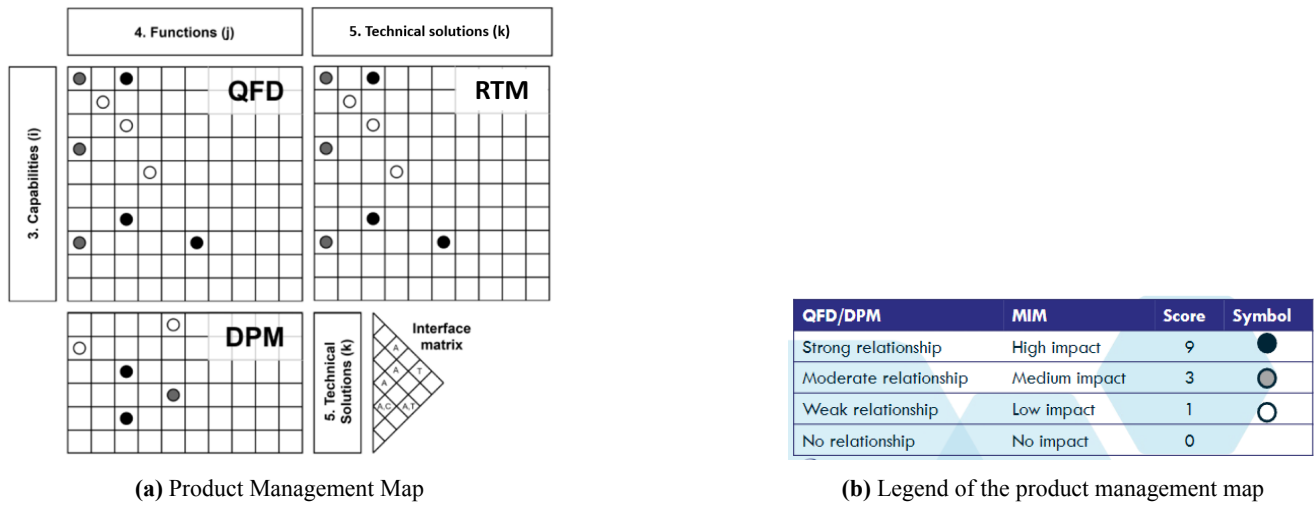

Every time the requirements, functional and logical structure have been defined, the market or in-house availability of a physical element should be checked that meets the RFL structure. In case it is not available, the RFL structure should be brought to a deeper level of detail. In case there is no further level of detail possible then it should be checked if multiple parts or components can be combined into a logical module. This stresses the need to constantly make the connection between the physical and logical analysis.

## Step 6: Validate the (re)design

As a way of checking whether or not the physical (sub-)system fulfils the desired functions, and whether these functions meet the requirements, a validation matrix can be filled in and to check the circular requirements the level of circularity can be measured. The validation is also known as a Product Management Map (PMM) and is shown in Figure 5. The PMM consists of four matrices where requirements are checked to functions (QFD), requirements to physical solutions (RTM), functions to physical solutions (DPM), and one where the interfacial connection is mapped between physical solutions. The

colour of the dot indicates the strength of the relationship between the requirements, functions and physical solutions. The darker the dot, the stronger the relationship. After the PMM has been filled out, the designer can see whether the physical solutions match all functions and requirements and if this is not the case, the designer can adjust the design or the requirements/functions.

To see whether or not a system meets the requirements in terms of circularity, the level of circularity needs to be measured throughout the design process and at the end of the design process. This can be done following the same procedure as described in Step 3. However, an advantage is that during the design a good overview of the whole system and its connections is already available. This makes it "easier" to make the breakdown of systems, sub-systems, components, etc. For this step, it is very important that, in case the circularity was also measured in step 3 an existing system, the same level of detail for the measurement is taken. Otherwise, the comparison is not fair and can result in an unreliable outcome. In case the outcome of the circularity measurement is not sufficient to meet the requirements, the design is not finished and there is a need for a designer to continue making alterations until all requirements are met.

for a circular economy. This does not mean that the goal is to make a 100% circular product or system, but that the system should be as circular as possible with the current technologies whilst also meeting the general requirements.

Damen Shipyards made a new, graphic design for a wheelhouse of a tug in 2019. Because the design of the "new" wheelhouse is in line with the design of the current tug boat type RSD Tug 2513, this is the vessel type that will be assessed. It can be concluded that there is a system present on the RSD Tug 2513 that meets the general goal but does not meet the circular goal (scenario 2). Therefore the current wheelhouse will be assessed in Step 2 and 3 of the case study.

Step 2: Identify and breakdown system, sub-system, components, sub-components, and parts

The wheelhouse is seen as the main system here and will consist of sub-systems. These sub-systems are identified by the information available at Damen Shipyards To limit the physical boundaries of the wheelhouse, it has been chosen to view the wheelhouse as everything inside (and including) the superstructure of the wheelhouse until the floor of the bridge deck. it is almost impossible to discuss every component in the wheelhouse and after that every part since there are so many components and parts. Therefore it has been chosen to select five sub-systems and examine them further. The sub-systems' names might sound like they are components or parts but sub-systems consist of multiple components and these components again out of parts.

- The captain’s chair
- The consoles
- The windows
- The superstructures
- The floor

As an example, the breakdown of the floor will be shown. Similar steps have been taken to analyse the other four sub-systems. The floor that will be assessed is not the floor presented in the RSD Tug 2513 at this moment, but the floor present in the ASD Tug 2312. This is because the floor in the RSD Tug 2513 is supplied by an "old" supplier, whilst Damen Shipyards is shifting toward the new supplier for their standardisation of the tug. This new standard is already present on the ASD Tug 2312 and this vessel has dimensions comparable to the RSD Tug 2513, therefore the floor on this vessel will be analysed. All the components and parts are identified and shown in Figure 7a

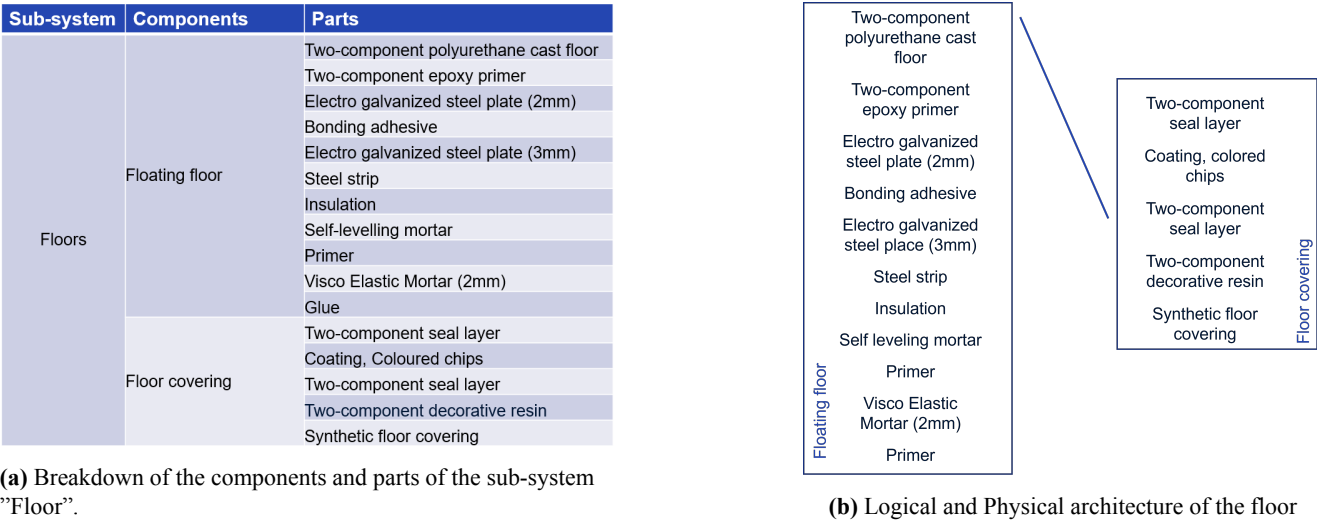

Figure 7: The breakdown into components and parts on the sub-system "Floor"

As can be seen in the breakdown, the floor consists of sixteen layers made from a lot of different materials. The layers are glued together and quite some layers are cast. The floor is made of primers, followed by isolation, covered with steel plates, and on top of that cast floor covering. The physical and logical architecture of the floor are shown in Figure 7b.

### Step 3: Determine the current level of circularity of existing design

The circularity level of current sub-systems will be analysed to show the need for a redesign when the circularity level does not meet the requirement. To measure the circularity of the five sub-systems, the weights need to be known, but also information about the key indicators needs to be acquired. To acquire the weight of different sub-systems, the "weight calculation" of the whole vessel can be used. In the weight calculation, the weights of all systems in the vessel are listed per system code. The system codes are specific for Damen Shipyards and divide the vessel into sections. To gather information about the key indicators, multiple paths have been explored. For the inflow, the most important indicator is the material choice. Information about the material of the components and parts can be often found on the bill of material of the sub-systems. However, the process of figuring out exactly what part of the material inflow which is stated on the bill of material is circular, is very hard. To determine the source of the material that is used in the four different sub-systems, the suppliers of the parts were contacted. Where data about the type of inflow was unavailable, use was made of the material database of Ansys Granta Edupack (2006). The lifetime of the sub-systems that were selected is therefore very likely to be equal to the industry average because they set the industry average. For this reason, it was chosen to not use the calculation of the utility ( $X$ ) in the calculation of the MCI because the value for the utility will be equal to 1. Because the systems that are analysed are not yet at the end of their lifetime, the outflow is not 100% sure. However, looking at the key indicators we can make an estimation or determine the potential regarding the destiny of the sub-systems at the end of life. For the outflow of materials, no standardised database exists and common practices were researched that will be discussed per sub-system

Finally, the calculated circularity of every sub-system is divided into circular inflow, outflow and the total circularity. The results are shown in Table 1.

**Table 1:** Results of the circularity assessment of the five sub-systems

	<b>Inflow</b>	<b>Outflow</b>	<b>Total MCI</b>
The Captain's chair	64%	94%	79%
The Consoles	19%	100%	59%
The Windows	14%	97%	57%
The Superstructure	35%	93%	67%
The Floor	19%	0%	9.6%

The combined circularity of these systems comes to 60%. This is mostly due to the superstructure's significant influence caused by its weight. Out of the five sub-systems, the floor has the lowest MCI mostly due to the lack of modularity and material choices in this sub-system. Due to the lack of modularity and the use of glue, the materials are not separable at the end of life, resulting in a circular outflow of zero per cent. Looking at the weight of the five sub-systems that were selected in comparison to the total weight of the vessel, the systems represent a small fraction of 2.62% of the total vessel weight.

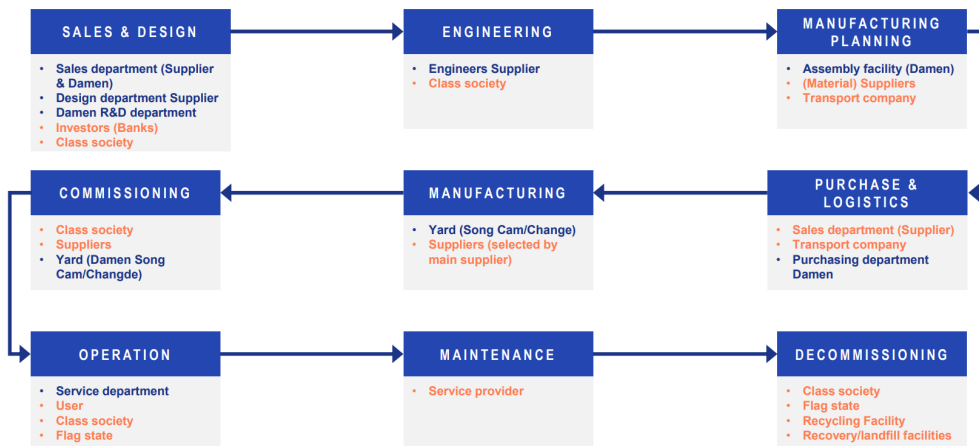

It is important to note that the percentages show the potential circularity and not the actual circularity since the systems are still operable and have not been shifted towards the end-of-life phase. Recycling is at this moment the most commonly used method to keep materials in the loop. However, recycling should be a last option when looking at the 10R principles and therefore the application of refurbishment, remanufacturing and repurposing should be considered more often. To do this, companies need to communicate with their supplier to explore the options of taking back products by the suppliers but also contact with other organisations that can help enable these strategies. Because the floor has the lowest MCI score and there is room for improvement, the floor will be worked out in more detail in the next steps. The low circularity of the floor is a result of the lack of non-virgin materials in the inflow and the low modularity, making it hard to separate materials for recycling/reuse/refurbishment at the outflow. Step four will still look at the life cycle of all five systems with an additional

focus on the floor, and steps 5 and 6 will only be completed for the floor.

#### Step 4: Map the system life cycle and associated stakeholders

The life cycle of the five presented sub-systems is different. This is because the chair is designed once and then manufactured many times because it is a universal product made by an "independent" supplier. This is contrary to the superstructure and windows, which are specifically designed for the RSD Tug 2513. The consoles are a bit in between the two since they are also used on other vessels but are still quite specifically designed for vessels built by Damen Shipyards. The floors have a standard design but are tailor-made in size for the application on the RSD Tug 2513. The Damen RSD Tug 2513s are not so-called "one-off" vessels so this means that there will not be a specific design for every new vessel that is requested but will be sold multiple times based on the same design. It can be concluded that the chosen sub-systems can be divided into two categories; Unique products and Multi-user products. A Unique product is identified as a product that is designed specifically for this vessel type and which cannot be used on other vessels, an example being the windows and superstructure. A multi-user product is a product that is usable in multiple vessel types or maybe even other types of systems, an example being the captain's chair and the floor. These two products have different life cycles because the design and manufacturing process is not the same. Multi-user products can be built in stock whilst unique products are built once the product has been sold.

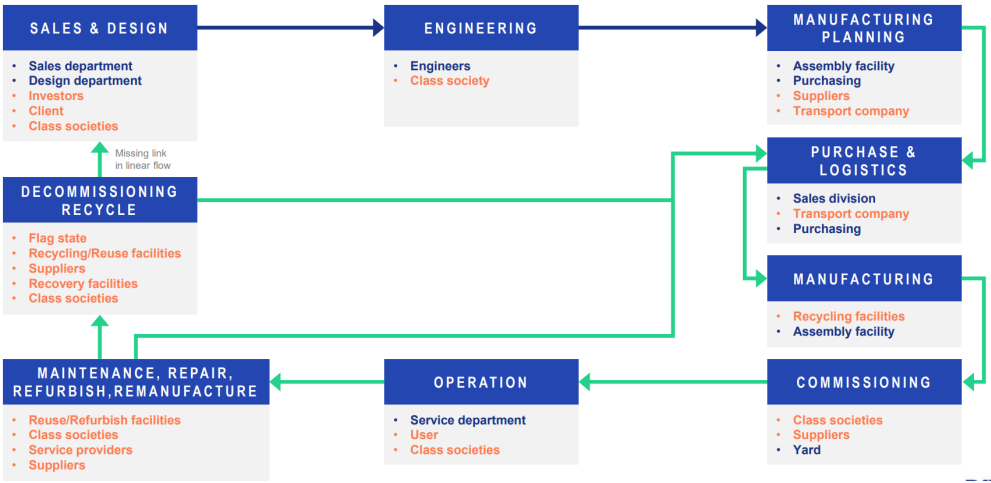

Looking at the current floor, the design process was done in close collaboration with Damen Shipyards' Research and Development department. The most prominent stakeholders in this process were thus the development departments of both the supplier and Damen Shipyards, but also other suppliers of the floor were involved to see what the physical options were that met the requirements. Next to that, a classification was involved with the RSD Tug 2513 design to get the vessel class approved. At this moment, the floor is quite a linear product following the flow that is presented in Figure 8 with associated stakeholders.

**Figure 8:** The life cycle and associated stakeholders for the current, linear floor

The figures show the current situation, but to shift to a circular approach, the flows will also have to shift from linear to circular loops. The circular loop is shown in Figure 9. In this shift, the connection needs to be made between the end-of-life stage and the design stage. This connection is not necessarily a material flow connection but needs to be a knowledge connection. Also, other flows start playing a role. Maintenance is extended with repair, refurbishment and remanufacturing and will loop back to the purchasing and logistics. Decommissioning is extended with recycling and will also loop back to purchasing and logistics. It is convenient for a client such as Damen Shipyards if the suppliers have a take-back process to repair, refurbish and remanufacture their systems. The role of suppliers in a circular material flow can be way more important than in a linear flow. Ideally, the supplier is willing to take back their supplied system at any time so in case of obsolescence of any kind the system can still come to good use. However, this means that a repair, refurbishment, remanufacturing

or even recycling process needs to be set up by the supplier. This supplier might in itself also be dependent on suppliers and so on. This means that to get the re-looping cycles in place a new supply chain needs to be set up where decommissioning parties, suppliers, purchasing and logistics and all circularity-enabling companies play a role.

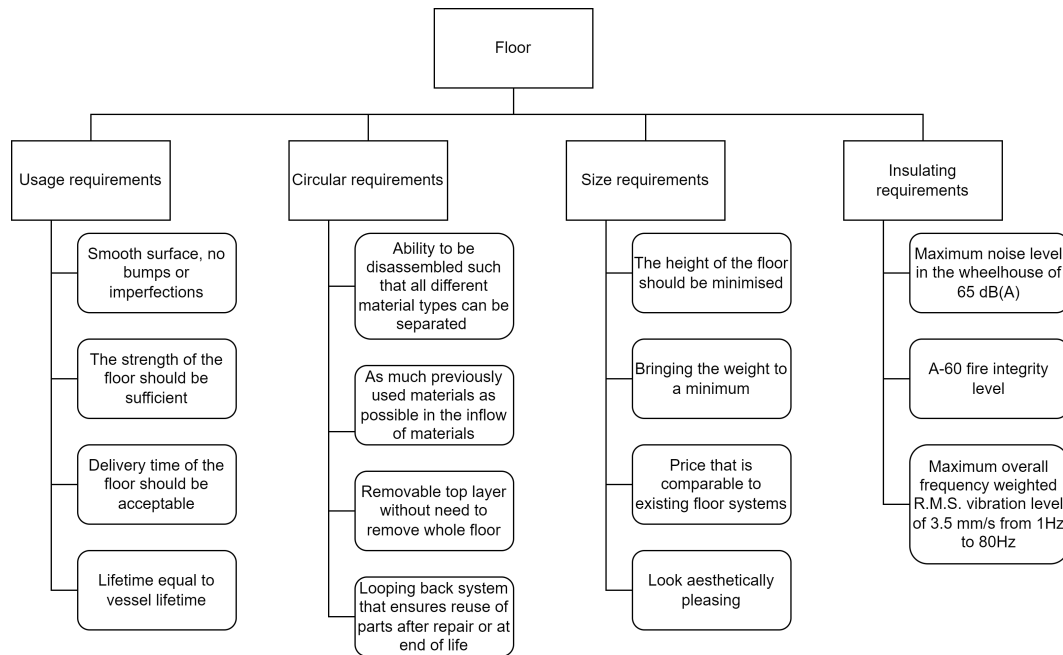

**Figure 9:** The life cycle and associated stakeholders for a circular floor

**Step 5: (Re)design the system by use of the RFLP method, applying circularity principles**

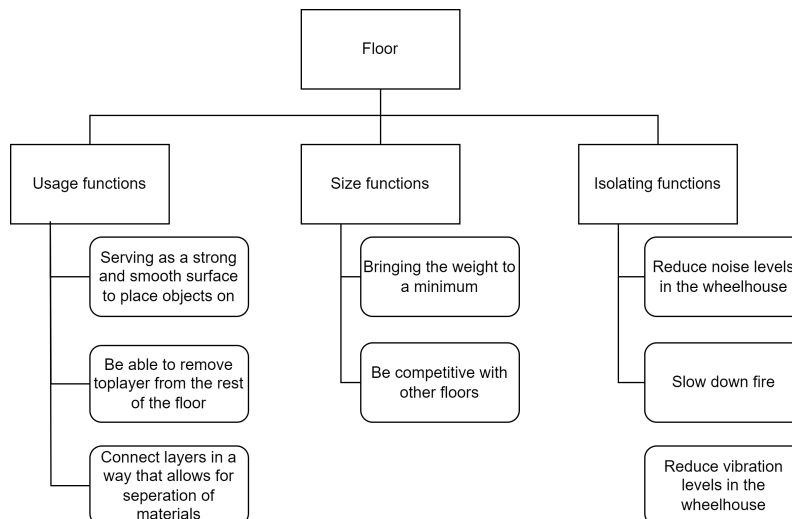

With all stakeholders identified, their requirements can be analysed. After that, these requirements translate into functions, these functions into a logical structure and in the end into a physical system. It is important to note that the goal is not to design the best floor technically, but the goal is to test the framework and show ways in which circular design strategies can be used for maritime systems.

During the design phase, there are three main stakeholders having a say: The design department of the supplier, the client (Damen) and class societies. Where the design department has to implement the requirements of the client and class societies. The eventual overview of requirements has been visualised in a breakdown shown in Figure 10.

**Figure 10:** Requirement breakdown structure for the floor in a wheelhouse

The main function of a floor is to be an isolating layer whilst providing a standing surface. The requirements can also be translated into more detailed functions. These functions can again be visualised in a breakdown structure. This is done in Figure 11. It can be concluded that quite some requirements cannot be translated to a function, but are more performance and physical requirements. The circular requirements also can be categorised as this type of requirement and are therefore not translated into functions.

**Figure 11:** Functions breakdown for the floor

In the logical phase, the focus should be on the composition of the system and the connections between the different components and parts. Common sense plays a role here in making logical connections between parts to combine them into components and in the end combine the components into systems. Some of these connections have already been made by cate-

gorising the requirements and functions into different subjects.

To come from the RFL overview to a physical solution, all possible options have to be considered. This is by use of a morphological chart. For the functions, multiple viable solutions have to be researched. This is done by literature research into materials, shapes, forms and other solution types that can fulfil the set functions. A morphological overview of the solutions linked to the functions is shown in Table 2. In the morphological overview, several lines have been drawn that show the best solutions in terms of price, weight, circularity and height. This way, several combinations of options can be explored.

Table 2: Morphological overview of the physical solutions matches with the functions

Function	Solution 1	Solution 2	Solution 3	Solution 4	Solution 5	Solution 6	Solution 7
Smooth surface	Synthetic cast floor	Carpet	Laminate	Steel plates	Vinyl	PVC	Carbon fibre
Removable top layer	Carpet	Laminate	Vinyl	PVC			
Strong surface	Galvanized steel	Carbon fibre	Aluminium	Cement			
Connecting two layers	Primer	Glue	Welding	Bolts and nuts	Magnets	Robe	Staple
Reduction of noise levels	Isover isolation	Visco-elastic mortar	Self leveling mortar	Stonewool	Cement	Steel plates	
Slowing down fire	Steel plates	Fire resistant glass	Concrete	Fire-retardend treated wool	Iron		
Reduction of vibration levels	Stonewool	Isover isolation	Visco-elastic mortar	Cement	Steel plates		

Cheap

Lightweight

Circular

After looking at the circularity of the current floor, it can be concluded that even though the lower four layers of the current floor might not be the most circular option for isolation, they are the best solution in terms of functionality and it is not technically possible to find another, more circular solution that still fulfils all functions. However, the primer can be made with a higher recycled content. The isolating layer will be further complemented with recycled isolation material and two steel plates made of recycled content. On top of the steel, many options are possible and the best option might be to let the client buying the vessel choose the surface as long as it is not a cast floor. For recycling purposes, PVC is the best option preferably in the form of planks that can be clicked together. If preferred, a sub-floor can be added but in terms of noise or vibrations, this should not be necessary. A visual of the redesigned floor is shown in Figure 12. However, to ensure a long lifetime and a good purpose for the materials at the end of the floor’s life, agreements need to be made between different stakeholders. Agreements such as the stone wool supplier taking back the wool for recycling or the supplier of the PVC laminate to reuse the laminate again on other vessels.

Figure 12: Visual of the redesigned floor

## Step 6: Validate the (re)design

As a final step of the framework, the redesign will be tested to the set requirements and functions, but will also be tested on the new circularity level. After this, it can be concluded whether or not the proposed solution is an improvement compared to the existing system.

In Table 3, the PMM is filled out for the redesigned floor. It can be seen that all requirements are matched to functions and the other way around. Additionally, all requirements and functions are translated into physical solutions. Therefore it can be concluded that, in terms of requirements and functions, the redesign is a viable replacement of the current design. However, for some requirements, there is only a weak relationship matched to a function or physical solution. So in case a new design is made, these requirements are where improvements can be made.

To further validate the design, once again, the circularity of the system will be measured. To compare the "old" floor and the redesigned floor, the circularity level of the "old" floor will also be calculated at the same level of detail as the new floor is built up. It can be seen that with the higher level of detail, the circularity of the "old" floor has increased a bit. However, comparing it to the new floor, the redesign shows a way higher circularity outcome. The table with the calculation is shown in Table 4.

The circularity of the floor has gone up from 15% to 90.5%. The biggest difference can be spotted in the outflow of the materials. For the "old" floor, there is no potential to win back materials due to the construction of the floor, but also due to the lack of agreements between stakeholders. For the redesign, all stakeholders will have to be on board to be able to keep the parts and materials in the circular loop. This means that with every supplier, agreements have to be made for taking back materials, or a separate stakeholder needs to be found that will reuse the materials. As an extra in-depth analysis, also alternative scenarios were researched where different requirements were left out.

**Table 3:** Filled in Product Management Map for the redesigned floor

		Functions								Physical solution			
		Serving as a strong and smooth surface to place objects on	Be able to remove toplayer from the rest of the floor	Connect layers in a way that allows for separation of materials	Bringing the weight to a minimum	Be competitive with other floors	Reduce noise levels in the wheelhouse	Slow down fire	Reduce vibration levels in the wheelhouse	Combination of Primer, VEM and Self leveling mortar	Isolation wool	Steel plates with bonding adhesive	PVC floor covering
Requirements	Smooth surface, no bumps or imperfections	●	○	○			○					●	●
	The strength of the floor should be sufficient	●	●		○		○	○	○			●	
	Delivery time of the floor should be acceptable					○				○	○	○	○
	Lifetime equal to vessel lifetime	○	○	○						○	○	○	○
	Ability to be disassembled such that all different material types can be separated		●	●	○	○	○			○	●	○	●
	As much previously used materials as possible in the inflow of materials				○	○				○	●	●	●
	Removable top layer without need to remove whole floor	○	●	○		○						●	●
	Looping back system that ensures reuse of parts after repair or at end of life		○		●	○					●	●	●
	The height of the floor should be minimised				○	○	○	○	○	●	●	●	●
	Bringing the weight to a minimum				●					●	○	●	●
	Price that is comparable to existing floor systems		○			●				●	●	●	●
	Look aesthetically pleasing	●				○				○	○	○	●
	Maximum noise level in the wheelhouse of 65 dB(A)						●		○	●	●	●	
	A-60 fire integrity level							●			●	●	
	Maximum overall frequency weighted R.M.S. vibration of 3.5 mm/s from 1Hz to 80Hz						●		●	●	●	●	
Physical solution	Combination of Primer, VEM and Self leveling mortar				○	○	●	○	●				
	Isolation wool		●	●	●	○	●	●	●	C.S			
	Steel plates with bonding adhesive	●	●	○	○	○	●	●	●	S	C.S		
	PVC floor covering	●	●	●	○	●				S	S	C.S	

The goal was to design three alternatives for the floor by leaving out requirements, compared to the previous sections. Since this research is about increasing circularity, the circular requirements were not left out. Looking at the influence of requirements on the design, it can be concluded that there is a big difference between the influence of the requirements on the design. The requirement to reduce the noise and vibration levels has by far the biggest influence. Since it is a requirement also by class to have a maximum noise and vibration level in the wheelhouse, this is not a requirement that is likely to be dropped, but one that might change with the ongoing developments regarding alternative propulsion options. To increase circularity, it could be seen that giving in on weight and cost can contribute in a positive way.

Next to that, this case study focused only on a few sub-systems in the wheelhouse, whilst when a whole vessel has to be designed, this will be a more time-consuming process, with more stakeholders and more agreements to be made. Also from this point of view, it is important that stakeholders assess their own process on the topic of circularity to make of designing circular vessels possible for the design and shipbuilding companies. Additionally, agreements have to be made with the owner of the vessel to actually use the supplier agreements to keep the materials in the loop.

**Table 4:** Comparison in MCI level of the "old" and "new" floor design

System	Parts	Mass	Inflow		Outflow					MCI	
		Mass [kg]	Virgin	Recycled	Refurbishment	Remanufacturing	Repurposing	Recycling	Recovery	MCI	Total MCI
Redesigned floor	PVC laminate	63,84	0,00%	100,00%	100,00%	0,00%	0,00%	0,00%	0,00%	1	0.905

## DISCUSSION

This study has shown that circularity can be implemented in ship design, with relative simple process adjustment. After testing this framework by a case study where the wheelhouse of an RSD Tug 2513 was subjected to the framework, it became clear that the framework has multiple limitations:

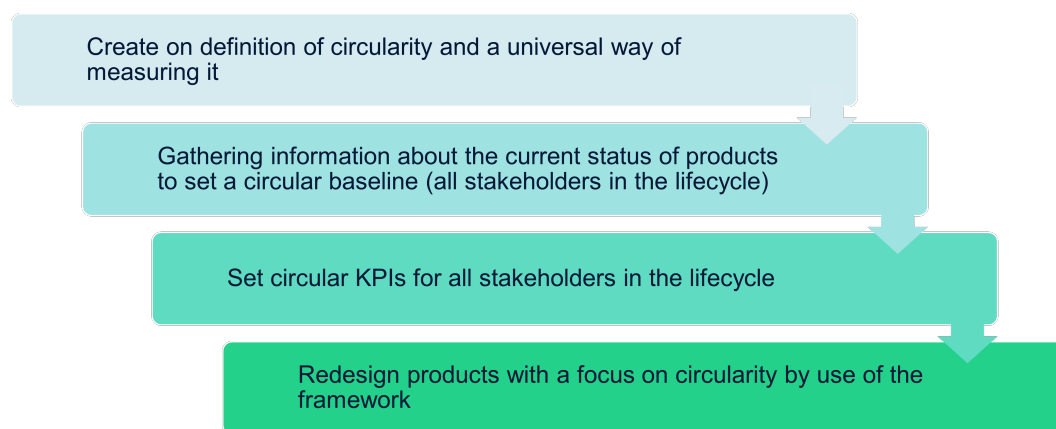

- The analysis/optimisation only looks at the inflow and outflow of materials in the end product, not at the materials used during the production or dismantling process, nor does it look at recycling efficiencies.
- The MCI calculation is based on weight, whilst hazardous and rare materials should also be considered an essential factor during the design phase.
- It is hard to compare a system's lifetime and use frequency to industry averages because the systems that are analysed set the average.
- The level of detail of the framework is highly dependent on the information available from suppliers, often resulting in an estimation based on industry averages with general weights.
- The use of industry averages is not a representative way of calculating the circularity level of a product.

Looking at all these limitations, it can be concluded that the provided framework is a concrete step in the right direction but further extensions can be made to solve these limitations. However, to implement the framework several steps are required.

First of all, a universal definition of circularity needs to be set to make sure all stakeholders are on the same page. After this, all stakeholders need to assess their own part of the supply chain in order to map the current status of the systems and set a circular baseline. Starting with the material extraction and ending with the final product going to the recycling facility, or even better, being reused, remanufactured, refurbished or repurposed. After successfully inventorying the current status of the circular economy in the ship design process, KPIs can be set for companies to determine a vision and future goals with regard to circularity. These KPIs can help a company with designing a new system or selecting (new) suppliers. After all this, the framework can be used. Since, in the ideal case, all stakeholders have already mapped their progress in terms of circularity, designers can now optimise their design based on all requirements, functions and logical structures set based on the needs in terms of general and circular demands.

For all this to work, incentives should be there for designers, such as the design department of Damen Shipyards, to start designing vessels with circularity in mind. Incentives can be government regulations and rules, but also clients asking for this. Additionally, the new CSR reporting requirements will help to give a push in the right direction for companies to start thinking about their circularity.

**Figure 13:** Steps for the implementation of the framework

Additionally, to continue research on the topic of circular ship design, multiple recommendations are formulated:

- When performing an analysis of the environmental impact of a system, often only the  $CO_2$  emissions are taken into account (Heijungs and Suh, 2002). It would be preferable to have a method that performs a life cycle analysis that takes both the "general" environmental impact and the circularity of the system into account. This way, trade-offs can be made between different systems whilst having a complete image of the possibilities.
- At this moment, circularity does not have a value that is expressible in a number. This results in companies having a conservative view towards circularity, often assuming it is more expensive than systems that follow a linear lifetime. Therefore it would be wise to perform a study into the reduction of the environmental impact a fully circular product makes, but also review the reduction or increase of the cost and lead time of a circular product and compare this to a non-circular product.
- The goal of a shipbuilding company such as Damen Shipyards can be to become 100% circular, but the process to get there involves many stakeholders. To start with implementing more circular components in the end product, a start could be to perform research similar to this research at an equipment manufacturer to see the more practical potential and also have the potential to change the business model of this manufacturer towards one where used products are taken back and directly reused in the production process to (re)new(ed) products.

- To help organise the available information on a system with regard to circularity, it would be helpful to set up an (international) system that captures all relevant information in a document (Circularise, 2023). This document could then be used during the lifetime and at the end of the life of a system to see the potential of all materials used in the system. This way, a client will also be able to compare products on their circularity level.

## CONCLUSION

To include circularity in the ship design process multiple principles and frameworks were combined. First of all, for the definition and ranking of circularity, the 10R framework was deemed the most appropriate, in combination with the adjusted MCI method for the calculation of the circularity level. With the 10R framework also come 10 design strategies for consumer goods that have been compared to the ship design approach of systems engineering. As a last theoretical step, key indicators were identified that influence the circularity of a system. After all this, the 10R framework for the definition of circularity, the corresponding circular design strategies, the method of systems engineering, and several key indicators were combined into a framework that represents a step-by-step guide on how to design a circular system. The main purpose of the framework is to prove there is a valid need for a (re)new(ed) system and starting at the beginning with the design process is to fully focus on a system's function instead of trying to improve an existing system that might not be the optimal solution for the function it needs to fulfil. To make the framework work, contact with the suppliers is a very important aspect since the information required to fill out the steps has to come from them. Next to that, changes to make products more circular will also require suppliers to change with regard to design and be more involved during the whole life cycle of a system to ensure that materials are kept in the circular loop.

# Early Risk Quantification Strategy for Design Space Reduction Decisions in Set-Based Design

J.B. Van Houten<sup>1,\*</sup>, A.A. Kana<sup>2</sup>, D.J. Singer<sup>1</sup> and M.D. Collette<sup>1</sup>

## ABSTRACT

*Perceptions of feasibility in design spaces are susceptible to change if new and conflicting information becomes available later. Design space reduction decisions made in set-based design can amplify vulnerability to new information if remaining design spaces and present perceptions are unable to adapt. This paper considers different ways new information can alter perceptions of feasibility for complex design problems and introduces an early, probabilistic strategy for quantifying the risk of eliminating potential design solutions based on the vulnerability of remaining design spaces to new information. Emergent designs of a set-based design process gauging this risk are evaluated against one neglecting it for an analogous design problem. Early results indicate that the probabilistic model is able to effectively delay design decisions and prevent lock-in while design space understanding is still growing.*

## KEY WORDS

Set-based design; Space reductions; Information; Fragility; Risk quantification.

## INTRODUCTION

Design decisions made within the web of interdependencies and requirements ingrained in the marine design process produce complex knowledge structures. While different methods have been proposed to characterize the knowledge generation accompanying these decisions (Braha and Reich, 2003; Hatchuel and Weil, 2009; Shields, 2017; Goodrum, 2020), each one seeks to track and better understand the emergence of (or lack thereof) design solutions. Decisions made in set-based design (SBD) build up these knowledge structures gradually, but they also leave design spaces vulnerable to emergent design failures if the information supporting them changes. Providing designers with a tool to understand the potential impacts of new information on a reduced design space after eliminating potential design solutions from consideration would assist them in making more informed space reduction decisions.

Using iteration to make decisions and generate knowledge is an understood reality of many complex design problems (Wynn and Eckert, 2017). Different studies have investigated how enhancing the allocation of resources (Smith and Eppinger, 1997) or communicative pathways (Mihm and Loch, 2006; Parraguez et al., 2015) between iterative tasks can promote more efficient information flow. As these strategies are improved upon to assist with iterative design decisions, they can fixate a designer's knowledge on one decision path, restricting the solutions that can be attained through others (Page, 2006). Examples of this fixation are shown in Van Houten et al. (2022) where viable solutions within a discipline's design space are significantly limited by the path chosen. In some cases, designers can lose influence if a finite set of absorbing paths constrain the knowledge structures generated from these temporal decision processes (Niese et al., 2015; Kana, 2017).

A consequence of becoming overly fixated on a particular decision path is leaving a design susceptible to emergent design failures. Dong (2017) discusses the prevalence of this problem in product development when companies introduce innovative technologies into their product's existing functional architecture. He argues that integration issues arise before the establishment of their product's physical architecture and should instead be attributed to the solution principles the design team committed to during development. He and others (Shields and Singer, 2017; Goodrum, 2020) insist that understanding emergent design failures requires a shift in viewing them from a product-centric to a knowledge-centric perspective. As Goodrum (2020) explains, a design decision is a commitment to a knowledge structure, and how those decisions affect future design activities will vary depending on how new knowledge integrates with existing knowledge.

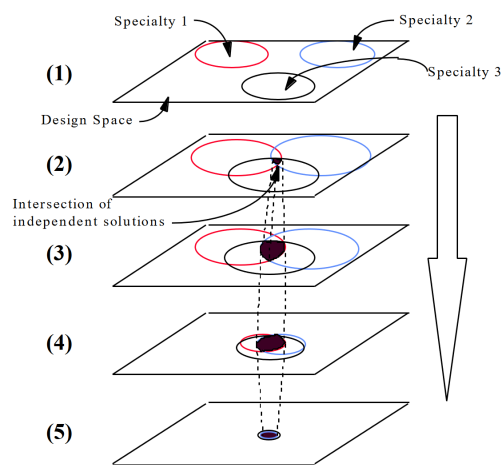

Set-based design (SBD) protects against emergent design failures stemming from path fixation by having design decisions focus on eliminating undesirable regions rather than making premature commitments to hard-set characteristics. By delaying commitments and keeping variable sets open, SBD decisions create low-risk knowledge structures (Shields and Singer, 2017) and allow designers to maintain influence over the design problem while their understanding of it grows (Bernstein, 1998; Singer et al., 2009). Advantages of SBD include basing the earliest and most critical design decisions on acquired data, promoting institutional learning within the design environment, encouraging concurrence in the design and manufacturing process, and supporting a search for more globally optimal designs (Ward et al., 1995). These advantages have fueled US Navy interest in making ship design and analysis tools compatible with SBD methods (Doerry, 2012) and applying SBD to various projects such as the Ship to Shore Connector (Mebane et al., 2011), Amphibious Combat Vehicle (Burrow et al., 2014), and Small Surface Combatant (Garner et al., 2015). Despite the advantages, it is still either infrequently applied to problems in industry or generally confined to introductory design stages (Toche et al., 2020). Singer et al. (2009) claim SBD's biggest obstacle in naval design coincides with current government acquisition policies conforming to point-based methodologies. Other hurdles are summarized in McKenney and Singer (2014) and Gumina (2019) and involve having to manage misconceptions *about implementation* and lacking a regimented process *for implementation*.

The SBD implementation process is multifaceted and has disciplines individually explore areas of their design spaces to accumulate information, form perceptions of preferred and nonpreferred areas from this information, and propose space reductions from these perceptions (Bernstein, 1998). A representation of an example design space is depicted in Figure 8 of Andrews (2018) where *space reductions* refer to reducing the range of potential design solutions being left open. A Design Integration Manager (DIM) will then consider the space reductions proposed and the information supporting them to finalize a conceptually robust set of space reductions across all disciplines (Singer et al., 2009). Each of these later steps are directly tied to the information gathered at the beginning, so effective decision-making in SBD necessitates robust information. Gembarski et al. (2021) evaluates the robustness of information in decision-making by using Bayesian probabilities to model uncertainties that originate from a scarcity of information. Sypniewski (2019) takes a different approach and assesses how the inherent biases of information that has already been gathered can lead to inadequate characterization of a design space and misinformed decisions. As the robustness of information pertains to decisions made during SBD specifically, research is limited. Doerry (2015) presents a method for measuring the diversity of information in a design space to increase the likelihood of viable solutions being found later; however, this method intends to insure reduction decisions against uncertain information rather than understand the uncertainty permissible for those decisions to remain advisable.

The purpose of this paper is to present a new approach for quantifying the risk of design space reduction decisions in SBD by considering the potential for new information to alter perceptions of feasibility and incite emergent design failures. Although in a much broader sense, the aim of this research is to assess how future information can undo the foundation of knowledge already established through previous design decisions. In the following sections, a brief background on SBD and a design space's fragility (or its vulnerability to new and conflicting information) will first be provided. Next, details of a SBD simulation will be presented for proposing reasonable space reductions. After explaining how the simulation works, an early framework built for assessing the fragility of design spaces and quantifying the risk of space reduction decisions will be explained. The developed fragility framework plugs in at the very end of the space reduction process. Finally, emergent design spaces for simulations performed on a problem analogous to complex design with and without the framework will be observed and discussed.

## SET-BASED DESIGN

SBD is a convergent design approach that seeks a final solution through the gradual elimination of design spaces rather than cycles of rework and refinement synonymous with most iterative approaches. Bernstein (1998) describes the *ideal* way SBD should be performed with illustrative help from Figure 1 developed by Dr. William Finch. In the early stages of SBD, disciplines individually explore areas of their design spaces and expand their ranges of potential design solutions. From a marine design perspective, these disciplines may consist of (but not be limited to) a weights division negotiating lightship and deadweight tonnage allotments along with center of gravity positioning, a stability division considering allowable beam and vertical center of gravity pairings, and a structural division contemplating various plate thickness and stiffener sizing schemes. As potential solution spaces are identified by each discipline, they work together to identify areas of overlap between their interdependent design spaces that satisfy all requirements of the design problem. For example, the weights division may have its own displacement and trim requirements to satisfy, but the vertical center of gravity of a load case cannot prevent the stability division from satisfying intact or damage stability requirements, and the lightship allotment must be sufficient for the structural division to satisfy material yielding requirements within a specific safety factor. As a solid understanding of potential design solutions and trade-offs is formed, nonpreferred areas of each discipline's design space are eliminated until a final solution remains.

**Figure 1: Ideal convergence of the SBD process through gradual elimination of nonpreferred areas (Bernstein, 1998)**

Through this process, a major principle of SBD is delaying decisions until the consequences of those decisions are understood (Ward et al., 1995; Singer et al., 2009). During discussions with managers utilizing “set-based concurrent engineering” at Toyota, Ward et al. (1995) learned that a critical aspect of their job is to discourage engineers from making important design decisions too soon. They believe it is necessary to delay decisions to ensure all the requirements of the customer are met while also ensuring that the design is manufacturable. Bernstein (1998) and Singer et al. (2009) discuss the benefits of delaying design decisions from the perspectives of accrued knowledge, committed costs, and stakeholder influence. They explain that knowledge of a design is gathered with time as designers run analyses to build their understanding of the characteristics and requirements driving the process. By delaying decisions through a set-based approach, designers can increase the influence maintained and decrease the costs incurred until the information and existing knowledge supporting these decisions is more robust.

The difficulty of eventually making these reduction decisions is that design spaces cannot be understood absolutely. Different disciplines often manage large design spaces that cannot be explored completely while tolerating analyses with varying degrees of uncertainty. Moreover, it is common for changes in design requirements as well as the fidelity or underlying assumptions of analyses to be introduced throughout the design process that shift preferred and nonpreferred areas. Shields and Singer (2017) assert that space reduction decisions create low-risk knowledge structures while also acknowledging that SBD relies on considerable knowledge generation and decision-making to work effectively. In their words, “Only making decisions when the supporting knowledge is well-understood and is unlikely to change leaves stable knowledge to be

further developed” (Shields and Singer, 2017). Each space reduction decision in SBD is supported by information that is incomplete, uncertain, and susceptible to change. If designers do not account for this uncertainty of information, their reduction decisions may lead to exceedingly fragile design spaces, or design spaces whose perceived feasibility is vulnerable to new and conflicting information. In instances when new information exposes fragile design spaces, designers using a SBD approach cannot simply rely on backtracking and reopening design spaces either, because their design timelines are limited by the considerable time already spent exploring those design spaces in the first place.

### Design Space Fragility and Reduction Decisions

To help visualize a design space’s fragility, Figure 2 has been created to mirror the third layer in Bernstein’s explanation of SBD. In Figure 2, the perceived feasible regions of each discipline are located within the red, blue, and black circles. The green regions signify perceived feasible areas of the design space for one discipline, the yellow regions signify the same perceived feasibility for two regions, and the orange region signifies the same perceived feasibility for all three regions. Suppose the fragility is being assessed from the red discipline’s perspective. One source of fragility is attributed to learning new information that alters the perceived feasible space of the red discipline itself, as depicted by the dashed red circle in Figure 3. As it pertains to the red discipline, the pink region captures newly perceived feasible space, and the grey region captures newly perceived infeasible space. If new information shifts the perceived feasible space of the red discipline such that the grey region outweighs the pink region, then that originally perceived design space would have been very vulnerable to the new information. Another source of fragility is attributed to learning new information that alters the perceived feasible space of an interdependent discipline, as depicted by the dashed blue circle in Figure 4. As it pertains to the blue discipline, the pink region captures newly perceived, shared feasible space, and the grey region captures newly perceived, shared infeasible space. If new information shifts the shared feasible space such that the grey region outweighs the pink region, then that originally perceived design space would have also been very vulnerable to the new information. In both scenarios, new information’s effect on perceived feasibility is determinant of a design space’s fragility.

**Figure 2: Overlapping regions of perceived feasible spaces for three disciplines of a design problem**

**Figure 3: Fragility attributed to design change of main discipline**

**Figure 4: Fragility attributed to design change of interdependent discipline**

While a design space’s fragility directly corresponds to its vulnerability to new information, that vulnerability can be amplified by the particular space reductions that have previously been made. In both Figure 3 and Figure 4, the DIM may have already decided to eliminate portions of the pink region. If that is the case, disciplines would be left without newly perceived feasible space, meaning that the grey region would further outweigh the pink region. Designers want to avoid space reduction decisions that lead to exceedingly fragile design spaces, yet they must make reductions to keep the design process moving. At each space reduction cycle, every design space is susceptible to increases in design space fragility that can be further exacerbated by previous reductions. And even though the figures have portrayed instances of increasing fragility in the context of new information and previous space reductions, the size of a feasible design space alone does not dictate its fragility. For example, if a multidimensional design space is very large, but one of its input variables only has two feasible values, then that design space is vulnerable to new information from its own discipline and/or other disciplines finding

those two values to be infeasible. By effect, there are varying levels of risk for space reduction decisions due to the varying levels of fragility that result from prior reductions and new information.

### Originating Sources of New Information

In the development of solutions to complex design problems, designers are compelled to explore and gain an understanding of their own discipline’s design space, integrate the understanding and preferences of designers from interdependent disciplines with their own, and endure changing design requirements and maturing analyses throughout the entire process. Bearing each of these challenges in mind, three different sources of new information are worth considering when characterizing the fragility of a design space: (1) newly explored design points of a directly affected discipline, (2) newly explored design points of an interdependent discipline, and (3) new or updated design requirements or analyses. In this work, only the first originator for new information will be considered, but it is important to keep the other two in mind for future improvements to the fragility assessment process.

To observe how new information originating from newly explored design points of a directly affected discipline can impact perceptions of design space behavior, consider Figures 5 to 6. In these figures, green points represent tested designs that are feasible, red points represent tested designs that are infeasible, green regions represent perceived feasible spaces, red regions represent perceived infeasible spaces, and yellow regions represent spaces of mixed feasibility. With the information from design points presently available in Figure 5, clear regions of feasibility have been formed for the discipline; designers of *this discipline* are perceiving smaller values of *Variable 1* to be feasible and larger values of *Variable 1* to be infeasible. However, those perceptions shift in Figure 6 when new information originating from newly tested design points becomes available. Larger values of *Variable 1* are still perceived as infeasible, but designers have also learned they may have less area to work with for smaller values of *Variable 1* than they previously thought. Before learning this new information, suppose the decision is made to eliminate some of the smallest values of *Variable 1* because, in contrast to this discipline, other disciplines prefer large values of *Variable 1* to small values. Designers of this discipline may be inclined to approve the space reduction thinking they still have plenty of feasible space with which to work. Later, they would regret to learn that the space reduction decision has limited far more feasible solutions remaining for them than they originally anticipated.

**Figure 5: Perceptions of feasibility before sampling new points within primary design space**

**Figure 6: Perceptions of feasibility after sampling new points within primary design space**

The intent of a fragility framework will be to protect design spaces against scenarios like the one described. DIMs may be capable of taking proposed space reductions from disciplines and carefully assessing the impact those reductions would have on other disciplines with the information *at hand*, but they lack a tool for understanding the consequences of those reductions if the perceptions formed from that information *changes*. Before introducing an early strategy for quantifying this space reduction risk, a SBD simulation to which a fragility framework can tie in must be developed.

## CREATING A SBD SIMULATION

Before discussing the logic behind a framework intended to evaluate the fragility of design spaces, a SBD simulation that proposes reasonable space reductions is needed. With the simulation, experiments can be run that compare emergent design spaces when there are fragility checks in place compared to when there are not. The decision was made to automate the simulation for a couple of reasons. For one, automating the simulation removes the impact that human inconsistencies would have on the emergent design spaces by ensuring the same criteria are used to explore design spaces and propose space reductions every time. Additionally, automating the simulation speeds up the process and cuts back on the time it would take for a DIM to evaluate the present state of the data and formulate their next exploration or reduction decision. The simulation is not meant to be a perfect replication of how SBD activities are performed and reductions are made because SBD is fundamentally a human-centric process that is driven by knowledgeable designers. A simplified depiction of how the SBD simulation works is shown in Figure 7, while a more detailed depiction of the simulation and the actual Python code can be viewed via the link in the Data Access Statement at the end of this paper. Different parts of the simulation fall under the groupings of problem setup, exploration, or space reduction.

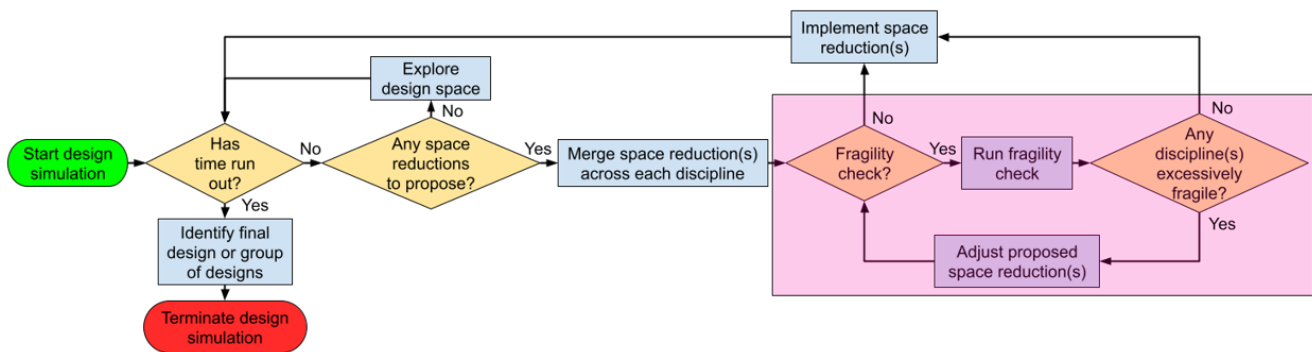

Figure 7: Simplified flowchart of the automated SBD simulation with a fragility framework plug-in

## Problem Setup

The problem setup portion initializes the design problem and prepares various aspects of the code for the time-based simulation. The user has the option to set certain user inputs that dictate characteristics of the design problem, exploration tendencies of the algorithm, and space reduction tendencies of the algorithm. The code is intended to work for any design problem as long as the user defines the input variables, output variables, initial input rules, initial output rules, and analyses of each discipline. To ensure exploration does not continue indefinitely, a bounded timeline is established, and the user must define how long the analyses of each discipline take to run during exploration. This portion of the code also sets an exponential-based function that encourages a minimum amount of each discipline's design space to be reduced relative to the time elapsed. An exponential function was chosen to promote exploration without required space reductions early on while saving more of the required space reductions for later once more information has been gathered. In an actual SBD process, there usually is not any sort of timeline established to keep space reductions on pace. However, for an automated SBD process without human involvement, it is important to ensure all of the space reductions are not delayed until the end.

## Exploration

The exploration portion is where each discipline is free to sample designs within their remaining design space. Exploration occurs whenever there is time remaining, there are no space reductions being proposed by any discipline, and there are no space reductions being forced because of the time that has elapsed compared to the size of each discipline's remaining design space. Based on guidelines set by the user in advance of the simulation, a specific amount of time will be dedicated to

sampling new points at each exploration cycle. The location of new points chosen for sampling are randomized throughout each discipline's remaining design space. Each discipline will then calculate the output values of the new points according to their specific analyses and check whether the calculated output values satisfy the current set of output requirements. Design time is only reduced during exploration as it is assumed that the time to run analyses is significantly greater than the time to propose space reductions or evaluate fragility.

For infeasible points, the algorithm is programmed to determine the extent to which each point fails. This failure calculation finds the difference between the calculated amount and the nearest threshold amount of each failing requirement (normalizing the difference to ensure no one requirement bears more influence on the failure amount than the others), and then calculates the root-mean-square deviation of the normalized differences. After going through this process, each infeasible point will have a failure amount assigned to it where values closer to zero indicate that the point is right on the threshold of passing, while larger values indicate that the point is very far off from passing. These calculated failure amounts come in handy when the SBD simulation goes through its space reduction and fragility assessment processes. Equation 1 shows an example calculation of the failure amount ( $FA$ ) involving three different requirements ( $y_1 > 0.2$ ,  $0.3 < y_2 < 0.6$ ,  $y_1 + y_2 < 0.8$ ), three different calculated amounts ( $y_1 = 0.1$ ,  $y_2 = 0.25$ ,  $y_1 + y_2 = 0.35$ ), and three different ranges of output values ( $y_1 \in [0.05, 1.2]$ ,  $y_2 \in [0, 0.9]$ ,  $y_1 + y_2 \in [0.05, 2.1]$ ).

$$FA = \sqrt{\frac{\left(\frac{0.1-0.2}{1.2-0.05}\right)^2 + \left(\frac{0.25-0.3}{0.9-0}\right)^2 + \left(\frac{0}{2.1-0.05}\right)^2}{3}} = 0.103 \quad (1)$$

For feasible points, the algorithm is programmed to determine the extent to which each point passes. This passing calculation is done in a similar process to that of the failure calculation with a couple of slight modifications. First off, the difference is now taken between the calculated output amount and the nearest threshold amount of each *passing* requirement. Secondly, rather than taking the root mean square of each requirement's normalized difference between the calculated value and threshold, the passing calculation simply takes the minimum normalized difference to gauge how close an output value is to failing the nearest requirement. By effect, passing amount values closer to zero indicate that the point is right on the threshold of failing, while larger values indicate that the point is very far off from failing. These calculated passing amounts also come in handy when the SBD simulation goes through its space reduction and fragility assessment processes. Equation 2 shows an example calculation of the passing amount ( $PA$ ) involving the same three requirements ( $y_1 > 0.2$ ,  $0.3 < y_2 < 0.6$ ,  $y_1 + y_2 < 0.8$ ), three new calculated amounts ( $y_1 = 0.4$ ,  $y_2 = 0.35$ ,  $y_1 + y_2 = 0.75$ ), and the same ranges of output values ( $y_1 \in [0.05, 1.2]$ ,  $y_2 \in [0, 0.9]$ ,  $y_1 + y_2 \in [0.05, 2.1]$ ).

$$PA = \min\left(\frac{|0.4 - 0.2|}{1.2 - 0.05}, \frac{|0.35 - 0.3|}{0.9 - 0}, \frac{|0.75 - 0.8|}{2.1 - 0.05}\right) = 0.024 \quad (2)$$

## Space Reduction

The space reduction portion is where each discipline can propose new input rule(s) that reduce design spaces if adopted by the DIM. The process each discipline goes through to propose these rule(s) involves a series of steps. It starts out by sorting all the failure amounts of previously explored points remaining in a discipline's available design space by magnitude. The algorithm then labels a percentage of the points with the highest failure amounts as "bad" while all of the remaining points are labeled as "good". Next, a decision tree classifier (DTC) is built in the design space based on these "good" and "bad" points. The goal of the DTC is to create boundaries within the design space such that all the "good" and "bad" points are grouped together as succinctly as possible. After the decision tree is formed, the boundaries of the decision tree grouping the highest fraction of "bad" points together are extracted to act as the threshold of a newly proposed input rule. A benefit of the decision tree is that each one of its boundaries are defined by a first-order equation only involving one input variable. This benefit reflects what is often seen in actual SBD as human designers tend to define simple rules for elimination rather than complicated equations cutting through the design space. The new input rule is finally checked against a set of user-

defined criteria to ensure it is supported by adequate information before a discipline can formally propose it.

If no rules are proposed by any discipline, then the simulation will ask whether a reduction should be forced for any discipline. If the answer to that question is yes (due to substantial space remaining relative to time remaining), then one of the user-defined criterion will be relaxed, and the disciplines will reassess if they have any reductions to propose. If the answer to that question is no, then the algorithm will continue to the exploration part of the simulation.

If one or more disciplines do have a new rule to propose, then the DIM becomes responsible for thoughtfully merging these requests based on available information and the impact each rule would have on other disciplines. This is a difficult part of the SBD process to reproduce because a preferred reduction for one discipline may not be preferred by another; human DIMs must often think critically when finalizing requests based on infeasibility and dominance. In the simulation, this merging process is handled by having each discipline directly affected by the input rule form an opinion on it that is represented by a value between 0 and 1 (where a value of 0 indicates the discipline is completely opposed to the rule, while a value of 1 indicates the discipline is completely in favor of the rule.) The opinions are quantified through each discipline's answers to two different questions:

1. Is the proposed space reduction removing clearly infeasible designs in your discipline's design space?
2. If the proposed space reduction is enacted, how less likely is it that feasible designs exist in your discipline's remaining design space?

To answer the first question, the area of the remaining design space that the space reduction would remove (the *eliminated design space*) is assessed. This area of the design space is discretized, and then a Gaussian process regressor (GPR) is trained with the available data from all of the explored points. The  $x$ -training data of the GPR are the input locations of the explored points, while the  $y$ -training data are the difference between each point's passing and failing amount. The trained GPR is then used to predict the difference between the passing and failing amounts at each discretized (unexplored) point in the eliminated design space. A negative value indicates the discretized point is predicted to be infeasible, while a positive value indicates the discretized point is predicted to be feasible. As the question is concerned with discerning *clearly infeasible* areas of the eliminated design space, the predicted difference between the passing and failing amounts is permitted to fluctuate between three standard deviations. The fraction of this range staying *below* zero for each discretized point is calculated, and the average value of those fractions acts as the metric answering the first question. Large values of this metric reflect *assuredness* that the eliminated design space is clearly infeasible.

The answer to this first question may be sufficient for validating proposed spaces reductions early in the SBD process when designers are purposefully delaying commitments to hard-set specifications and working with large infeasible spaces. If the answer to this question is a resounding yes for all disciplines involved, then the DIM can move forward with the space reduction for the universally infeasible design space. However, later on in the SBD process when these infeasible spaces have diminished, dominance-based decisions may be required that consequentially cut away at some of the feasible spaces of various disciplines. In these cases, the second question becomes more important to ask to ensure that a dominance-based reduction decision does not end up severely limiting any one discipline from producing a feasible design.

To answer the second question, the area of the design space that would remain after the space reduction (the *reduced design space*) is assessed in relation to the original design space before the space reduction (the *non-reduced design space*). The same trained GPR is now used to predict the difference between the passing and failing amounts at each discretized (unexplored) point in the reduced and non-reduced design spaces. However, now the question is concerned with discerning *likely feasible* spaces to ensure the space reduction does not significantly reduce the potential of finding a feasible design. In this case, the normal distribution about each discretized point's predicted value is determined, and the average fraction of those distributions falling *above* zero is calculated for both the reduced and non-reduced design spaces. The ratio of the reduced average to the non-reduced average acts as the metric answering the second question, where large values reflect *little reduction* in the *likeliness* of finding feasible designs in the reduced design space.

With metrics produced that quantify a discipline's answers to both questions, the influence that each metric should have on a discipline's overall opinion of a space reduction can be determined. Equation 3 is used to quantify this opinion ( $OP$ )

where  $m_1$  and  $m_2$  are the metrics for the first and second question, and  $w_1$  and  $w_2$  are the weights assigned to each metric. Because the second question only comes into play if the answer to the first question is not a resounding yes, the weight of the second metric is dictated by the value of the first metric. If  $m_1$  is high because clearly infeasible spaces would be eliminated, then  $w_2$  should be low because those spaces are not needed regardless. On the other hand, if  $m_1$  is low because clearly infeasible spaces are *not* being eliminated, then  $w_2$  should be high to account for how much the space reduction would actually hinder the remaining space in the opinion formulation. To reflect this behavior while not limiting the relationship between  $w_2$  and  $m_1$  to a linearly inverse correlation, a user-specified quadratic Bezier curve between the two variables is adopted. Once  $w_2$  is determined,  $w_1$  is calculated through the equation  $w_1 = 1 - w_2$  to ensure the overall value on the opinion stays between 0 and 1.

$$OP = w_1 * m_1 + w_2 * m_2 \quad (3)$$

Once the opinions are formed, the DIM can finally decide how much influence each opinion should have when finalizing the universal set of input rule(s) for the newest space reduction. In the simulation, this decision is made by establishing a threshold which permits a discipline to veto an input rule based on the value of their opinion in relation to the opinion of the discipline proposing the new input rule(s). Early on in the SBD process when space reductions do not necessarily need to be forced by the DIM, this threshold is low to allow for more vetoing of rules and less dominance-based reduction decisions. Later on in the SBD process when space reductions are becoming more forced by the DIM, this threshold is high to prevent more vetoing of rules and allow for more dominance-based reduction decisions.

At the end of this space reduction process, the DIM will have decided on a universal set of space reductions by which all disciplines must abide. Again, it is not meant to be a perfect representation of how space reduction decisions are made in SBD. Rather, it is meant to consistently produce reasonable space reductions for both infeasibility and dominance-based decisions so that the fragility of those decisions can be studied.

## FRAGILITY FRAMEWORK

Traditionally in SBD, the space reduction decision process ends with the universal set of reductions instituted by the DIM. At this point, designers have explored their own design spaces to form perceptions and propose space reductions, and the DIM has merged them together with the information available through infeasibility or dominance. As discussed though, this process, which only considers present information, leaves reduced design spaces vulnerable to new information.

The intent of a fragility framework is to gauge the vulnerabilities of each discipline's design space to new information before committing to any space reductions. To accomplish this goal, a developed framework will require components that address various complexities inherent to the space reduction process. Table 1 summarizes those space reduction complexities and corresponding fragility framework requirements. In this work, a Probabilistic Fragility Model (PFM) is introduced for fragility assessment. The PFM is still a work in progress and does not address every framework requirement outlined in the table. Still, it addresses many complexities inherent to SBD's space reduction process and has the potential to be expanded further in future work. After discussing the underlying logic behind the PFM, it is incorporated as the final step in the SBD simulation's space reduction process.

### Probabilistic Fragility Model

The main idea behind the PFM is to characterize a discipline's present understanding of a design space with straightforward probabilities of feasibility and infeasibility and then to quantify its vulnerability based on how likely that understanding is to change. There are three main parts to the PFM which include forming perceptions of feasibility in the design spaces, determining potentials for regret and windfall from those perceptions, and using metrics to compare those potentials between the reduced and non-reduced design spaces.

In the first step, designers need to form perceptions of feasibility throughout their design space by leveraging data from their explored points thus far. To meet this requirement, the same GPR from the space reduction process is used to predict the difference between the passing and failing amounts (pass-fail) for all unexplored areas of the design space. With these predictions, designers can form perceptions for feasible and infeasible areas depending on if the pass-fail value is positive or negative. Designers will also have an idea of how much different areas are passing or failing depending on its magnitude. Figure 8 depicts this process for the remaining areas of a design space involving two input variables ( $x_1$  and  $x_2$ ). On the left-hand side of the figure, pass-fail amounts are formed for three explored points. Data from those explored points train a GPR, and then the trained GPR forms predictions for the discretized areas of the design space.

**Table 1: Complexities that exist when making space reduction decisions with uncertain information and the corresponding fragility framework requirements addressing these complexities**

Space Reduction Complexity	Framework Requirement
Space reductions are focused on eliminating undesirable solutions from a ranging design space. The desirability of solutions are rooted in perceptions of feasibility formed by running <i>discrete</i> design points through the analyses established by each discipline.	The framework needs to form initial perceptions of feasibility with presently available information. A technique for converting information from explored points and their output values into perceptions of feasibility <i>throughout</i> each discipline's design space is required.
Perceptions of feasibility are uncertain because they are formed with incomplete information within a discipline's design space. Information from newly analyzed design points <i>within a design space</i> could alter perceptions.	Formed perceptions of feasibility for unexplored areas of the design space are not definitive. The framework should account for the possibility of new design points being tested with feasibility that is contradictory to expectations.
Perceptions of feasibility are uncertain because of the <i>interdependencies</i> that exist through shared variables between disciplines. Vulnerabilities of one design space to new information could directly or indirectly amplify the vulnerabilities of other design spaces.	The framework must include a cross-discipline component that ties the individualistic fragilities of each discipline together such that the vulnerabilities tracked across interconnected design spaces are representative of their dependencies on each other.
Perceptions of feasibility are uncertain because they are formed with output information that is susceptible to change. New information originating from <i>changes to design requirements or analyses</i> could alter perceptions.	The location of calculated output values within the objective space must not be treated as definitive. Instead, the framework should account for the possibility of output values and requirements shifting in relation to each other.
A design space may be fragile when considering all input variables together (i.e. $x_1, x_2, x_3$ ) and when considering various <i>combinations</i> of input variables (i.e. $x_1, x_2$ ).	The framework cannot only measure the fragility of a design space as a whole. It must be flexible enough to also identify component-based fragilities.
The number of ways new information can alter perceptions of feasibility within a design space is <i>unbounded and unknown</i> until the information is made available. The risk of a space reduction in context of itself is unlimited.	Comparing the fragility of a reduced design space to a non-reduced design space and determining what new information a discipline <i>can</i> handle rather than it would <i>have to</i> handle will narrow the DIM's scope and allow space reduction risk to be quantified.

**Figure 8: Forming perceptions of feasibility for unexplored areas of the design space**

In the next step, designers need to consider the consequences of their formed perceptions of feasibility being incorrect. This requirement leads to the introduction of regret and windfall in a design space. Suppose the sampled design space in Figure 9 is considering the space reduction depicted by the black box. The space reduction would eliminate portions of the design space perceived as feasible (top-left) as well as portions of the design space perceived as infeasible (top-right). Now suppose new information comes along that throws off those perceptions of feasibility as depicted by the left-hand design space in Figure 10. This new information would cause designers to regret the space reduction if they are left *with infeasible* space that was expected to be feasible or left *without feasible* space that was expected to be infeasible (instances of regret). In contrast, the new information would benefit designers if they are left *with feasible* space that was expected to be infeasible or left *without infeasible* space that was expected to be feasible (instances of windfall). Before committing to a space reduction, the PFM considers these *potentials* for windfall and regret for the reduced design space in context of the non-reduced design space (right-hand side of Figure 10). This logic allows designers to consider the consequences of moving forward with a space reduction compared to forgoing the space reduction.

**Figure 9: Design space considering a proposed space reduction (signified by the grey box)**

Considering the consequences of a space reduction alone is not enough as there are different likelihoods of these consequences actually coming to fruition. Fortunately, probabilities of feasibility can be calculated from the predicted pass-fail values of the GPR to account for the regret and windfall likelihoods. Figure 11 depicts this process for the PFM. Once all

Figure 10: Instances of regret and windfall for the reduced design space (left) and non-reduced design space (right)

discretized areas of the design spaces are labeled as feasible or infeasible based on their predicted pass-fail value, the value itself and the accompanying standard deviation are used to create a normalized probability distribution on each prediction. The probability of feasibility or infeasibility is determined based on the portion of a point's probability distribution maintaining the predicted positive or negative pass-fail value. Finally, the potentials for regret or windfall are taken from the complementary probabilities of feasibility for each discretized point. Whether the complementary probability results in a potential for regret or windfall will depend on where the discretized point falls in the non-reduced or reduced design space.

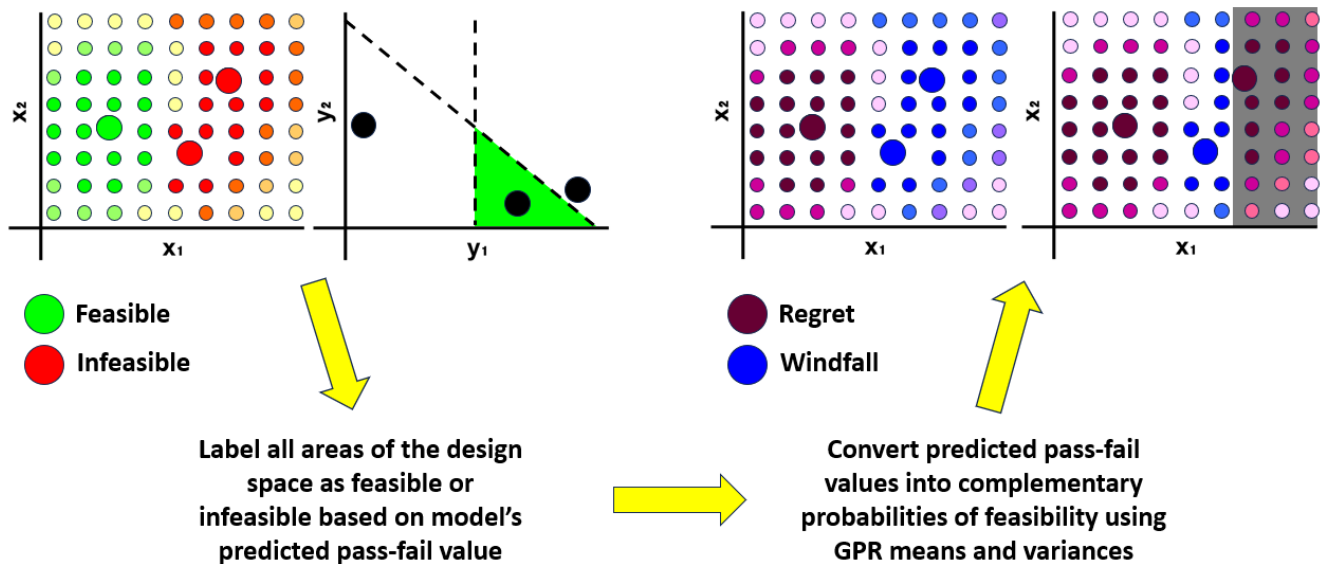

Figure 11: Converting perceptions of feasibility into potentials for regret and windfall for a non-reduced and reduced design space

The last step in the PFM involves gauging regret and windfall potential for the entirety of the reduced design space from each discretized point. A straightforward method to do so is summing up each discretized point's regret and windfall potentials. However, to actually understand the *risk* of a space reduction from these potentials, further context is needed. This context is provided by calculating the same summation for the non-reduced design space as is done for the reduced design space and then calculating the *added* potentials for regret and windfall (shown in equations 4 and 5). Working with these added potentials for regret and windfall allow a DIM to understand the risk of moving forward with a space reduction in context of leaving the design space untouched. High risk space reductions correspond to large positive values of added potential for regret and large negative values of added potential for windfall, which would reflect a reduced design space taking on more potential for regret and giving up potential for windfall. In equations 4 and 5,  $\Delta_{reg}$  and  $\Delta_{wind}$  are the added potentials for regret and windfall,  $p_{reg,red}$  and  $p_{wind,red}$  are a discretized point's probability of regret and windfall in the reduced design space, and  $p_{reg,nonred}$  and  $p_{wind,nonred}$  are the same probabilities for the non-reduced design space.

$$\Delta_{reg} = \frac{\sum_{i=1}^n p_{reg,red}(x)}{\sum_{i=1}^n p_{reg,nonred}(x)} - 1 \quad (4)$$

$$\Delta_{wind} = \frac{\sum_{i=1}^n p_{wind,red}(x)}{\sum_{i=1}^n p_{wind,nonred}(x)} - 1 \quad (5)$$

## Incorporating Fragility in SBD Simulation

In the SBD simulation, fragility checks occur immediately after the DIM has merged proposed space reductions into a universal set, as depicted by the red box in Figure 7. Up to this point in the simulation, all space-reduction-related decisions are solely supported by present information that is assumed not to change. The fragility framework intends to protect design spaces against this assumption and consider the effect that the space reductions would have on the remaining design spaces if new information were to alter the perceptions formed.

After calculating the added potential for regret and added potential for windfall, the amount of risk a DIM is willing to take on must be determined. In this work, a maximum risk threshold that increases exponentially with project time is established. The idea behind choosing an exponential threshold is to undertake little risk in space reduction decisions early on when conflicting information can be more common and influential on design space perceptions, and to increase the amount of risk endured later when conflicting information is less common and design spaces are more locked in.

With the exponential risk threshold set, the actual risk experienced from a space reduction in the simulation is set as the added potential for regret subtracted by the added potential for windfall. This risk setup allows the DIM to weigh each discipline's shift in potential to be hurt and helped by new information following a space reduction. In any given space reduction cycle, disciplines are permitted to keep proposing space reductions that can be added by the DIM as long as the risk does not exceed the threshold for any one discipline. If the threshold is exceeded, the input rule that put the risk over the limit is temporarily banned from being proposed again until design spaces have been explored further.

With that, the SBD simulation is established with the option to include a probabilistic fragility check before fully committing to each space reduction decision. After first validating the pre-fragility portion of the simulation with a simple SBD problem, emergent design spaces of the design problem with and without the PFM are ready to be observed.

## VALIDATING SIMULATION WITH A SBD PROBLEM

Investigating the impact of this new fragility framework on emergent design spaces requires a simple design problem. Testing the framework on a simple problem directs focus on the framework and makes interpretation of results in its early stages

more straightforward. After first describing the problem, it will be used to validate the efficacy of the SBD simulation without yet incorporating the PFM. Once the simulation is validated, it will then be used to assess the vulnerabilities of emergent design spaces for SBD simulations with and without the PFM.

## SBD Problem

A design problem has been created for testing the developed fragility framework. As shown in Figure 12, the design problem involves three different disciplines having some shared input variables and unique output variables. The input variables are analogous to the different ship characteristics that a discipline has influence over, while the output variables are analogous to the different ship performance characteristics with which a discipline is concerned. Circling back to the marine design disciplines used as an example in the *SET-BASED DESIGN* section, Discipline 1 could represent the Weights division, Discipline 2 could represent the Stability division, and Discipline 3 could represent the Structural division. It is important to note that only a simple design problem is being investigated right now, and there are numerous other disciplines and sub-disciplines (e.g. arrangements, powering, seakeeping, maneuvering) that would tie into more complex problems.

**Figure 12: Input and output variables for three disciplines of SBD problem**

Each one of these disciplines have analyses that calculate the output variables from the input variables to provide insight on how a potential design solution will perform. For this design problem, arbitrary mathematical equations act as the analyses for each discipline as shown in equations 6 to 10. These equations are analogous to the different parametric models or design programs used to evaluate performance metrics of a potential design solution.

*Discipline 1:*

$$y_1 = 0.8x_1^2 + 2x_2^2 - x_3 \quad (6)$$

*Discipline 2:*

$$y_2 = 1.25x_5 - 12.5x_3^3 + 6.25x_3^2 \quad (7)$$

$$y_3 = (x_4^3 + x_5)^2 \quad (8)$$

*Discipline 3:*

$$y_4 = 2x_5 + 0.2 \sin(25x_6) - x_1^{\frac{1}{5}} \quad (9)$$

$$y_5 = x_1^{\frac{1}{3}} - \cos(3x_5) \quad (10)$$

Each of the input and output variables have requirements that must be satisfied. The bounds on all the input variables are normalized such that they must fall between 0 and 1. The bounds on the output variables are unique and described as follows:  $0 \leq y_1 \leq 0.4$  or  $1.2 \leq y_1 \leq 1.6$ ,  $0.5 \leq y_2 \leq 0.7$ ,  $0.2 \leq y_3 \leq 0.5$ ,  $0 \leq y_4 \leq 0.5$ ,  $0.8 \leq y_5 \leq 1.6$ . These

requirements are analogous to the different stakeholder or industry-set design requirements that the design must satisfy. In marine design, the bounds on the input variables could be normalized length, beam, depth, etc. ranges, while the bounds on the output variables could be standardized displacement, wind-righting arm, yielding stress, etc. ranges.

The equations and required bounds of the design problem produce the feasible spaces depicted in Figures 13 to 15. In each of the figures, red points represent discrete design solutions not meeting output requirements, while green points represent discrete design solutions meeting output requirements. The feasible boundaries are unknown to the designers of each discipline, so they must form their perceptions of these feasible boundaries solely from the discrete points they decide to test. The equations and bounds are formulated in such a way that the feasible spaces have complex boundaries for designers of the SBD simulation to learn.

## Validating SBD Simulation Approach

The code simulating SBD decisions needs to be validated to ensure reasonable space reductions are being proposed from the present information. The aim of the fragility framework is to evaluate the suitability of a space reduction decision based on the potential for perceptions of feasibility to be altered by *new information* rather than present information. Even so, if unreasonable space reductions that neglect infeasible areas and surround feasible areas are proposed, then new information could not make perceptions any worse, and the framework would never find a reduced design space to be fragile.

**Figure 13: Feasible bounds of Discipline 1 depicted with 2,000 sampled points**

**Figure 14: Feasible bounds of Discipline 2 depicted with 2,000 sampled points**

**Figure 15: Feasible bounds of Discipline 3 depicted with 2,000 sampled points**

To validate the SBD code, 200 runs of the SBD problem without the fragility framework were executed. Table A1 shows all of the user inputs selected for these simulations. Short analysis run times ([2, 3, 4] iterations) relative to a long project timeline (1000 iterations) were chosen to ensure ample time is given to build up information for proposing reasonable space reductions. Each discipline was also given the goal of reducing their designs space's down to at least 5% of their initial size.

Figures 16 to 18 show locations of remaining solutions in each discipline's design space at the end of all 200 runs with the tan-colored points. The more opaque points show where remaining designs are most commonly found in each discipline at the end of a run, while the more transparent points show where remaining designs are less commonly found or not found at all. The surfaces show the feasible bounds of the design problem unknown to designers in the simulation. As can be seen in each figure, the remaining solutions are most commonly found within or around each discipline's feasible areas. This finding shows that remaining designs are being narrowed down to these feasible areas without actual knowledge of them, indicating that the SBD code is proposing reasonable space reductions.

**Figure 16: Locations of remaining design solutions for Discipline 1 at the end of the simulation**

**Figure 17: Locations of remaining design solutions for Discipline 2 at the end of the simulation**

**Figure 18: Locations of remaining design solutions for Discipline 3 at the end of the simulation**

## ASSESSING FRAGILITY IN SBD PROBLEM

With the SBD code validated, experiments can be run comparing the emergent design spaces of SBD simulations including the PFM to those that do not. As the proposed method does not yet consider the potential of analyses or requirements to change, random design changes do not need to be introduced to the simulation. The PFM currently only considers the impact that new information arising from newly tested design points in a primary discipline would have on a remaining design space. The results focus on evaluating the fragility of design spaces following space reductions by tracking remaining designs as the simulation progresses.

### Experimental Setup

Experiments are run for two different scenarios. In the first scenario, emergent design spaces with and without the PFM are compared to each other when a large amount of time has been allotted to the design problem relative to analysis run times. These test cases will have more time to generate information and presumably form more stable perceptions of design space behavior before proposing various space reductions. In the second scenario, emergent design spaces with and without the PFM are compared to each other when little time has been allotted to the design problem relative to analysis run times. These test cases will have less time to generate information and presumably form less stable perceptions of design space behavior before proposing various space reductions.

Table 2 highlights the differences made in the simulation between these two scenarios, while all other design parameters selected for the simulations match up with those shown in Table A1. The first and third test cases do not include any sort of fragility checks, but the second and fourth test cases include the PFM. Each test case is executed over 200 runs, and the averages of those runs are observed when examining the emergent design spaces.

**Table 2: Independent variables for various test cases of the SBD simulation**

Design Parameter	User Input	Test Case 1	Test Case 2	Test Case 3	Test Case 4
Project timeline (iterations)	iters_max	200	200	1000	1000
Fragility check	fragility	False	True	False	True
Starting Fragility Threshold	fragility_shift	0.0	0.2	0.0	0.2

### Results and Discussion

While executing the runs of each test case, the total design space remaining and the remaining number of feasible solutions are tracked across each discipline. Figures 19 to 21 display these results as various percentages. In each figure, the “Total Space” curves show the average percentage of the remaining design space, the “Feasible Space” curves show the average percentage of the remaining feasible designs, and the “Feasible-to-Remaining” curves show the ratio of the remaining feasible designs to the remaining design space, all over the elapsed project time.

One immediate takeaway from each of the figures is that including fragility checks with the PFM does not result in a higher ratio of feasible designs to space remaining by the end of the simulations. When comparing test cases of the same project timeline in each figure, the ratio of feasible-to-remaining designs is generally the same or slightly higher for test cases that do not include fragility checks. For Test Case 1 and Test Case 2 in Discipline 3, the ratio of feasible-to-remaining designs is much higher (roughly 25%) for simulations without the PFM. While these results may seem deterring, one explanation for them is there being more total space remaining at the end of the simulations with the fragility checks. In Discipline 3 specifically, there is on average about 10% more designs remaining in Test Case 2 at the end of the simulations than every other test case. More test cases remaining can result in a lower ratio of feasible-to-remaining designs. This occurrence is confirmed by the fact that despite its much lower ratio, Test Case 2 has more remaining feasible designs than Test Case 1 at

the end of the simulation for Discipline 3. Regardless, the behavior this work is more concerned with studying occurs for the emergent design spaces rather than the final design spaces.

Another takeaway is that having more time to explore each discipline's design space does lead to a higher understanding of the space. Across each discipline, Test Cases 1 and 2 (having an 80% shorter project time) consistently retain fewer feasible designs than Test Cases 3 and 4. As Test Cases 3 and 4 have more time to explore areas of their design space before proposing space reductions, they can be more careful about eliminating feasible solutions. It is worth noting that the feasible-to-remaining design space ratio of Test Case 1 does rapidly catch back up to Test Cases 3 and 4 towards the end of the simulations. While it would require further investigation to confirm this explanation, the smaller dispersion of designs in Figure 18 than Figure 16 and Figure 17 hints that this behavior may be attributed to the actual equations and requirements established for Discipline 3 in the SBD problem. The feasible solutions for Discipline 3 can vary over the entire range of its unique variable ( $x_6$ ) but has distinct feasible regions for its shared variables ( $x_1$  and  $x_5$ ). This coincidence gives designers of Discipline 3 some more freedom to still find feasible designs in their design space whether or not any sort of premature design lock-in has occurred for its shared variables.

Circling back to the fragility aspect of the simulations, the total space remaining results show that simulations including the PFM support a more gradual reduction of design spaces with less lock-in than simulations neglecting fragility checks. For most of Discipline 1's reduction time and for all of Discipline 2 and 3's reduction time, simulations including fragility checks maintain a larger remaining design space than simulations without them. The PFM is effectively delaying the space reduction process and forcing disciplines to really consider the potential consequences of a space reduction before they commit to it. Those consequences are being realized at the "notches" in Test Case 1 and 3's total space curves just past the 40% elapsed timeline, primarily in Disciplines 2 and 3.

The rapid decline in total space remaining and apparent change in pace at each notch suggests the disciplines are eliminating infeasible areas of their design spaces without much hesitation and then finding themselves locked in on the design solutions that remain. While design changes are not introduced in the experiments conducted for this work, the design spaces of Test Cases 1 and 3 find themselves very vulnerable at this point to new information stemming from slight changes to requirements or analyses. Whereas the design spaces of Test Cases 2 and 4, who do consider the consequences stemming from new and conflicting information, are more prepared to handle design changes. Test Case 4 in Discipline 2 does see a similar notch in its total space remaining curve at the same elapsed project time. However, it tries to correct for this rapid space reduction to a greater extent than Test Cases 1 and 3, almost to the point of meeting back up with the total space remaining curve of Test Case 2 at 70% of its elapsed timeline. For what Test Case 2 sacrifices in extra space retained at the end of SBD process, it makes up for in flexibility to handle new information.

As a whole, the results are encouraging and support introducing a step for fragility assessment to support DIMs making space reduction decisions. Using the PFM to make these fragility checks is a promising first attempt, but it is by no means perfect. The PFM meets many of the framework requirements laid out in Table 1, but it is still lacking in a few areas. Namely, the PFM has no such network component that considers vulnerabilities of interdependent disciplines, it does not account for the possibility of calculated output values or design requirements shifting, and it is not yet built to identify any component-based fragilities. Furthermore, the PFM has only been tested for space reduction decisions of a simple design problem involving just three interconnected disciplines. To really justify the PFM's incorporation into the space reduction process, it needs to be proven against more comprehensive design problems while tracking metrics such as the diversity of remaining design spaces to better substantiate claims of rapid convergence and lock-in. Future work will focus on addressing each of these shortcomings.

**Figure 19: Size of Discipline 1's total design space, feasible design space, and feasible design space relative to remaining design space over the elapsed project time**

**Figure 20: Size of Discipline 2's total design space, feasible design space, and feasible design space relative to remaining design space over the elapsed project time**

**Figure 21: Size of Discipline 3's total design space, feasible design space, and feasible design space relative to remaining design space over the elapsed project time**

## CONCLUSIONS

The intent of this work is to introduce a framework to help DIMs make more informed space reduction decisions in SBD by considering the vulnerabilities of remaining design spaces to new information. The framework, or Probabilistic Fragility Model (PFM), uses present perceptions of feasibility formed from sampled points in a design space to gauge the potential and likelihood for those perceptions to be altered by new information. An automated SBD simulation is built to observe the emergent design spaces of a space reduction process including the PFM against one that does not for a simple design problem involving three interdependent disciplines. When tracking their emergent design spaces, initial results indicate that the framework could be a useful tool for delaying space reduction decisions and preventing designers from fixating on certain design solutions while new knowledge is still integrating with existing knowledge. Such a framework could become a critical final step to ensuring space reduction decisions are made with both present and future information in mind.

## DATA ACCESS STATEMENT

All code for the SBD simulation and fragility framework along with data for each of the test cases can be publicly accessed at [https://github.com/Marine-Structures-Design-Lab/DesignSpace\\_Fragility/releases/tag/IMDC\\_2024](https://github.com/Marine-Structures-Design-Lab/DesignSpace_Fragility/releases/tag/IMDC_2024).

# Enhancing Hull Form Design for Robust Efficiency: A Data-Enhanced Simulation-Based Design Approach

Yasuo Ichinose<sup>1,\*</sup> and Tomoyuki Taniguchi<sup>2</sup>

## ABSTRACT

*This paper presents a design approach that integrates machine learning techniques with traditional physics-based simulations/models to enhance the ship design process with robust efficiency. While generative machine learning methods, which can directly produce design outputs such as the 3D hull form, have the potential to transform the design strategy, ship design inherently involves a decision-making process that requires consensus among stakeholders based on a foundation in physics-based simulations/models. This paper proposes a practical design strategy that positions physics-based simulations/models at the core of the design process, augmented by data-driven models. The paper first classifies hybrid types of the two models and integrates them into a practical design process. Finally, it demonstrates the effectiveness of the proposed design approach by showcasing the impact of data circulation, which accumulates and reinforces data in day-to-day design operations, on improving design outcomes.*

## KEY WORDS

Ship Design Methodology, Simulation-Based Design, Data-driven Model, Physics-based Model, Hybrid Model

## INTRODUCTION

Until now, the application of machine learning in hull form design has primarily involved using parameters that surrogate the hull form, such as principal dimensions, instead of directly dealing with the detailed 3D hull shapes. However, recent developments have begun to propose methods that handle the detailed 3D shapes directly as design outputs. Khan has proposed a machine learning model that uses a deep convolutional generative model to produce multiple 3D hull shapes from a latent input vector (Khan et al., 2023). Similarly, Ichinose has proposed a surrogate model for viscous Computational Fluid Dynamics (CFD) that uses a Convolutional Neural Network (CNN) to estimate the hull resistance, surface pressure distribution, and wake flow distribution at the propeller plane (Ichinose & Taniguchi, 2022) in real-time on a web browser, following to changes in the hull form (Ichinose & Gaspar, 2023). The significant difference between machine learning methods traditionally presented at naval architecture conferences and those proposed more recently lies not in predicting scalar values such as horsepower, which are one of the evaluation values but not the design products themselves, but in the use of decoder models represented by image-generating AI to handle 2D and 3D data, namely the design outputs themselves, including hull shapes and pressure distributions.

The emergence of data-driven approaches capable of directly outputting design products has been impacting ship design strategies. Erikstad has classified Marine system design methodology at the strategy level into four categories:

Optimization, Set-based, System-based, and Configuration-based, as an evolution from conventional design spiral methods (Erikstad & Lagemann, 2022). Each method has its advantages and disadvantages, and the choice among them is significantly influenced by design time constraints dictated by commercial practices. Bulk carriers, tankers, and container ships, which are predominantly built in East Asia, are often designed under strict time constraints due to negotiations with shipowners, making it difficult to move away from Design spiral methods. Papanikolaou, in the HOLISHIP project (Papanikolaou, 2022) aimed at Optimization, is constructing surrogate models for CFD calculations, which have been a bottleneck in multidisciplinary optimization due to their time dominance. Additionally, in adopting a system-based strategy, efforts are being made to optimize the entire process using a fast-responsive simulator known as 1D CFD (Perabo et al., 2020). In hull form design, which addresses the highly nonlinear flow around the hull, fast and accurate surrogate models for CFD are essential for designing environmentally friendly ships. Energy Saving Devices (ESDs), installed either before or after the propeller, are adapted on most ships to reduce the environmental impact of their operations. Viscous CFD calculations are the only way to design ESDs while considering the interaction effects between the hull form and the propeller. Integrated design of a hull form, a propeller, and ESDs can improve propulsive performance by a few percentage points compared to the sequential design method (Ichinose & Tahara, 2019). Aiming to enhance the integrated design of a ship's propulsive performance, accurately modeling time-dominant viscous CFD calculations becomes a key technology for adopting next-generation ship design strategies.

Physics-informed machine learning (ML) is one approach to accelerate time-consuming CFD calculations using ML. Raissi has estimated the flow field around a 2D cylinder by applying the Navier-Stokes equations as the loss function during Neural Network training (Raissi et al., 2018). A significant benefit of Physics-informed machine learning is that it eliminates the need for time-consuming mesh generation, which still requires some expert's techniques. Furthermore, "Physics-informed neural networks can seamlessly integrate multi-fidelity/multi-modality experimental data with various Navier-Stokes formulations for incompressible flows" (Cai et al., 2021). Multi-fidelity CFD, a combination of potential-based and RANS-based CFD, has been developed for hull form optimization to expand the exploration space in designing hull forms (Peri & Campana, 2005). Physics-informed neural networks have the potential to smoothly combine these multi-fidelity physics models, which could significantly alleviate the bottleneck in the overall optimization of ships by integrating one-dimensional and three-dimensional CFD methodologies.

On the other hand, ship design is an integral component of larger engineering projects and necessitates a comprehensive design methodology that accommodates the decision-making process, including achieving consensus among stakeholders. While machine learning models and generative AI can offer significant advantages, one of their notable drawbacks is the potential to produce misleading information. Therefore, to facilitate consensus-building and ensure robust decision-making, it is crucial to strategically combine these models with physics-based simulations. Employing machine learning models in a controlled setting, integrated with reliable simulation techniques, is essential for enhancing the accuracy and reliability of ship design processes.

This study discusses how to integrate data-driven approaches with physical model simulation design from a practical perspective. After organizing the structural challenges of current Simulation-Based Design, this paper proposes a practical data-driven method that integrates traditional simulation design with a data-enhanced, rationale-based design approach to overcome these challenges. Finally, demonstrating the proposed method shows its effectiveness. The core of our proposed design strategy is the effective circulation of data, which accumulates and is reinforced through day-to-day design operations. This paper partially showcases the impact of this data circulation, providing partial evidence of the efficacy of our approach.

## **CHALLENGES IN SIMULATION-BASED DESIGN ARCHITECTURE**

First, this paper discusses about challenges in the conventional Physics-Simulation-Based Design architecture. The design of hull form has benefited from the adoption of Simulation-Based Design since around the year 2000 (ex. Matsumura & Ura, 1997). This led to have reduced the number of model tests and contributing to the reduction of design costs. Moreover, flow field information such as the pressure distribution on the hull surface and the wave height distribution provided by CFD outputs has deepened researchers' and designers' understanding of physical phenomena. However, the current architecture of Simulation-Based Design is described as a closed system that combines performance evaluation tools, shape

deformation tools, and optimization tools (Tahara et al., 2003). Nevertheless, this architecture has the following practical challenges:

1. Limited Design Space: The time-consuming CFD forces to constrain the design space to exploration in the optimization process.
2. Lack of Information for Robust Efficiency: Decision-making suffers due to a lack of information during the design process.
3. Lack of Design Reusability: Designs can't be reused for similar projects.

Figure 1 illustrates the configuration of the Simulation-Based Design (SBD) architecture and its three challenges. The SBD architecture consists of three components: a Performance Evaluator, which estimates performance using methods such as CFD; a Geometry Manipulator, which performs shape modifications; and an Optimizer, which optimizes these components. This study proceeds with discussions based on this architecture.

### Conventional Simulation-Based Design System

**Figure 1: Challenges of Conventional Simulation-Based Design System.**

The first challenge in conventional SBD architecture is that time-consuming CFD calculations, especially those solving the Reynolds-averaged Navier-Stokes (RaNS) equations through direct discretization, restrict the design space that can be explored. As a result, a broader exploration beyond basic hull parameters is often left to the designer's tacit knowledge, not covered by the design system. To address this issue, Kandasamy has proposed a method to explore a wider space by combining potential flow calculations with RaNS-based CFD in a multi-fidelity optimization approach (Kandasamy et al., 2010). Furthermore, Diez have suggested a method for dimensionality reduction of the design space through eigenvalue analysis of hull form deformation parameters (Diez et al., 2015). Indeed, these methods accelerate CFD calculations. However, they do not address the challenges of high-dimensional spaces encountered with the parametric hull form deformation methods currently used as Geometry Manipulators. As a solution to these high-dimensional challenges, Ichinose has proposed the use of machine learning to analyze a hull form database through the Hull-form Coordination System (Ichinose, 2022).

The second challenge is that the output of the SBD system is insufficient for design decisions such as determining the hull form, which is the main objective of ship design. The system lacks integration of information on simulation uncertainties, as well as information on other evaluative factors affecting the hull form that are not related to simulation, such as stability, structure, productivity, and propulsive performance. Factors like CFD calculations, scale effects of actual ships, and wave conditions have high uncertainties not currently considered in the SBD architecture. To address this, Tahara have proposed a method that theoretically handles variations in sea conditions and other factors using reliability optimization

theory (Tahara et al., 2014) . Meanwhile, Ichinose and others have suggested visualization of the design space, which is compatible with data-driven approaches (Ichinose, 2022).

The third challenge is the lack of a mechanism within the SBD architecture to reuse data obtained from SBD in subsequent projects, necessitating almost starting from scratch for each redesign. This issue stems from the absence of an information feedback mechanism within the architecture, suggesting that a solution could potentially be found through Data-driven approaches.

## **FOUR HYBRID MODELING APPROACHES COMBINING PHYSICS-BASED MODEL/SIMULATION AND DATA-DRIVEN MODEL**

In ship design, the integration of physical simulations and data-driven methods is not actually a new concept. Ship design has long utilized design charts and empirical formulas from past data as data-driven tools. The direction of integrating physical simulation and data-driven approaches in this study involves replacing these design charts with machine learning models that are more accurate or advanced, and these models will be combined with physical simulations. Especially, the physical explain ability and reliability of the final design outputs based on physical simulations are particularly important considerations. On the other hand, introducing machine learning requires building mechanisms different from before. These include methods of databasing and data visualization, which become new considerations necessary for handling large-scale data.

Kanazawa has classified the enhancement methods of a ship dynamic model for ship motion prediction into four modes (update mode, convert mode, serial mode, parallel mode) while using a physics-based model as the foundation model to ensure physical explain ability and reliability (Kanazawa, 2023). These classifications, which include methods of correcting physics-based simulations and ways of applying machine learning loss functions, aim to increase the reliability of physics-based simulation results.

Moreover, design is a series of processes, and the integration methods of data-driven models with physics-based simulations are not solely for the purpose of improving reliability. That is, in the challenge of how to efficiently and robustly explore the design space to produce the optimal design output, several integration methods of data-driven models and physics-based simulations can be considered.

This study classifies and discusses the integration relationship between physics-based models and simulations and data-driven models in the ship form design process into four models, as shown in Figure 2.

- A) Surrogate Model: The purpose of this model is to speed up time-consuming physics-based simulations. This integration method is particularly effective in multi-disciplinary optimization for overall optimization across various fields.
- B) Complementary Model: This model is used in the process of narrowing down the design space. Currently, the design space is narrowed down using design databases and design charts based on key hull parameters, and detailed shape design is performed within this narrowed range using physics-based models such as physics-based simulations and model tests.
- C) Correction Model: This model corrects the results of simulations or model tests using a design database. It is the most commonly used method in engineering, including scale effect correction of model test results for actual ships and data assimilation.
- D) Constrained Model: This model involves setting design conditions and operational scenarios from operational data and designing with physics-based models. In the aviation field, Kim has proposed a model where machine learning models based on flight data set the simulation's flight phases and constraints(Kim et al., 2022).

**Figure 2: Schematic Representations of Four Hybrid Modeling Approaches Combining Physics-Based Model/Simulation and Data-driven Model**

The hybrid models of physics-based models/simulations and data-driven models in the design process can be organized into four categories. However, as these hybrid models are incorporated into the design process, there may be instances where each model is sequentially combined or nested in accordance with the level of detail in the design deliberations. Therefore, when integrating physics-based models and simulations with data-driven models throughout the entire hull design process, it is necessary to appropriately apply these four models to each area of the design process. The next section will discuss how to practically construct a process that integrates physics-based models/simulations with data-driven models.

## DATA-ENHANCED SBD ARCHITECTURE

This section discusses how to practically implement the hybrid models explained in the previous section into a practical design process.

### ① Automatic Hull Form Generations

### ② Systematic Database Management

### ③ Surrogate model of CFD

Image-based Hull Form Representation (Ichinose, 2022)

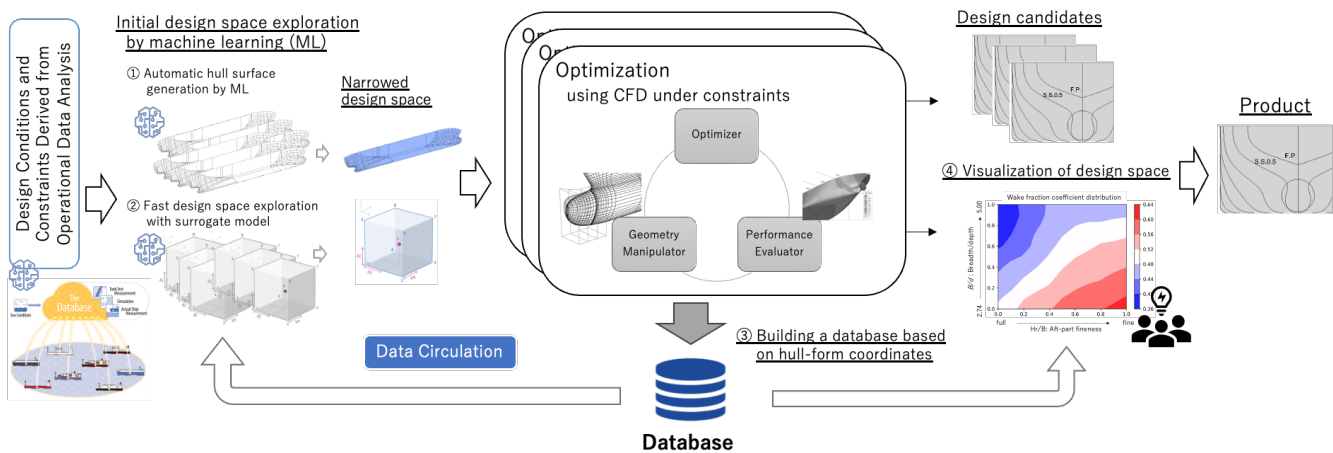

### ④ Analysis and Visualization of Design Space

**Figure 3: Component Technologies for Integration into Data-Enhanced Simulation-Based Design.**

Figure 3 shows four data-driven design technologies that are considered capable of overcoming the challenges of the traditional Simulation-Based Design architecture discussed in the previous section. The first is an automatic hull-form generation tool. A hull design tool that automatically generates multiple design candidates from latent vectors (Khan et al., 2023) or past linear databases (Ichinose & Tahara, 2019) is one of the most critical technologies in the hull design process utilizing data-driven methods. Many conventional formulaic hull representations and parametric hull deformation methods are used for local hull modifications, but not extensively for entire design processes. This is because it is challenging to encapsulate the tacit knowledge of past designs, an asset of shipyards or experienced designers, into formulaic or parametric expressions with limited hull parameters. The second method, the Hull-form Coordination System (Ichinose, 2022), has potential to overcome this difficulty. It uses assets of past design project as basis vectors, allowing systematic expansion (interpolation) of hull form which was unable to express in conventional formulation. The purpose of interpolating hull form to increase database density is to create a CFD Surrogate model. For example, expanding the database with the Hull-form Coordination System by dividing 15 basic hull forms into four parts can automatically generate 15,504 ( $=_{15+(4+1)} C_{15}$ ) hull forms. With a system that constantly runs CFD calculations in the background for these hull forms, the database and CFD Surrogate model (Ichinose & Taniguchi, 2022) continuously update based on accumulating day-to-day design work. Naturally, this database can also include data generated by traditional parametric hull representations and deformation methods. The last of the four is the method for analyzing and visualizing the database. Nonlinear optimization methods for designing hull forms within specific constraints often result in local optimal designs with uncertainties questioning their robustness. This necessitates further investigation by designers before deciding on the final design of a ship. The method for analyzing and visualizing the database enhances the robustness of these designs by allowing for analysis and visualization of the design space surrounding the optimal solution.

#### Data-enhanced Simulation-Based Design System

**Figure 4: Overview of Data-Enhanced Simulation-Based Design system.**

Considering the ways of integrating models discussed in the previous sections, this paper proposes the Data-enhanced Simulation-Based Design method illustrated in Figure 4. Here, based on the observation that the decision-making of the design process is always carried out based on physics-based model and simulation such as CFD and towing tank tests, the term "Data-enhanced" is used to explicitly denote the enhancement of processes using data, signifying the symbiotic relationship between data-driven methods and physics-based simulation.

As shown in Figure 4, the foundational Simulation-Based Design architecture is incorporated within the proposed method, enveloping it with the application of hull form databases and machine learning methods to overcome the three challenges of traditional SBD. First, regarding challenge 1 – limitation of the design space, the proposed method features initial hull form recommendations using the hull form database (1 in Figure 1) and narrowing down the design space with a CFD calculation Surrogate model by machine learning (2 in Figure 1). Next, for challenge 2, the proposed method addresses this challenge through two methods: proposing robust hull form selection using the Visualization method of the design space shown in 4 in Figure 4 (Ichinose, 2022), and multi-objective optimization considering general arrangement, stability, structure, and productivity (Papanikolaou, 2022). Lastly, for challenge 3, the proposed method enables data reuse in similar projects by

creating a database of all CFD calculation results and hull information, including performance evaluation results of hull forms discarded during optimization calculations, by databasing them based on the Hull-form Coordinate System treating each hull shape like a gene, thereby creating a cycle of data.

DEMONSTRATION OF THE PROPOSED METHOD

This section demonstrates the effectiveness of the proposed Data-enriched Simulation-Based Design method through a partial demonstration.

This paper takes as an example the design database shown in Table 1, which simulates an asset in a shipyard. Generally, shipyards tend to build ships with similar principal dimensions which they have built in the past, due to factors like crane capacity and dock size. The designs of these previously built ships are saved as CAD data along with CFD calculation data. These data have not been able to be organized by a set of hull parameters, making it difficult to database them. The Image-based Hull Form Representation method (Ichinose & Taniguchi, 2022) holds the hull form as the surface data of CFD structural grids, saving this data in a format similar to image data, which is more manageable for machine learning methods, thus allowing for databasing. This makes it possible to database nearly all hull forms that can be represented by structural grids.

Furthermore, the Hull-form Coordination System can generate new hull forms from this database. This method allows for the automatic expansion of a denser hull form database suitable for machine learning. The 20,952 data points shown in Table 1 are from a hull form database expanded from 20 basis hull forms using the Hull-form Coordination System. This expanded database is utilized as a surrogate model for CFD calculations by a Convolutional Neural Network (CNN) model.

Table 1: Overview of Database for the Demonstration

Ship Type	Container Ship, Pure Car Carrier, Bulk Carrier, Chemical Tanker, Oil Tanker, Mathematical Hull Form with Buttock Flow Stern
Basis Ships	20
Total Number of Ships	20,952
Length/Breadth	5.00 – 7.50
Breadth/Draft	2.0 – 3.60
Blockage Coefficient	0.47 – 0.88

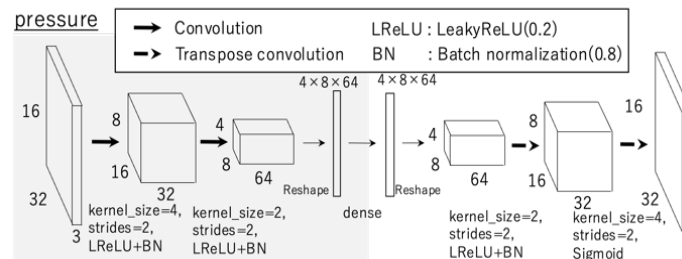

Figure 5: An Examples of Hull Forms and on the Database generated by Basic Ships

A feature of this proposed method is that the items related to estimated propulsive performance are not limited to integrated values such as resistance values, which have traditionally been estimated by design charts. By incorporating a Decoder model

into the Neural Network architecture, as shown in Figure 6, it is possible to present information useful for designers to understand physical background and deepen the insight, such as the pressure field on the hull surface and the wake flow distribution on the propeller surface. The Decoder model is a type of generative AI model used for creating images. Historically, the application of machine learning in ship design has been confined to tasks such as classification and scalar value inference. While scalar values, such as main engine output, are essential estimations for design, they do not provide guidance on which specific parts of the hull form could be improved. In contrast, models utilizing the Decoder model can estimate the pressure distribution on the hull surface and the wake distribution behind the propeller. This capability marks a significant shift as it offers detailed guidelines on how to modify the hull form for design improvements, providing much-needed directional insights for enhancing overall ship design.

Moreover, the estimation time for this surrogate model by machine learning is less than 0.1 seconds, significantly faster than the hours it takes for one case of RaNS-based CFD. Although the design space that can be covered by machine learning is limited in this example, in actual operation in shipyards, it is assumed that the design exploration range of this surrogate model is almost equivalent to the entire expected design space due to the abundance of conventional databases and the ability to semi-automatically construct a large amount of hull form data using Hull Form blending methods or FFD methods.

**Figure 6: Architecture of neural network for prediction of pressure distribution**

Figure 7 shows the difference between the resistance coefficient predicted by the CNN model and the true value (CFD calculation value). The dataset shown has not been used in the machine learning training. The results in Figure 7 confirms that the resistance values are estimated within  $\pm 5\%$  accuracy that is sufficient for practical design across a wide range of ship types and principal dimensions. This estimation is intended for narrowing down options in the preliminary phase of traditional design.

**Figure 7: Comparison of prediction and grand truth of resistance coefficient**

Next, Figure 8 compares the predicted and true values of the pressure distribution on the hull surface by the CNN model. The figure shows the pressure distribution from the bow to the stern from left to right, and from the bottom to the water surface in the girth direction from bottom to top, accurately reproducing the island-like shape of the pressure distribution that creates the adverse pressure gradient significant for resistance at the stern bilge. Such information is necessary for designers to physically understand why resistance has increased. Even while using an estimation method that can easily become a "black box" like machine learning, providing a means to understand physical phenomena is one advantage of the proposed method.

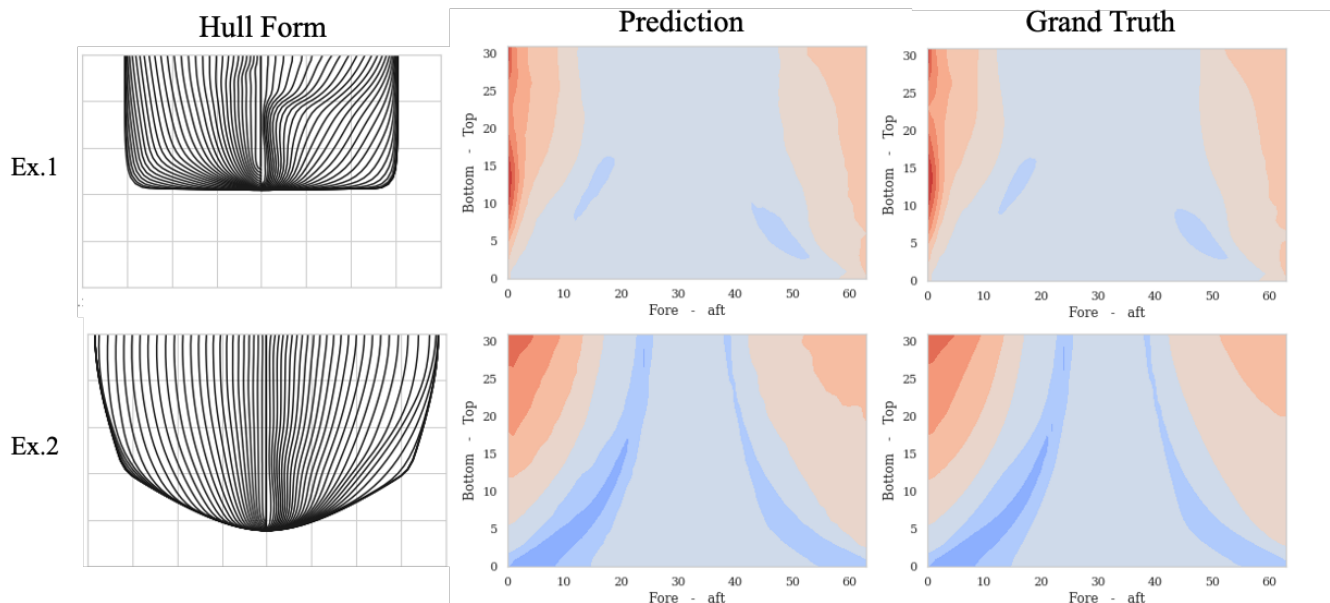

Figure 8: Comparison of prediction and grand truth in pressure prediction

## CONCLUSIONS

In conclusion, this paper has explored the transformative potential of machine learning techniques for directly producing design outputs, such as the 3D shape and pressure distribution of hull forms, within the realm of ship design. However, it also underscores the critical importance of achieving consensus among stakeholders in the inherently complex decision-making process of ship design, a process deeply rooted in physics-based simulations/models. This paper proposes a design strategy that leverages the strengths of both physics-based and data-driven models, positioning the former at the core of the design process while enhancing it with the latter.

This paper has systematically outlined a method for hybridizing two model types and demonstrated their effective integration into a practical design process. This approach not only adheres to the traditional reliance on physics-based models but also leverages the efficiency gains provided by machine learning. The demonstration confirms that the CNN model, serving as a tool for initial exploration across a wide design space, can predict resistance performance with an accuracy of  $\pm 5\%$ , which is sufficient for practical design across a broad range of ship types and principal dimensions. Additionally, this machine learning model is capable of estimating pressure distribution in viscous flow with high Reynolds number within 1 second, thereby enabling designers to incorporate physics-based insights to achieve robust efficiency.

# The Method to Navigate the Forward and Backward Path of a Towing Tractor for Transporting Aircraft

Ki-Su Kim<sup>1</sup>, Kwang-Phil Park<sup>2,\*</sup> and Sang-Hun Kang<sup>3</sup>

## ABSTRACT

*Aircraft carriers are the backbone of the Navy. They are equipped with aircraft, and their ability to take off and land aircraft quickly and efficiently determines their performance. Therefore, the number of aircraft is a key consideration in the design of an aircraft carrier and ensuring that they can be operated in the space of the aircraft carrier is an important factor in the arrangement design as well. On the other hands, towing tractors are used to move aircraft around. Towing tractors must safely move aircraft in open spaces while avoiding multiple obstacles, which requires skilled operators. In this study, we propose a method to automate the path of a towing tractor and then follow it. First, we studied the kinematics of the towing tractor and aircraft carrier, considering the wheel movement and steering angle. Then, we calculated the optimal path of the tractor and aircraft considering both forward and backward motion. Finally, we applied dynamics to verify that the towing tractor and aircraft carrier could follow the calculated path. We tested the proposed method in a field with various obstacles and in a narrow area such as a parking lot and confirmed that it was effective.*

## KEY WORDS

Aircraft carrier; Towing tractor; Navigation; Optimal path; Dynamics.

## INTRODUCTION

Traditionally, aircraft carriers are the main power of major powers as well as the navy. (Ryan et al., 2011) Aircraft are typically equipped in aircraft carriers, and how many and how fast they can take-off and land determine the performance of aircraft carriers. In general, for preparing the take-off and landing sequence of aircraft, a towing tractor is used. On land, this work can be carried out smoothly like airplane at general airports along guidance lines and work instructions. However, as described above, since this process must be performed in limited space in an aircraft carrier lined with many aircraft and equipment, the time and efficiency of moving aircraft depend on the proficiency of the towing tractor operator. Therefore, it is necessary to automate the path of the towing tractor and follow it. this study proposes a method of optimizing and following the path of the towing tractor in the aircraft carrier.

Various methods have been proposed for utilizing towing tractors to determine and track the optimal path for aircraft carriers. Gomez-Brabo et al. (2005) proposed a method for planning the path of a tractor-trailer, predicting the path based on the kinematics and restricted maneuvering modeling of the tractor-trailer's motion. They then utilized fuzzy system inverse mapping to generate the optimal path for movement. Similarly, Elhassan (2015) performed modeling to predict the path of the connected vehicle and then used the rapidly exploring random tree (RRT) method to generate the optimal path. This was then applied to the docking task. In addition to the aforementioned studies, our research has explored various methods for generating and tracking the optimal path for aircraft and towing tractors.

## KINEMATICS

When moving aircraft in a hanger or deck on aircraft carrier, it does not move by itself with propulsion, but uses a tractor to tow the ship. Therefore, the tractor fixes the nose wheel and then tow it to move aircraft. This movement becomes very similar to the movement of a general tractor-trailer, which is expressed in figure 1. And if kinematics is derived for this, it can be expressed as equation 1.

$$\frac{d}{dt} \begin{bmatrix} x_1 \\ y_1 \\ \theta_{CA} \\ \theta_T \end{bmatrix} = \begin{bmatrix} v_T \cos \beta_{CA} \cos \theta_{CA} \\ v_T \cos \beta_{CA} \sin \theta_{CA} \\ \frac{v_T \cos \beta_{CA} \tan \beta_{CA}}{L_{CA}} \\ \frac{v_T \tan \beta_T}{L_T} \end{bmatrix} \quad [1]$$

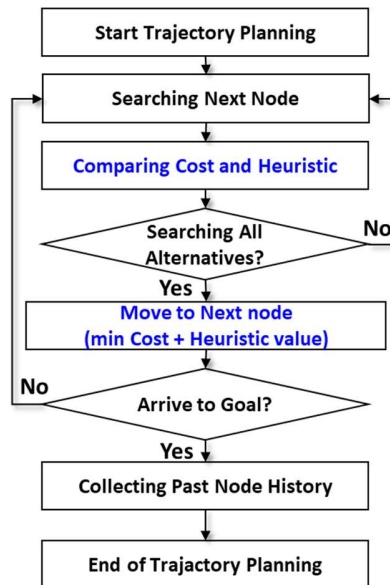

Figure 1. Schematic of towing tractor and aircraft

There are two wheels, an axis, and a nose wheel in front of the rear wheel. And the distance between the axes of the loader is called  $L_{CA}$ , and  $\theta_{CA}$  is the angle of the loader based on the fixed coordinate system. And  $\beta_{CA}$  is the angle between the nose wheel and the central axis of the loader, and  $x_l$  and  $y_l$  are the absolute coordinates of the center of the rear wheel shaft of the loader. The distance between the axes of the turning tractor is  $L_T$ , and the rotation angle and steering angle of the tractor are  $\theta_T$  and  $\beta_T$ , respectively. And the speed of the tractor is set to be  $v_T$ .

## HYBRID A\*

In general, Dijkstra's method (Dijkstra, 1959) or A\* method (Russell, 2018) is used for path search. However, in the case of this method, as a method designed for graph search, a graph is generally constructed based on grid and used to find a path. Therefore, there is a great disadvantage that the search area is limited due to grid. Hybrid A\* method was designed to apply dynamics or kinematic to the A\* method. If the existing A\* method moved within a predefined grid, the hybrid A\* method is a big difference in that the node for search is not the center of the grid or a point based on the grid, but a point considering the kinematic model at the current node. Therefore, it is possible to construct a node in consideration of dynamics that could not be considered in the existing grid-based method. Path search scheme using hybrid A\* for towing tractor and aircraft can be expressed as figure2.

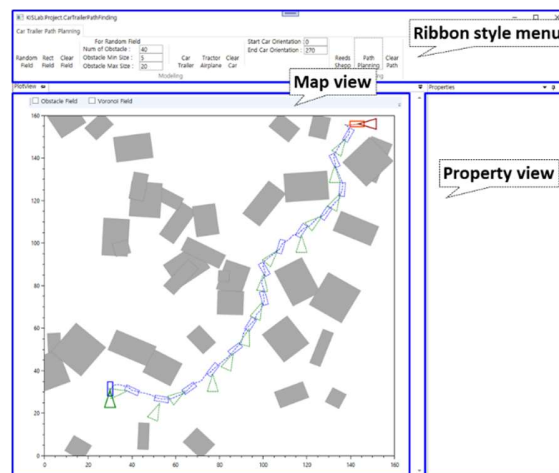

**Figure 2. Path search scheme for towing tractor and aircraft using Hybrid A\***

The cost function is a function representing the cost required to proceed to the node, and in general, the distance is often used as a cost value for the shortest distance search. In the case of our problem, the distance between the two nodes was considered as a cost because the shortest distance had to be considered basically. And in the case of backward movement, an additional cost was added because it is a relatively more difficult path than forward movement. In addition, in the same way, an additional cost was added when the direction was changed from forward to backward or from backward to forward. Here, the additional cost was selected in consideration of the interval between nodes and configured to be changed according to the needs of the user.

## APPLICATION

In this study, a user program based on the kinematics and hybrid A\* described above was implemented. The program can generate simple fields and examples for the towing tractor and aircraft. The program was developed in a .Net environment using the C# language, and a GUI was implemented using the MVVM pattern. The GUI configuration is shown in figure 3.

**Figure 3. Configuration of in-house program for applications**

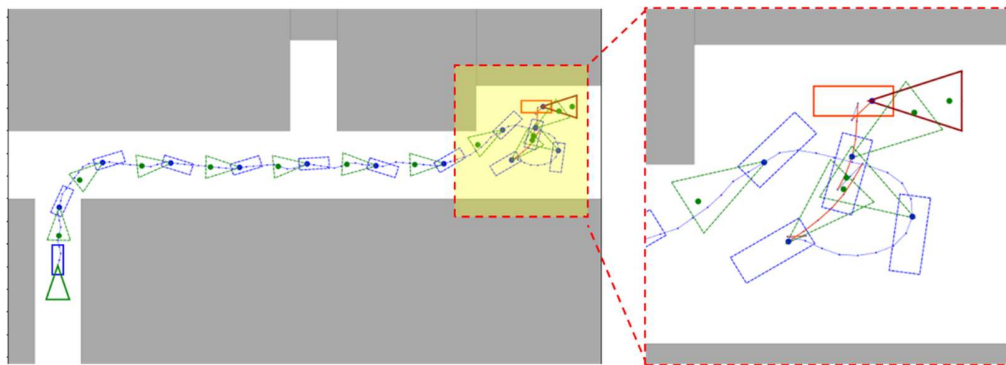

The hangar of the aircraft carrier is very crowded with aircraft and equipment. Therefore, assuming the situation, two examples were carried out under the assumption that the aircraft is carried from a narrow field to a towing tractor as follows. The first example is how to get the aircraft back to its destination after the turning of the towing tractor. This requires very precise transportation, and of course, the backward movement must be carefully performed in consideration of the jack-knifing.

**Figure 4. Path planning for backward movement**

As can be seen in figure 4, while considering kinematics, it is important to pay attention to collisions with the surrounding environment when reversing. The blue path is forward movement and red path is backward movement. The following path was shown that forward and backward movement were harmonically used as a skilled operator and it can be seen that the path is found smoothly.

The second example is for parallel parking. Since the aircraft acts like a cargo of a truck, parallel parking is a much more difficult maneuver than normal parking. Figure 5 shows a path of parallel parking of an aircraft in a very narrow environment. As can be seen in figure 5, the towing tractor is rotated, and parallel parking is performed smoothly as operators driving pattern.

**Figure 5. Path planning for parallel parking**

## CONCLUSIONS AND FUTURE WORKS

In this study, we proposed a method to find a path that can effectively transport an aircraft in the aircraft carrier, which is a limited space for the towing tractor. This method is based on the kinematics for the towing tractor and aircraft. And using this, hybrid A\* method was used to find the path considering forward and backward movement. For implementing this, in-house program was developed and applied to two cases. Two cases were modeled after frequently performed operations in aircraft carriers. The results show that generated path for towing was acceptable and similar to real operations.

The proposed method in this study is a path planning method that considers the connection between a aircraft and a tractor. However, it can also be applied to path planning for large ships being towed by tugboats in narrow coastal waters. Therefore, in the future, we plan to expand this method to towing problems for large ships in coastal area. In this case, the ship's equations of motion will be mainly used, and the ship's optimal fuel consumption and time will be considered accordingly.

# A Service Blueprint Approach in Shipbuilding Activity Mapping

Yong Se Kim<sup>1,\*</sup>, Junsong He<sup>2</sup>, Ludmila Seppälä<sup>3</sup>

## ABSTRACT

*In the evolving landscape of shipbuilding, the confluence of innovative methodologies and advanced technologies is reshaping paradigms in ship design and production. The industry's quest for multidisciplinary methods that elaborate representing diverse ship building activities and boost efficiency in managing these activities has unveiled the potential of the service blueprint, a tool used in service design, which addresses design of activities and determining who does what activities when in collaboration with whom.*

*Our proposition centres on the structured activity mapping representation, a novel activity map that utilizes service blueprint with detailed description of activities with rich and structured representation of context. The framework offers a comprehensive perspective, illuminating intricate processes such as concept design, detailed design and production stages as well as service and operation stages. This mapping would ensure alignment of each activity with overarching project objectives, encapsulating values, interactions, collaborations. This paper illustrates the approach of service blueprint in representing ship building activities with discussion on improvement potential of current activity mapping through the service blueprint approach as being conducted in the SEUS EU Horizon project.*

## Key Words

Shipbuilding Process Methodology, Human-Centricity, Activity Mapping, Service Blueprint

## Introduction

The European shipbuilding industry is currently navigating a complex landscape with challenges, including intensified competition from thriving Asian counterparts, economic volatility, and a growing demand for environmentally sustainable and technically advanced vessels (Seppälä et al., 2023). This paper examines these challenges as the industry stands at the intersection of addressing current impediments, redefining its competitive strategies for the future, and embracing the shift into a more human-centric paradigm. This paper is based on research conducted within the Smart European Shipbuilding (SEUS) project.

One of the primary challenges faced by European shipyards is the rising competition from Asian nations such as South Korea, China, India, and Vietnam. These competitors have progressively expanded their market share, driven by factors like robust economic growth, substantial government support, reduced production costs, and technological advancements (ECORYS, 2009). To ensure a sustainable competitive advantage, European shipyards may make a prudent decision by placing greater emphasis on the concept design phase. It is asserted that a substantial 80% of the total life-cycle costs of a product are determined during the design and planning stages. Therefore, the concept design holds a crucial role in the overall process of product development (Ohtomi, 2005). A typical commercial ship takes about two to three years to build (Payne & Chokshi,

<sup>2</sup> Turku Design Studio, University of Turku, Turku, Finland; ORCID: 0009-0006-3405-9109

<sup>3</sup> Marine Industry Business Development, CADMATIC, Turku, Finland;

\* Corresponding Author: email yskim83395@gmail.com

2020). A well-conceived concept design, characterized by a comprehensive integration of emerging technologies, business prospects, and human ingenuity, would bring a competitive advantage (Agis, 2020). In this context, the question arises: How can we foster innovation by adopting more comprehensive and advanced perspectives?

In shipbuilding industry, needs, functions and structures of typical design issues are applied in the concept design phase of shipbuilding to enhance resilience by considering latent capabilities (Pettersen, 2018). It emerges that value considerations should be articulated early in the design process to enhance the concept design phase. This will empower designers to make informed decisions and integrate values into technological innovations, leading to responsible and accountable design outcomes (Van Den Hoven et al., 2015). Thus, the value issues should be addressed in the concept design phase because it helps to empower the design process by ensuring that the project aligns with the organization's diverse values and goals. By considering the value perspective, the design team can ensure that the project is not only technically feasible and efficient but also aligns with the organization's mission, vision, and culture. Shipbuilding activities vary across different shipyards due to different contexts (Strandhagen et al., 2020). Various shipyards may prioritize distinct values, such as a commitment to environmental sustainability, and may emphasize the transition towards advanced technologies (Olorunfemi et al., 2023). Furthermore, it is important to acknowledge that there are additional values that could be considered in the decision-making process.

Now the research issue is to develop a methodology with a proper tool to enable considerations of diverse value perspectives in an integrated manner to encompass the overall shipbuilding process including concept design, detail design, production, and operation and use stages at a high-level so that value issues of diverse stakeholders are reflected. This paper presents an approach to address this research issue as being developed at the SEUS project. Specifically, this is done with overall shipbuilding planning and management with human-centric representation and management of shipbuilding activities and interaction and collaboration of various shipbuilding actors including ship owners, operators, and service providers as well as users and passengers.

The paper first reviews of service design and a method with a tool used in service design so that activities of diverse stakeholders are designed and represented. Service design results are typically represented as service blueprints. Shipbuilding activity mapping is briefly reviewed. Then a service blueprint approach of activity mapping is sketched as this would allow planning and management shipbuilding activities with emphasis on human-centric perspectives. The next section summarizes findings on current practices of activity mapping in two shipyards including their unmet needs and expectations. In the following section, a structured activity mapping framework is proposed with detailed explanations including a sketchy utility of the proposed framework in enabling comprehensive integration of shipbuilding process including concept design, detail design, production, and operation and use stages for the next-generation shipbuilding competitiveness. The paper is concluded with discussions on novel characteristics of the proposed activity mapping framework as well as future work.

## **Service Blueprint Approach in Activity Mapping**

### **Service Design and Service Blueprint**

A service blueprint has been used in designing services (Shostack, 1982), and is a visual representation of the process involved in delivering a service, specifying the linkages between different activities and the roles of different actors involved in service delivery (Patrício et al., 2011). The service blueprint prioritizes roles and activities of actors over individual tasks. Utilizing service blueprints, the process of shipbuilding activity mapping can place a greater emphasis on human-centered perspectives.

Service design and service blueprint are receiving greater attention because they play critical roles in creating new forms of values co-created with customers, organizations, and experts, and service innovation involves a new process or service offering that creates value for one or more actors in a service network through a human-centred and holistic thinking approach (Patrício et al., 2018). In simpler terms, service blueprints prioritize human-centric issues such as customers, service providers and other stakeholders within the entire system of value chain. The real virtue of service design has been verified with cases in various industries, particularly in the context of experience-centric services (Zomerdijs & Voss, 2010). Moreover, the emphasis on human-centricity in manufacturing-oriented industries through service integration has been in a growing trend in Product-Service System (PSS) development (Goedkoop et al., 1999; Costa et al., 2018). Note that a PSS is a system of products, services, supporting networks and infrastructure that is designed to satisfy customer needs and to generate values (Goedkoop et al., 1999; Tukker, 2015). Note that, in recent view of human-centered PSS design perspective, values are elucidated by activities and experiences that human stakeholders make using product artefacts in collaboration with other stakeholders of the ecosystem, rather than directly from artefacts (Kim, 2023).

In essence, service design is the process of designing human activities of service provider and service receivers. A service blueprint is a visual representation of all activities in the entire system, which helps to identify which stakeholder is engaged in which activities, in relation to which other stakeholders and in interaction with which other stakeholders. That is, a service

blueprint, a tool used in service design, addresses design of activities and determining *who does what activities when in collaboration with whom*.

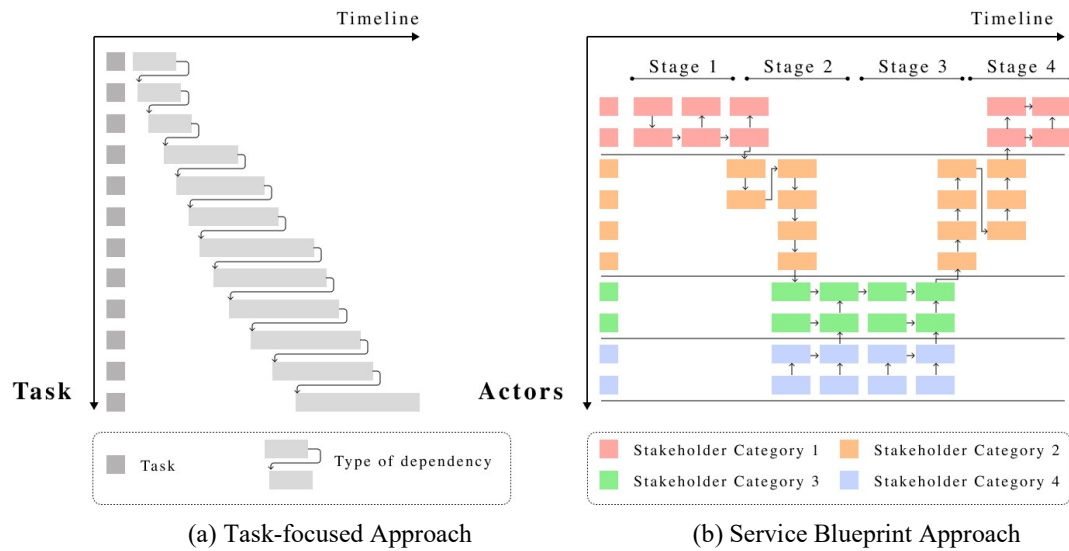

### Shipbuilding Activity Mapping

Bruce (2021) explains what shipbuilding activity mapping in detail as follows. Shipbuilding activity mapping refers to the process of creating an overview of ship production, outlining the stages of a ship project and the major functions within a shipyard. Shipbuilding activity addresses a set of tasks, processes, or events related to a particular project. Shipbuilding activity can include financial planning, schedule planning, design work planning, design team organization, reporting, staff meetings, action items, master calendars, security classification and document marking. According to our interviews with two shipyards participating in the SEUS project, as summarized in the third section, current shipbuilding activity mapping practices concentrate on tasks and schedules. This current approach supports in planning, tracking, and monitoring all ongoing tasks and resources, ensuring timely delivery to ship owners.

### Toward Human-Centric Shipbuilding Activity Mapping

There are extensive and diverse range of stakeholders and subcontractors involved in shipbuilding activities. They may include ship owners, government agency representatives, port engineers, ship supervisors and risk insurers; designers, naval architects, inspectors, marine engineers, and estimators; shipyard personnel, major vendors, major subcontractors, consultants, contract preparers; project managers, project planners, superintendents, maintenance supervisors (Bruce, 2021). It is important to recognize that these individuals are active actors with intent, motivation, expertise and relationships with other actors. Human-centricity issues are significant as reflected in Industry 5.0 (Xu et al., 2021).

Conventional shipbuilding activity mapping primarily centers on tasks. That is, activity mapping addresses how tasks are assigned considering resources and when tasks are done. Tasks are shown vertically with timeline progresses as in Figure 1 (a). By incorporating the service blueprint approach, actor-centered considerations including relationships among actors can be addressed with primary focus. In this approach, on the other hand, actors are shown vertically with horizontal timeline as in Figure 1 (b). Moreover, diverse values can be specifically associated with activities by utilizing the context-based activity modeling (CBAM) method. Please note that the CBAM method has been devised to represent activities in service design field with a formal and rich representation together with context elements (Kim et al., 2020) as briefly reviewed in a later section.

**Figure 1: Shipbuilding Activity Mapping Approaches**

### Emerging Demands in Activity Mapping Practices: Cases of Two Shipyards

The current practices of two shipyards, Shipyard A in Spain and Shipyard B in Norway, in their activity mapping have been investigated through semi-structured interviews. Three kinds of questions were made on how their activity mapping practices are done currently, on their unmet needs and expectations, and on their visions on the next-generation activity mapping. Key contents of the interviews have been summarized in Table 1. Their approaches to planning and managing shipbuilding projects have been understood and some insights were obtained.

<i>Activity Mapping</i>	<i>Shipyard A</i>	<i>Shipyard B</i>
How shipyard maps the activity nowadays	<p>Microsoft Project serves as the primary software for activity mapping.</p> <p>The primary emphasis lies in scheduling functions, encompassing coordination of tasks and monitoring project progress.</p>	<p>Microsoft Project is employed currently.</p> <p>There is a lack of dedicated software for facilitating communication with suppliers.</p> <p>No software exists to help manage resources and retain their knowledge and experience.</p>
Needs and expectations	<p>A strong interest and need in the integration and analysis of data to derive actionable insights, generate reports, and establish benchmarks.</p>	<p>A desire for collaborative tools to engage with ship owners and to boost collaboration among supervisors and team members.</p> <p>The expectation of data integration across design, production, sourcing, and engineering.</p>
Vision of next generation activity mapping	<p>A high level planning of high of task, resource, allocation, schedule, and team.</p> <p>The detailed activity information about “who does what activities when in collaboration with whom”</p>	<p>The emphasis is on thorough planning, covering major milestones, dependencies, and confirmations.</p> <p>Extension to detailed activity information, specifying task ownership, collaboration with others and understanding the relationships between different activities.</p>

**Table 1: Interview Results of Two Shipyards**

As shown in table 1, regarding the current practices employed by both shipyards in mapping project activities, it is discerned that software tools are integral to their methodologies. Notably, Microsoft *Project* serves as the primary software for activity mapping in Shipyard A, with a predominant focus on scheduling functionalities. Shipyard B also uses *Project*. Shipyard B would want collaborative tools to engage with shipowners and to boost collaboration among project supervisors and team members. Shipyard A expressed interest in the integration and analysis of data to derive actionable insights, generate reports, and establish benchmarks. Similarly, Shipyard B would like data integration. Both shipyards desire hierarchical and structured activity representation tools which support high-level planning capability encompassing tasks, resource allocation, schedules, and team coordination, as well as a detailed activity information system specifying the who, what, when, and collaborative engagements involved in the shipbuilding process.

## Proposed Structured Activity Mapping Representation Framework

A structured activity mapping representation is proposed in this section. In contrast to shipbuilding activity mapping currently used as in (Bruce, 2021), the stages addressed in activity mapping can be expanded to include maintenance, operation and use by reflecting PSS concept as shown in the activity mapping framework of Figure 2. Within this framework, activities conducted by various stakeholders in the shipbuilding process are organized across these stages so that activities of stakeholders are described horizontally in corresponding lanes of actors with stakeholders as used in service blueprints. Activity mapping can be represented with specific value dimensions highlighted in corresponding value layers as shown on the right part of Figure 2. A layer with values for human-centric issues, PSS, and knowledge management is shown on top. Layers with each of these three value viewpoints are shown below respectively. The incorporation of value layers can help quick and efficient identification and attention of relevant activities associated with specific values.

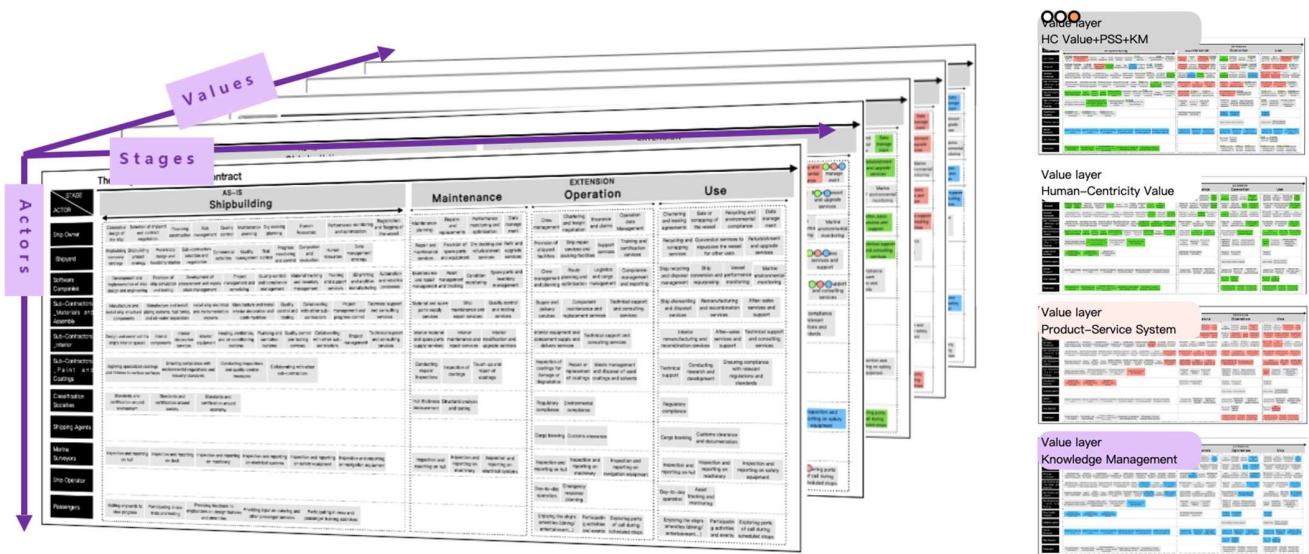

Figure 2: The Activity Mapping Representation Framework

## Stages

Taking a cruise ship as an example, the duration required to construct such vessels may vary, typically ranging two to three years. For instance, the construction of the *Icon of the Seas*, the world's largest ship, spanned a period of about 29 months. In contrast, the operational lifespan of a cruise ship commonly exceeds 20 years. Comparing the 20-year operational span with the construction period of two to three years, it becomes evident that the operational and usage phases are significantly longer, implying ample opportunities for value creation and business development in the post-construction phases reflecting the PSS perspective. In Figure 3, we broaden the perspective beyond the current emphasis solely on the construction phase. We extend this perspective to include maintenance, operation, and usage phases.

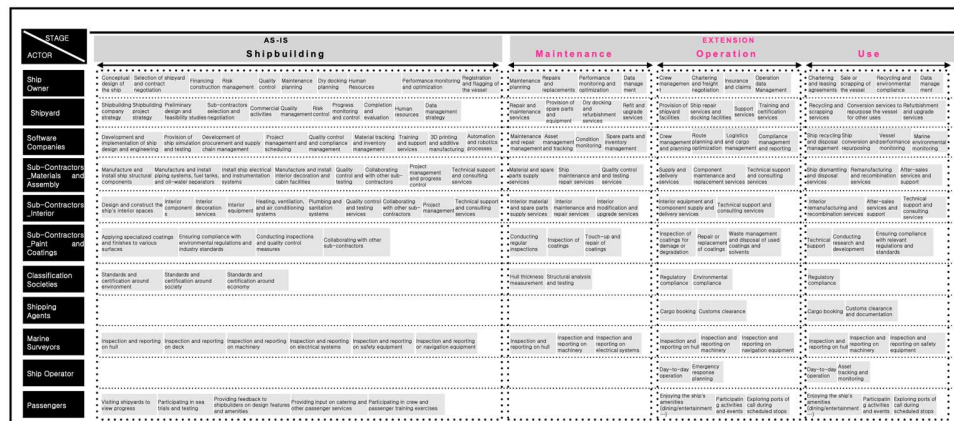

Figure 3: The Activity Mapping Representation Framework: Stages

## Actors

There are extensive and diverse range of stakeholders and subcontractors involved in shipbuilding activities as Bruce (2021) highlighted. Stakeholders, also referred to as actors, play crucial roles. Service blueprint representation of activities of a project allows actor focused representation of the process of a project as shown in Figure 4. The service blueprint of Figure 4 illustrates how a PSS development project is represented so that how activities of different stakeholders interact and how stakeholders collaborate can be represented and interrogated in a structured manner (Kim and Lee, 2021). In this representation, stakeholders are presented vertically, emphasizing their central role, while arrows show the interrelations between different activities. Each individual box represents a high-level PSS development activity conducted by specific stakeholders. Three top lanes in blue

show activities of a company with different responsibilities. The PSS design team activities are shown with two lanes in light yellow. Activities of other relevant stakeholders are represented as well. The second column shows that the CEO of the company and the leader of PSS design team collaboratively determined the servitization strategy of PSS development. This is then followed by the activity of servitization direction decision collaboratively conducted by three stakeholders from three organizations as shown in the next progress step. In this way, the service blueprint representation of PSS development process shows *who does what activities when in collaboration with whom*. Our objective is to develop a comprehensive, human-centric representation and management framework for shipbuilding, fostering interaction and collaboration among diverse stakeholders, including shipowners, operators, service providers, users, and passengers. Central to our approach is the emphasis on stakeholders and their respective activities, facilitating clarity regarding roles, responsibilities, and collaborative dynamics.

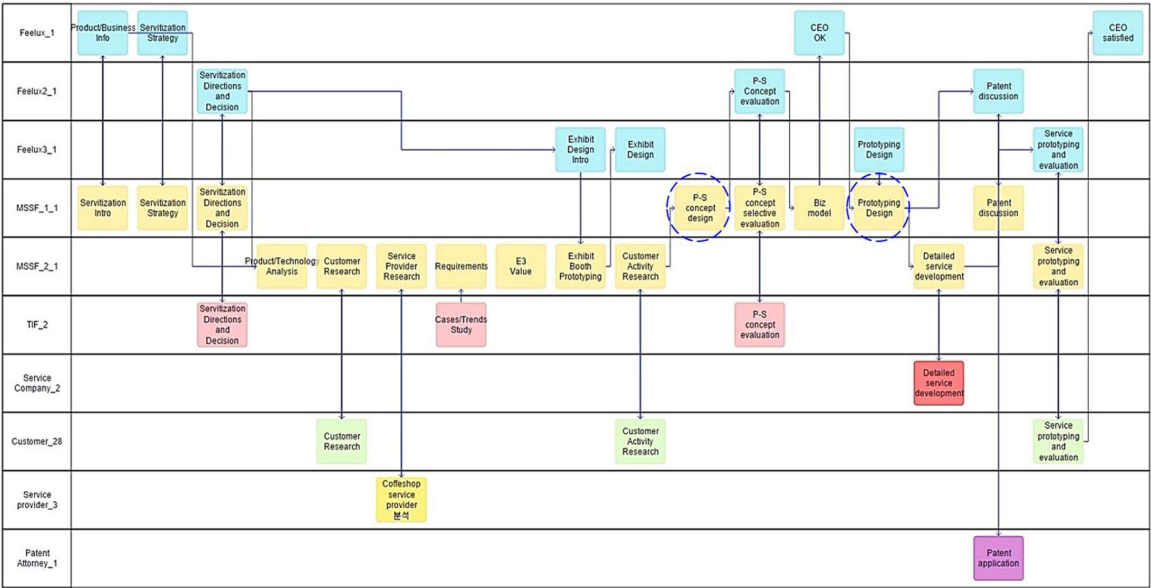

Figure 4: Service Blueprint Representation of a PSS Development Process (from (Kim and Lee, 2021))

### Values

Different shipyards and shipowners may prioritize distinct values based on their individual contexts. As depicted in Figure 5, the integration of value layers enables the emphasis of activities associated with specific values. For instance, if the value of *human-centricity* is emphasized, corresponding activities will be highlighted in green. Similarly, activities linked to *PSS* or *knowledge management* will be highlighted in red or in blue respectively if those values are prioritized. In cases where multiple values are emphasized, all relevant activities will be highlighted accordingly.

Figure 5: The Activity Mapping Representation Framework: Values

## Context-Based Activity Modeling

Human activities have been the object of designing services, and detailed representation of activities has been achieved through the CBAM method (Kim et al., 2020). Note that activities in a service blueprint would be represented by CBAM specifically. The CBAM method of modeling activities is illustrated in Figure 6. The activity description is centered around the action verb. The object of the action is specified as the *object* element of the activity. The *active actor* is the subject stakeholder of the activity who performs the action. In some cases, the *passive actor* and/or the *third-party actor* are specified as well. The *tool* of the activity is specified when a tool is used in the action. Another element of the activity in CBAM is the *context*, which is in turn described by the following 4 context elements: the *goal context*, the *relevant structures*, the *physical context*, and the *psychological context*.

Note that the goal context can be either other activities which the current activity supports or value themes derived by the current activity. The relevant structures are the entities associated with the object element in the action. Note that the relevant structure context represents various entities related to the object in this specific activity. This allows representation of relations of the object with various specific structure components. The physical contexts such as location and time are specified. The psychological context such as emotional states and motivation level can be associated. CBAM offers systematic and rich representation of context information of an activity. The psychological context includes sub-fields like social context, motivation context and emotional experiences, and can contain specific placeholders for specific value themes and their elucidated levels. In this way, CBAM enables specific association of various value items to activities.

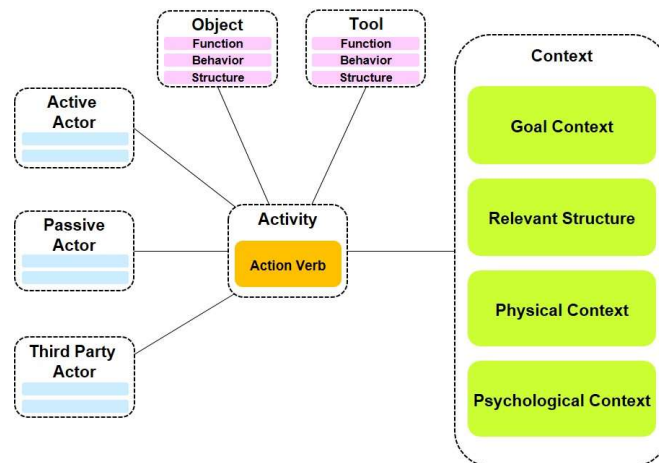

Figure 6: Context-Based Activity Modeling (from (Kim et al., 2020))

## Toward the Next Generation Shipbuilding with Comprehensive Integration

With the proposed structured activity mapping framework, comprehensive integration of shipbuilding over stages and over a longer span of shipbuilding business can be envisioned with a smart PSS perspective supported by data-driven approaches. Considering cruise shipbuilding cases, as exemplified in Figure 7, the following three pivotal situations can be postulated: (1) the completion of building a cruise ship several years ago, (2) the ongoing building of a new cruise ship, and (3) the early planning of building of a later cruise ship. These situations correspond to distinct phases of *operation and use*, *building*, and *design*, respectively. The cruise ship built earlier, now in operation, presents abundant opportunities for gathering insights and addressing needs by comprehensively analyzing data from various stakeholders involved, including end users, shipowners, operators, service providers, and related communities. The building of a new cruise ship provides another avenue for identifying needs and insights, involving stakeholders such as ship builders, architects/engineers, construction contractors, subcontractors, regulatory authorities, and suppliers. Through data from an operating ship, production of a new ship can be improved. Furthermore, insights obtained from an operating ship and current ship production as well as various stakeholders can even improve designing of a future ship.

By integrating insights and opportunities across these three situations and engaging stakeholders in collaborative efforts, competitive advantages can be harnessed. With the proposed activity mapping framework and repository of activity maps of diverse ships and various shipyards, the next-generation shipbuilding can be postulated with data-driven ship design and building encompassing design data, production data and use data. Beyond utilizing design data in production planning and shipbuilding, shipbuilding activity information can support maintenance and operation. Moreover, various use and experience data from use, operation and service can support design of future ships.

- 1 Cruise ship built 3 years ago
- 2 Cruise ship being built now
- 3 Cruise ship to be built in 3 years

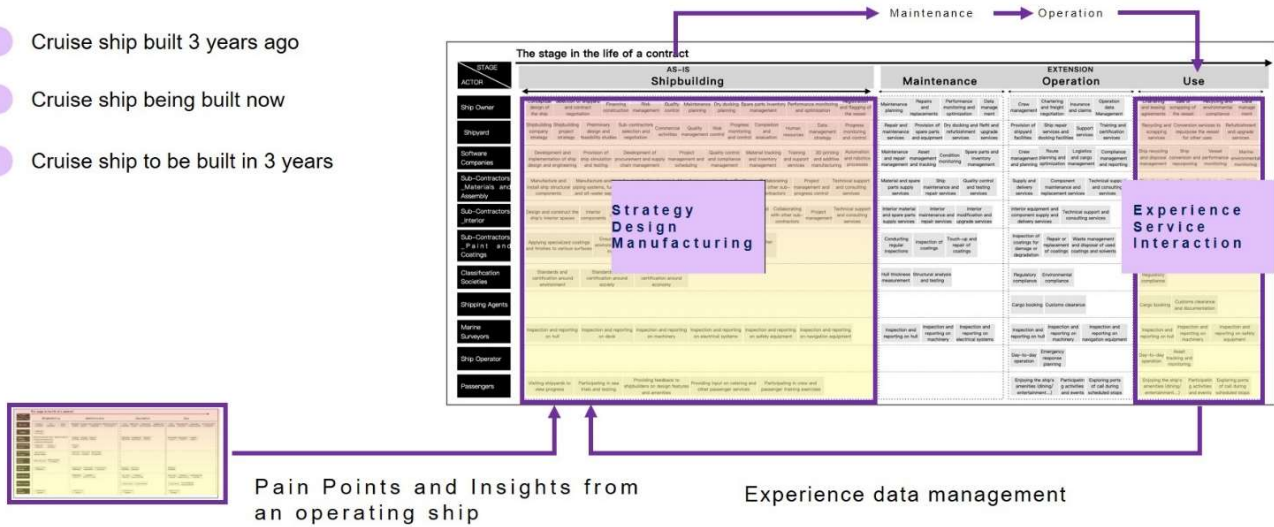

Figure 7: Integration of Design, Production, Service, Operation and Use Stages

## Discussions and Conclusion

The objective of the SEUS project is to create a framework for European shipyards by architecting and developing an integrated platform for data-driven shipbuilding, with a focus on human-centricity, smart technology, digitalization, and cyber-physical systems, to improve efficiency, reduce engineering time, and provide a competitive advantage through cost- and time-saving innovations (Seppälä et al., 2023). Within the SEUS framework, our research centers on representing shipbuilding activities with a focus on prioritizing human-centric approaches. This paper contributes to that overarching goal.

Specifically, in this paper, the human-centric approach in shipbuilding with a structured activity mapping framework was described as proposed in the SEUS project. The service blueprint representation of shipbuilding activities inherently focuses stakeholders as the activities are arranged for stakeholders, not for tasks. This is a significant improvement over the perspective where people are regarded as resources like in the case of Bruce (2021). Furthermore, specific values can be associated to activities through the detailed and rich representation of activities by utilizing the CBAM method. This human-centric approach with detailed value association enabled by the proposed structured activity mapping framework would be comprehensively applicable whether activities are about ship production or about customer involvement.

Furthermore, interaction and collaboration of actors are the most important part of activity management whether the activities are about strategies and contracts or about production and test. Representation and management of collaboration and coordination of diverse shipbuilding stakeholders are particularly important for human-centricity in the era of digital transformation. Note that *smartness* can be assessed based on how rich co-creative activities were done in various parts of shipbuilding activities. For example, shipbuilding activity staging, that is, determining which actors are involved in what phase in collaboration with which other actors should be effectively supported in the proposed activity mapping framework.

Moreover, to address after-sales services, such a human-centric approach is very important. Considering the use stage, various stakeholder experience data can be obtained as well as diverse artefact data so that truly data-driven ship experience design could be realized as explained in (Kim, 2023). We believe people aspects are getting more and more important as digital technologies are utilized in more and more parts of ship design, production, operation and use stages. The proposed activity mapping framework would work as a major enabler for smart data-driven ship design and ship experience design as a high-level planning tool addressing vast range of ship design and building stages and as a detailed information provider for activities. In this way, the activity mapping with service blueprint representation would make a significant next-generation shipbuilding competitiveness management tool.

Future work on this activity mapping research would include the following tasks. Efforts will be made to accommodate different shipbuilding contexts and shipyard characteristics in a structured manner in shipbuilding activity maps. This will allow repositories of diverse ship design and building cases so that smart data-driven ship design and building can be supported. Immediate future work will address systematic development of cases. This will entail selecting and combining scenarios from

various shipyards, each with distinctive priorities and contexts. This will be structured with four main aspects: shipyard activities for planning and building phases, strategic mapping of activities during design phase, defining ship owner activities related to customer experience during operation and use stage, and scenarios focusing on systematic considerations guided by diverse data-driven methods. How specific collaborations were done in previous shipbuilding cases can be captured and represented as knowledge so that future shipbuilding cases will exploit this. With digital technologies, collaborations are happening with wider partnership and these kinds of knowledge would be important as closer feedback from various stakeholders are enabled in such a collaboration.

# Piping Layout Integrated in Ship Design and Stability Assessment

Herbert J. Koelman<sup>1,\*</sup>

## ABSTRACT

*Damage stability assessment in ship design is a well-established area of our trade. However, where originally only a limited number of aspects were involved, gradually more details are included. Notably compartment connections by pipes and ducts etcetera. Combined with a high number of damage cases, in practice this results in a set of computations which is not complex as such, yet complicated by its sheer size. Although in the PIAS ship design software suite quite some dedicated tools are available, those have never been designed to support the requirements from today. In this light the software has been extended with a new system to fully define shape and topology of compartments and their connections. This paper reports on the system design, its application in damage scenarios, and on complications.*

## KEY WORDS

Damage stability; Piping; Time-domain; Ship design.

## INTRODUCTION

If a compartment is damaged in such a way that it is open to the sea, then it will obviously be flooded, which can also extend further into the vessel through all kinds of openings or connections between compartments. In stability regulations, the word *progressive flooding* is mostly used for this, but we rather avoid that because it suggests that the flooding continues until it is fatal, which is not necessarily the case. The ship design and stability suite [PIAS](#) accommodates this phenomenon, by a sub-system *complex intermediate stages of flooding*, which dates back to the nineties. This works on the basis of non-uniform filling percentages per compartment, where necessary supplemented by virtual compartment connections. Although this has served the program users well over the past decades, it has some limitations:

- It supports only *virtual* connections between compartments. That means that a point in 3D space can be assigned as being ‘the connection location’, without any physical object connected to that point.
- Only one single location is supported as connection point between two tanks.
- Data input and output only in text.
- Supports computation of time to equalization. Yet only a) for a single compartment connected to the sea, and b) as disconnected calculation, not integrated in the stability computation and assessment.

Although as such it works well and is widely used, this system has never been conceived for intensive usage. While on the other hand we can witness an ever-increasing attention to effects of filling and flooding through holes, openings, ducts and pipes. Which is caused by stringent rules, increasing scrutiny by authorities and classification societies, hence increasing awareness of ship designers and shipyards, and finally increasingly complex vessels (from the layout design point-of-view). So, in order to satisfy this market demand, it was about time for a new PIAS subsystem for next-level damage stability assessments, including major effects of internal flooding and its progression.

In the set of rules and regulations on ships and shipping literally dozens of places can be identified where aspects of openings, internal connections and damage to piping systems are addressed. Although it is not the intention to provide a full overview here, some examples will be presented. For example, in IACS Unified Interpretations, notably No. 110, on tankers, chemical

---

<sup>1</sup> SARC, Bussum, The Netherlands

\* H.J.Koelman@sarc.nl

tankers and gas carriers: “Progressive flooding through internal pipes: In case of damage of an internal pipe which is connected to an undamaged compartment, the undamaged compartment should also be flooded, unless arrangements are fitted (e.g. check valves or valves with remote means of control), which can prevent further flooding of the undamaged compartment”. Another example, taken from IMO (2020), on Probabilistic Damage Stability: “The factor  $s_i$  is to be taken as zero in those cases where the final waterline immerses the lower edge of openings through which progressive flooding may take place and such flooding is not accounted for in the calculation of factor  $s_i$ . Such openings shall include air pipes, ventilations and openings which are closed by means of weathertight doors or hatch covers”. Finally, MSC (2020) links consequences to equalization times by cross-flooding arrangements (which are constructed to reduce the heel in the final equilibrium condition), with thresholds of one and ten minutes.

Until now, we have discussed the realm of requirements. Now we will briefly revisit recent related advances in modelling of algorithms on internal flooding after damage. Both Vermeer et al. (1994) and Ruponen (2007) researched in detail flooding scenarios after collision damage. Although this has created valuable insights, the applications were quite detailed and focused on specific specimens. Ruponen et al. (2012) have compared cross-flooding times as derived with different methods, and concluded amongst others that the simplified formula from IMO resolution MSC.245(83) satisfies well in case of small pressure variations, however, this conclusion may not be extended to different flooding cases. In Kariolus et al. (2019) a probabilistic assessment of progressive flooding has been proposed which takes into account the probability of opening internal watertight doors etcetera. In Braidotti & Mauro (2019), a fast method for the calculation of progressive flooding is presented, based on an analytical solution of the linearized system of differential equations.

## THE NEW PIPING-BASED SYSTEM

Although from the viewpoints of regulations and science on the models and scenarios of flooding and related residual stability the last word has not been said, our aim in the development of the new system was not on advancing the latest theoretical insights. Instead, our contribution lies in helping our software users by taking one step forward from the conventional, while still maintaining an understandable and traceable modelling and computation method. With this background a design specification has been drafted, which was circulated under PIAS’ customer base. Some replied with valuable remarks or ideas, which have been processed in the specification and the subsequent implementation.

In the remainder of this section, we will discuss the modelling methods, followed by an overview of the computational approach, and finish with a few core computational details.

### Topology And Geometry of Openings, Pipes and Ducts

A foundational choice for the new system was to build the data entities and mutual relationships onto a specific standard for a sector which is — as a matter of speaking — littered by pipes and their purpose: the process plant industry, ISO (2019). However, this ISO 15926 standard is conceived for a wide range of industries and applications, so unavoidably quite broad, and yet unfocussed. Fortunately, for the process industry this has been further detailed by the DEXPI association, DEXPI (2019). From this extended standard five entities have been used which are sufficient to model a shipboard piping system for our purposes:

- **Equipment**, which is a thing, not being a compartment, connected to a pipe line but not part of it. Such as an engine or a chiller. Equipment play no role in computations, it is just defined for the completeness of definition and drawings.
- A piping **system**, which is an administrative collection of pipes of the same type, for example ‘ballast’ or ‘Methanol’.
- A piping **network**, which is one closed system of connected pipes, which belongs to a piping system. This is the core of the piping data structure.
- A piping **segment**, which is one branch of a piping network, and extends between two points without sub-branching in between.
- A piping **connection**, which is a part located at the extremities of a piping segment. These come in six types:
  - Branch, where multiple piping segments meet.
  - Unprotected opening, external (so, to the outside of the ship).
  - Opening + Weathertight Air Pipe Closing Device (WAPCD) a.k.a. vent check valve.
  - Terminator, which closes a dead-end segment.
  - Compartment, or, more precisely, a connection to a tank or compartment at a certain location. So, a compartment may have multiple connections. The representation method of compartments will not further be discussed here, that has been elaborated in De Koningh et al. (2011).
  - Equipment, or, more precisely, a connection to a piece of equipment at a certain location.

- A piping **component**, which is a part located in a piping segment. This can be a waypoint, elbow, valve, pressure relief valve, reducer, check valve, internal WAPCD or a straight pipe section.
- A schematic example of a piping system, including these entities and their relationships, is sketched in Figure 1, while an (other) example of the PIAS GUI implementation is reproduced in Figure 2. Space does not allow here to discuss all tools and features of this GUI, so we suffice here with this [link to the manual](#).

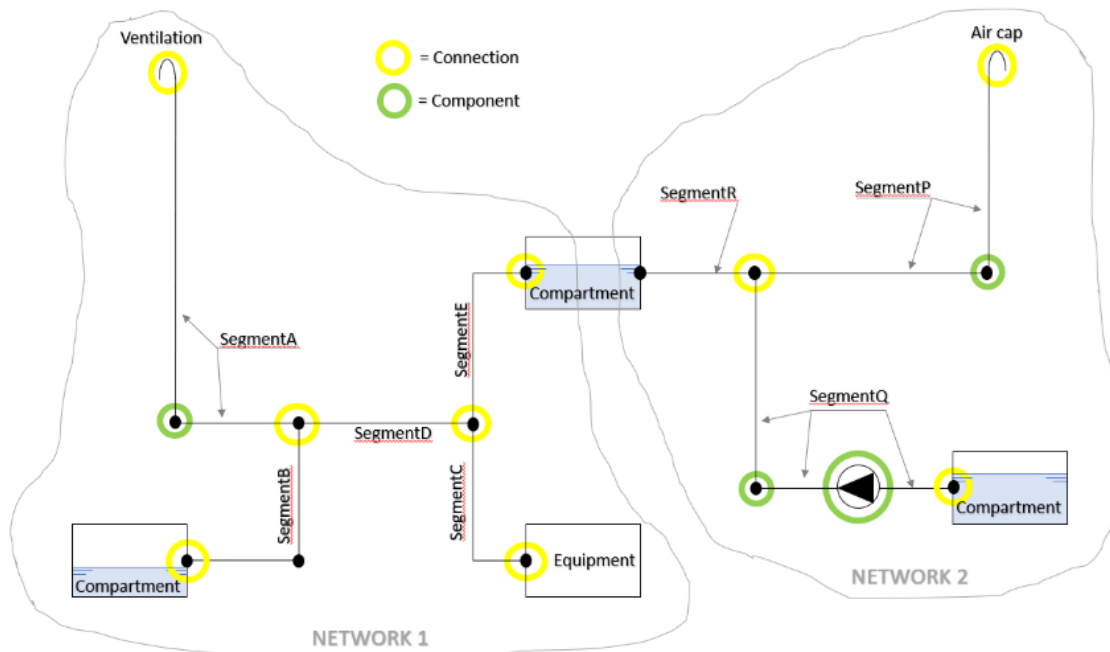

Figure 1: Schematic example of a two piping networks

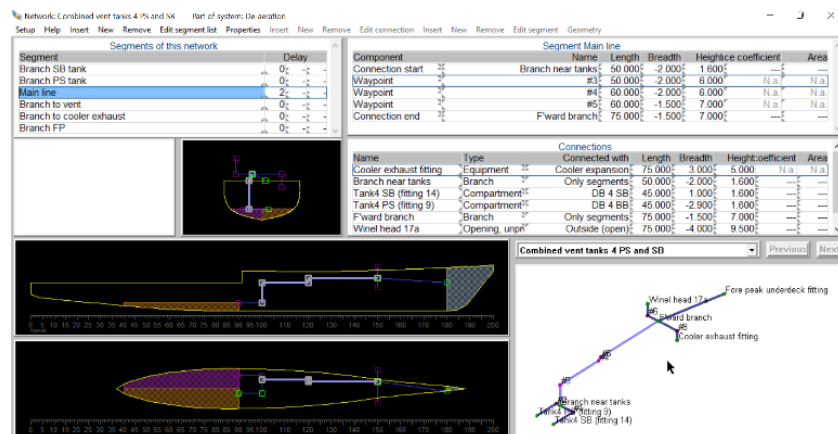

Figure 2: GUI implementation, showing a single network including connected compartments

## Two Categories of (Damage) Stability Computations Including Pipes and Ducts

As elaborated in the introduction, the aim of our developments has been to create a framework for next-level damage stability assessments, which is a) suitable for large-scale application, b) efficient from the viewpoint of human effort and c) understandable by the commonly trained naval architect. The presented piping networks, combined with existing representations of loading conditions, hull shape and compartments, open the way to a twofold of such applications:

- A time-domain analysis. For the reasons that a) this has a clear physical meaning, so b) it represents reality an order better than conventional ‘intermediate stages of flooding’, while c) time as such plays a role in some stability criteria and time-to-capsize assessments.

- Something that resembles ‘stages of flooding’. For the mere fact that such stages are anchored in tradition, and hence in textbooks and regulations.
- Combined, the new system, which embraces these two calculation types, is called *Consecutive Flooding*.

We start the discussion with **time domain** because its physical background makes it easy to grab. In line with the premise to create a practically useful system, the simplifications which are common in stability assessment have been applied here as well. These concern the omission of inertia of ship and fluids, temperature effects and the impulse of the inflowing water. Furthermore, the following assumptions apply:

- Ultimately, in fully damaged condition all initial damaged tank content is lost and fully replaced by sea water.
- Fluids mix instantaneously and fully, so there is no density gradient. For a damaged tank with intact fluid this implies that a stage at 99% of total flooding time will contain a mixture of intact and ingressed fluid, which introduces a discontinuity with the previous bullet. This is addressed by the computation of two variants at the moment of total flooding, the first with a mixture of fluids and the second with sea water. The first represents the condition directly after full flooding, the second at a long time after that.
- Non-damaged tanks, which are filled through connections with other tanks, receive a new density which is the proportional mix between original and ingressed densities. So, the intact content is never fully replaced (unless it flows out through another pipe connection), regardless the size of the connection.
- The volumes of the connecting pipes are neglected.
- Components have a single resistance coefficient, so there is no transition between laminar and turbulent flow.

With the latter simplification, the effort comes down to applying Bernoulli's equation in discrete time steps. In Ruponen (2006) this numerical differential equation was solved by a second-order scheme, which is more efficient than linear. However, it also requires that discontinuities (in flow vs. time) are identified, which is easy to do with time-based events (e.g. opening a valve) but less easy to identify in case of geometric effects (e.g. a large discontinuity in the shape of a tank). For that reason we have chosen first-order Euler integration. In each integration step the following actions are performed:

- Set the positions of pressure relief valves.
- Extending pipe openings with an outflow above a fluid surface with an additional, artificial pipe perpendicular to that surface. For the reason that pipe flow theories are based on pipes and reservoirs, and don't support waterfalls.
- Converting this piping network into a (mathematical) graph.
- Identifying closed loops in this graph, with a method for finding Fundamental Cycles.
- Applying Kirchhoff's laws around these loops and all nodes, as illustrated in Figure 6.25 from White & Xue (2021). This leads to a system with N equations and N unknowns.
- The resulting flow multiplied by the time step gives the fluid quantities per tank. These are capped if that leads to overfilling (>100%) or underfilling (<0%) of a tank in that time step.

With the second system the flooding is modelled with **intermediate stages of flooding**, so without explicit time. This implementation was conceptualized given two facts:

- Standard stability regulations apply the concept of ‘intermediate stages of floodings’ of fixed percentages, i.e. 25%, 50%, 75% and 100%.
- Not all compartments are always flooded with the same percentages, i.e. with small connections between compartments the flooding of the connected compartments may lag behind the flooding of the ruptured compartment.

Our system maintains the notion of ‘percentual stage of flooding’, because a) this is a fundamental concept in present damage stability regulations, b) therefore this concept is familiar to authorities and classification societies and c) the concept is easy to understand. To have a shorthand word for this concept it was labelled *fractional*, because essentially it fills compartments by ‘fractions’ of the final volume. Additionally, an integer *delay* is available to specify a lagging in time. All in all, this is a simple system, supporting conventional intermediate stages and a bit beyond. Those interested in examples are directed to this [section in the manual](#).

## Core Computational Details

Besides the core of the computation, some additional facilities and choices are of interest. The first is the **WAPCD** (Weathertight Air Pipe Closing Device), which besides its common *modus operandi* according to IMO/SOLAS interpretation, in our implementation also supports an additional *safety distance*, hence accommodating European Inland Waterway tanker regulations ES-TRIN, CESNI (2019).

**Frictional resistance by pipes** is in the essence a complex issue. In practice, however, a number of practical methods and parameters exist, some of which have been implemented:

- The (cross-sectional) shape. Choice of round or square, the most common shapes.
- The cross-sectional dimension. If round then diameter, if square then edge length.
- The (dimensionless) resistance coefficient, for which three common methods are available:
  - According to IMO resolution MSC.362(92), where the frictional resistance per meter length is  $0.02 \div \text{hydraulic diameter}$ .
  - With a user-specified Darcy-Weisbach coefficient, where the frictional resistance per meter of length is that coefficient  $\div$  hydraulic diameter.
  - With a user-specified resistance coefficient per meter of length.

A second issue is the energy loss due to **fluid outflow from a pipe**. For flow resistance of pipes and components, IMO has adopted a family of resolutions, namely A.266 1973, MSC.245(83) 2007 and MSC.362(92) 2013. To support the stability assessment of elder vessels, our system supports all three. A central element in these resolutions is the so-called ‘reduction of speed’,  $F$ , which is directly related to component resistance coefficients. A confusing factor is that in the three resolutions the equations for  $F$  are similar, but not equal, because two of the three have a factor *one* in the denominator, which the other lacks. This factor is to account for the energy loss due to outflow from the end of a pipe, Söding (2002). In order to harmonize these regulations, as well as to accommodate more than a single pipe outlet, the user can choose between implicit (= with the *one* in the denominator) or explicit (= user-defined) outflow energy loss. By the way, in the mentioned IMO resolutions the underlying outflow differential equation is (after some simplifications) solved analytically, which leads to a closed-form expression of equalization time. Instead of that expression, in our approach the flow resistance factors from these resolutions are used directly during the numerical integration of the differential equation.

Finally, the issue of **larger angle stability**, the computation of the GZ curve. From the viewpoint of consistency this is a bit of a strange phenomenon, because it is artificial. In the physically based time domain computation, no force or moment exists that forces the ship to heel. And there is not sufficient time to heel, because the next unheeled time step is ready to commence. This is solved by a) computing GZ without time effects, while b) omit possibly ingressed or shifted fluid *during heel* in the next time step. Still, there is an open question on how to determine whether fluid is transferred through pipes or openings during heel. In case of a small diameter pipe it is obvious that the roll period is not sufficiently large to allow for significant fluid transfer during heel. While a half-height bulkhead allows a waterfall over the bulkhead edge during heel (possibly without backflow when heeling to the other side). To differentiate between the two cases, a user can specify a ‘minimum cross-sectional area for instantaneous fluid passage’, which gives the program a handle to either allow flow through pipes and openings (if the actual area is larger than this minimum) or block the flow (if the actual area is less).

For all intermediate stages a GZ curve will be computed and assessed. In time domain for each time step full stability could be computed as well, however, this would lead to a large number of computations without much added values. For this reason, the program has a few switches to balance the amount of GZ evaluations. Anyway, for each time step draft, trim, heel and fluid quantities are available.

## CHOICES AND OBSTACLES

Although the basic functionality and procedures are rather straightforward, completing it into a computer program usable in day-to-day ship design practice requires quite some deliberations and choices, in which we also encountered an unexpected obstacle here and there, which will be discussed in this section.

### Permeabilities

There is this [famous Monty Python sketch](#) about an accountant, Herbert Anchovy, who gets bored of the dullness of his work. Well, our profession equally knows a Herbert who also has that feeling, about a small detail that has haunted him for more than four decades; the permeability of a tank. We all know that for the computation of tank tables a 2% reduction on volume is a common estimation to account for internal construction of steel vessels. Hence, a permeability of 98%, while all damage stability regulations impose a 95% permeability for tanks containing liquids. As such it is silly to apply different permeabilities for the same space; suppose a double bottom (DB) is fully filled with sea water. When it becomes damaged, due to some magical intervention from above suddenly 3% of the content is assumed to vaporize. And suppose the ship has separated SB and PS DB tanks, with the SB tank damaged and PS intact. Then, due to this loss of weight at SB, the vessel will slightly heel over to PS. While in reality nothing happens.

In the 1980s, for PIAS the choice has been made to interpolate permeabilities based on the stage of flooding, in order to achieve continuity at 0% stage = intact, and 100% stage = fully damaged. But now, with pipe connections, the situation is even more confusing. Take, for instance, a tank which is not ruptured but nevertheless flooded by seawater through a pipe, which is on its

turn connected to a second, damaged, tank. What should then be the permeability of the first tank, damaged or intact? Consulting the regulations does not provide a unison answer, for IMO (2016) provides a different choice than IMO (2020). So, a program setting was created for this, including [a paragraph in the manual](#) with some more details.

Later in this paper the verification process will be discussed, and it can already be revealed that on many occasions we thought to be looking at wrong results, which later turned out to be correct. Had permeability again played tricks on us.

### Intermediate stages of flooding

The whole assumption behind the idea of a *fraction* (a generalization of an intermediate stage of flooding) is that the immediately affected compartments will be flooded through a small damage. After all, if the damage were large, the ingressed water would spread rapidly, and the intermediate stage would be so short that it would have no effect on ship's position and stability. So, then the intermediate stage would actually not exist. Based on this physics-based reasoning, a distinction is made between large and small damages.

To assess stability in damaged condition, the worst-case scenario will have to be considered and since it is not known in advance how large the damage will be, cases with both a large and small damage are calculated. In the event of large damage, seawater can flow freely in and out of the damaged compartments, so that even during roll the water level in those compartments is equal to the sea water level. Because this all happens so quickly, intermediate stages do not actually emerge. In the case of a small damage, on the other hand, the water flows through the hole so slowly that the intermediate stages can take a long time, and thus should be considered in separate consideration. However, if the water flows slowly, then during rolling it does not have time to flow in or out significantly. So, in this case the volume of water in a compartment can be assumed to be constant for all heeling angles. Suppose intermediate stages of 25, 50 and 75% are specified by the user, the complete damage stability evaluation will consist of:

**Table 1: Damage stability assessment stages.**

Damage	Stage	Water in compartment	Verification against stability criteria for
Large	Final	Freely flowing in and out	Final stage
Small	Final	Constant, as at equilibrium heel (call that W)	Final stage
Small	Intermediate	75% of W	Intermediate stages
Small	Intermediate	50% of W	Intermediate stages
Small	Intermediate	25% of W	Intermediate stages

### Damage stability criteria

Table 1 already shows which criteria for final or intermediate stages of flooding are applied. For the time domain computation, for (user-configurable) time intervals a full stability calculation can be made and verified against criteria. The question whether to apply criteria for final or for intermediate stages can be derived if a time limit is given, for example the 10 minutes from MSC (2020).

Another dilemma with stability assessment is the displacement through which the uprighting moment is divided, in order to obtain uprighting lever. Intact displacement or damaged displacement? Quite often, in literature this aspect is related to the lost buoyancy vs. added weight issue, but that is utterly confusing, for this issue is related to two separate *computation methods*, while our dilemma is just the choice of a denominator in an arithmetic division. Even in my favorite textbook on stability, Biran & Lopez-Pulido (2014), the method (lost buoyancy) is confused with the denominator equaling the intact displacement (which is called *constant displacement* in some stability regulations). Because different stability regulations dictate different denominators, our program has, reluctantly, been equipped with [a setting where the user can specify the applicable choice](#). *Constant displacement* has been the program's default since the 1980s, a choice that has recently conveniently been formulated by eq. 3 of Ruponen et al. (2018).

## Program settings

In the ideal world, where everything is equal, a computer program needs no settings. In reality, preferences, traditions, ships and regulations differ, so there is a compelling need for settings in a program or app. Quite some settings have already been discussed in this paper, while some additional remarkable settings will be elaborated in this section.

The whole idea of a time domain calculation is to calculate the **time in which the fluids equalize**. The flooding process is finished when the whole system of vessel and fluids have come to rest. However, towards the end of the process the fluids start to flow slower and slower; after all, the level differences get smaller, and hence the pressures and the flow velocities and flow rates. In essence, it is an asymptotic process (in particular exponential, see Braidotti & Mauro (2019)) where after, so to speak, many hours, milliliters are still flowing through the pipelines and openings. Indeed, in theory, equalization time will always be infinite. In practice, a certain tolerance can be set, so that if e.g. the difference in draft between two consecutive time steps is less than a mm or 1/10 mm, that is considered as ‘rest’. However, that is an arbitrary tolerance that unintentionally has a large outcome on the final answer; at 1/10 mm, the equalization time can easily be twice as long as at 1 mm.

One might think of implementing a practical limit; after all, we are interested in the tons flowing through the system in the early time, and not so much in the milliliters in the last seconds. With that idea, a criterion can be formulated that is related to the transferred weight. For example ‘if 98% of the total, final, fluid weight has flown through then I consider the system at rest’. The default percentage used in PIAS is indeed 98%, but this setting allows the users to adjust it as they see fit.

Another aspect is the concept of **equalization time** itself. In MSC (2020) this appears to be a strong issue, although the concept is not crystal clear. We assume that the idea is that an asymmetric damage is equalized by fluid flowing through a cross-flooding device, to the other side of the ship. And that, in the ideal world, this process comes to an end when symmetry has been achieved. But what when the geometry as such is not purely symmetrical, when, for instance, the tank at the other side is slightly smaller than the ruptured tank? Then a symmetrical condition will never be reached, and hence it will never be equalized? Unless MSC (2020) is augmented with explanatory notes, this will be an issue for subjective preferences by ship designer or inspection body. Hence, a cause for a setting.

Finally, **conflicting settings** may exist in our program. As such, this does not raise an alarm, it is just a matter of choices, some of which were made decades ago. Quite some of these conflicts are not fundamental, it is just that we don’t consider it to be economical to allow for a certain combination of features, such as *heeling angles larger than 90 degrees* (which exists in PIAS since 1982, and has been used a few dozen times) combined with this new *Consecutive Flooding* system. Others are intrinsic, such as that this advanced *Consecutive Flooding* cannot be combined with the approximative method of accounting free liquid surfaces by only their transverse moment of inertia. That is fundamentally impossible. Anyway, when conflicting options have been set, the conflicts are reported in a matrix in a popup box to the user, so he or she can make an appropriate choice. We realize that such messages are always a bit annoying when popping up, but they are inevitable given the sheer size of computation options in PIAS. An alternative would be to discard elder options, but we never know who in the customer base will still want to use such a legacy feature, for whatever reason, one day.

## Effects of internal openings on the GZ curve

Figure 3: GZ curve with internal opening submerged at angle P

How does our program deal with an internal threshold or pipe which is submerged, and consequently allows transfer of water, at an angle of heel which is beyond the static equilibrium? Take for example the GZ curve from Figure 3, where at angle P the upper edge of a partial bulkhead overflows, leading to the filling of an adjacent compartment and therefore a deteriorated stability. It will be undebatable that the GZ will initially follow curve A, until angle P is reached, where a greater amount of

ingressed water will lead to reduced curve B. However, the question is what happens on the “way back”, i.e. with decreasing angle of heel? The water will not fully flow back over the bulkhead, so a curve as indicated by C can be expected. And the subsequent question is which curve to use for the verification of GZ against stability criteria, A+B or C+B?

In PIAS, the past decades A+B has always been used — numerous calculations have been issued at classification societies and shipping inspections, and approved — based on the reasoning that the notion “way back” is never properly addressed, neither in literature nor in regulations. A few more arguments can be made in favor of this choice:

- The example above is expressive, but counter examples also exist. Take the GZ curve from Figure 4, with the partial bulkhead now immersed at an angle P which is much larger now. If the vessel is subject to IMO's Intact Stability Code then the maximum heel for criteria evaluation is 50° — the weather criterion — while angle P is much larger than 50°. So, this loading condition meets all stability criteria long before P is reached, and a reduced C-branch will not be applicable.
- Will 50° then be the determining angle? In many cases not, because dynamic stability equality (area A=B from the weather criterion) may have been reached at a much smaller angle. So, the possible branching of the GZ curve should be related to the applicable stability criteria, one way or another.
- Assume now that at the same large angle P not an internal opening spills over, but an external opening (e.g. a ventilation inlet), which sinks the ship. Then beyond P, the GZ curve will vanish, so also branch B. If one would argue that with an internal opening branch C should be taken, then the same reasoning should be applied to external ones. However, with branch B also C has vanished, so using this branch will render the whole GZ curve non-existent. Nobody — user, researcher, authority nor classification society — has ever suggested such a ‘solution’, because it would be unrealistic.

Supported by these arguments, it was chosen to keep the computation method for this subject in PIAS as it always has been. This is an implementation choice, not the irrevocable result of the modelling method. So, alternative choices could be made, if there would be a generic reason, such as clear and unambiguous guidance by rules or regulations, or unified regulations from institutions, such as IMO, IACS or national authorities.

Figure 4: GZ curve with internal opening submerged at a large angle

## VERIFICATION AND ACCEPTANCE

The whole idea behind this software is that it satisfies user demands, for which it needs to be practically usable, efficient, and reliable. The first two aspects have permanently been in the background, in the discussion of the software design so far. Anyway, all three issues will be addressed in this section.

### Manufacturer’s verification

For verification of the proper functioning of software, the first impulse is mostly to maintain a few test cases on file, which can be used to verify the outcome at regular intervals. Although this is as such a feasible approach, it has a few drawbacks:

- In practice it is not easy to keep the test cases stable. If, for example, for a specific test or demonstration somebody changes something in the ship data, or even in a setting, some outcomes may change. But not necessarily all outcomes, which makes the change sometimes hard to notice.
- If multiple settings should be tested, then multiple instances of the same test cases are required. If, subsequently, something changes in the test case then that change should be (manually?) copied to the other instances.
- Automated comparisons are not feasible without special provisions. Each and every change in a piece of static text in the output (a word, a unit) leads to a difference. Indeed, all outputs are different anyway, because of different times and dates!

So, for the piping-based computations a different approach is used. The basis is still some pre-defined data in PIAS format, although only from shape of hull and compartments. All other elements are added by a specific test program, which generates

variations in openings, pipes, connections, loading and program settings. In that way the consistency of the test cases is guaranteed because the variations are not stored, but re-generated when necessary. This test program — which is actually very short, and relies for all computations on the same libraries as the regular program — redirects the computational results to a plain text file, without pages, dates or much text. These text files are fit for automatic comparison on a regular basis. Obviously, the output of the end-user's program should still correspond with these text files, which requires a manual verification. However, if later undeliberate program modification destroys some output then it will be quickly apparent. The consequences of an unintended change in computation is much more dangerous, because it is not always visible. And that has been covered by the test program.

The test program generates some 50 independent test cases, with varying levels of complexity. All these cases are in separate documents compared with independent verifications, which are as such quite basic, for example by spreadsheet or by comparing with other PIAS output (such as that the 0% intermediate stage of flooding should equal the intact loading condition). Obviously, verifying all computation steps would be too labor intensive, so e.g. in a time domain computation of 800 time steps, a few samples have been verified manually.

These verification documents form a part of our IP, and will not reach the public domain. Although one or two of the test cases will be commented and released, to serve as example for others to do similar exercises. Because the underlying calculation steps are so elementary, with a simple test ship, tables of (inclined) hydrostatics & tank volumes and workable knowledge of Bernoulli's equation, every naval architect should be able to verify (samples of) these calculations with spreadsheet or calculator. That is not the prerogative of SARC.

## Anticipated embracement by users

Inspired by literature on engineering design, in particular Horváth (2007) and Gero & Kannengiesser (2004), for new software functionality we apply a stepwise process, including a number of feedback loops. The steps comprise 1) Establishing the need, 2) Analysis of task, 3) Conceptual design, 4) Embodiment design, 5) Detailed design and 6) Implementation and dispatchment. Usually, a written specification of the first four steps is drawn, while the last two steps are set during implementation or short pre-implementation tests. For the software under consideration, such a specification of the first four steps, with an outlook to the fifth, has been reviewed by (some) program users, so a thorough design document was available at the start of the implementation.

Although this specification was very much aimed at the *solution* — the data structure and visual appearance of the new system — the *fundamental reason* for change was also addressed, and recognized by the reviewers. So, in principle we have no reason to doubt a warm reception by the community of PIAS users, although we always have to wait and see how the market reacts when such a plan is actually put into software form, including a price tag (no matter how modest). A possible reluctance could be caused by the concern that calculation times may increase, because where previously a few intermediate stages of flooding were considered to be sufficient, today, in time domain mode, some hundreds of time steps will be calculated. Indeed, here and there processing time may increase, although some counterarguments can be made as well:

- Determining (temporary) equilibrium in each time step requires iterations, and hence computing time. However, each iteration starts with as initial condition the previous time step, which in general will not differ much from the final condition in that step. So, the number of iterations *per step* will be less than with conventional stages of flooding.
- For a ship with a device that acts for cross-flooding, the time to equalization should be determined anyhow. That used to be done in a separate assessment, with the outcome to be processed manually. So we can ask the user what he or she prefers; spending manual time or let the computer do the work?
- In PIAS many intensive computation tasks are spread over multiple cores or threads. That will also become available for these *Consecutive Flooding* computations, so up to a maximum of (today) twenty damage stability computations can be performed simultaneously.
- Experiments have indicated that total computation time on one core of a single time domain computation consisting of roughly 1000 time steps takes some 5-20 seconds, depending on level of detail of hull form and compartments. Concentrating on Probabilistic Damage Stability, in combination with an efficient method for determining the probability of damage  $p_i$  — such as by *Numerical Integration*, Koelman (2006), a variant of what is nowadays called the *Monte Carlo Method* — this delivers a good balance between accuracy and processing time.
- Indeed, Braidotti & Mauro (2019) proposed a computational more efficient method for progressive flooding, at the cost of increased algorithmic complexity. If computational costs of the internal flooding in time domain would become an issue, such a method could be investigated. If..would..could, because a sensible adage in software development is to only solve real problems.

# Appraisal by national authorities and classification societies

It could have been an option to distribute mentioned specification to inspection bodies as well, for their comments or advices. However, the question is what we would have gained by this. Because it's been quite a few years now, when SARC developed another new piece of software, on heeling and stability around an arbitrary axis. Similarly, we had drawn up a rather detailed elucidation of the proposed computational approach, including algorithms and references to specific and high-level literature, such as Pawlowski (2016). For comments we had sent that to a few inspection bodies, from whom most did not reply, while one wrote a short email reading “we use computer program ABC, and if your software provides the same results as ABC then we agree”. Although multiple normative, administrative and practical comments can be made regarding this statement, this particular paper is not the place for that. Let it suffice that we trust the reader appreciates that we lost appetite for this path.

Fortunately, the design of our piping software, and its underlying algorithms, data structures and choices are rather well documented, by its specification document, this paper and a bit more extensively in the manual. Additionally, on request some more design considerations or sketches from the implementation records can be made available. That should enable inspection bodies to perform their independent verification of the proper functioning of the software. A reassuring idea, incidentally, is that a time domain calculation is explicitly supported by regulations such as MSC (2020).

Concerning the ship design verification (i.e. the appraisal of damage stability computations), the obviousness of the ship model will only improve. Where with elder PIAS’ compartment connection facility the physical reality was to be translated into tables with numbers from virtual ‘connection’, now the basis is a topological and geometrical model which is easy to verify, as demonstrated by the report of the input from Figure 5.

Figure 5: Small part from program output of a piping network

## FURTHER DEVELOPMENTS

The software system as described offers these advantages:

- Physics-based computations on basis of a model which includes topology, geometry and true features of the piping system. So, no artificial notions or concepts; WYSIWYG (What You See Is What You Get).
- Intuitive definition of compartment connections, by just adding shape and types of pipes and their components.
- As a result, interfacing with other CAD/CAE software is in principle doable, as the same concepts (pipe shape and connections) form their basis.
- Both conventional (stages of flooding) and time domain damage stability computations.
- Easy generation of complicated stages of flooding.

The next developments of this system will comprise:

- Time domain computations *integrated* in Probabilistic Damage Stability. So, the effect of exceeding maximum allowable equalization time (for example 10 minutes, for SOLAS 2020) can automatically be determined, and incorporated in the table of results of damage cases and their *a* probabilities, and ultimately in the Attained Subdivision Index.
- With damage *to* pipes. For example, in PIAS' Probabilistic Damage Stability module the damage cases are presently generated on the basis of compartment boundaries. This will be extended to include piping edges and corners as well.

These are internal developments, which can be realized at SARC, independent of others. It is different when exchanging data with other CAD/CAE software. Ideally, this would be elaborated on the basis of a common data standard, which includes geometry, connectivity as well as functionality (e.g. the opening pressure of a pressure relief valve), while still being easy to manage and not too elaborate. Preliminary investigations have indicated that such a standard is not available, at least not widely used in the maritime domain. So, finding a solution is a challenge, which is at present being undertaken within a consortium where shipyards, universities and software suppliers are collaborating to develop a next-generation maritime software framework, SEUS (2023). In that context, lately we have been experimenting with a Graph Database, see Koelman et al. (2024), which most probably offers the flexibility to represent the piping data structure as described in this paper. This flexibility goes so far that, in addition to database capacity for pipe geometry, components and connections, there is also capacity for other facets of the pipeline system, such as its requirements and functions, as well as the design validation. This opens the door to a representation of the piping system which is extended with concepts of Systems Engineering — functional definition, physical definition, design validation (see Kossiakoff et al. (2011) — and hence support for a Model-Based Systems Engineering framework.

Where our computation method for the modelling of the flooding process will be adequate for many practical applications — and offers the advantage of traceability — it is not at the technological cutting edge. As SARC does not have the ambition to extend to more enhanced computation methods — such as a 6-DOF motion analysis, or the effects of waves, ship's inertia and the momentum and sloshing of the ingressed water — there lies an opportunity for interfacing with specialized third-party computational analysis software that covers this area.

## CONCLUSION

In this paper a new system for modelling geometry and connectivity of pipes, ducts and openings is presented, including the application of these data in damage stability analyses. The status is that this is fully implemented in PIAS' deterministic and probabilistic damage stability modules, including the corresponding manual pages. After a small addition (consisting of some more intermediate results) it will be ready to be distributed for production use. That will be the first independently usable and useful release of PIAS' *Consecutive Flooding* system, including both the systems of delay factors (an extension of stages of flooding) and time domain. On this basis, more extensions will follow, either on the computational side, such as time domain integrated in Probabilistic Damage Stability, or on interfacing with external software. From the user's perspective this new software tool will come with some uncertainties — such as how to determine a crisp equalization time in the asymptotic flooding process, or how to cope with differing permeabilities for the same space — as elaborated in this paper. However, one must realize that these ambiguities have always existed and are now surfacing through the use of sophisticated software. The hope and expectation is that regulators will eventually make responsible choices here.

Occasionally we are asked to indicate the effect of this new software on a particular ship design, however, the prime motive for this new development lies in the process, not in optimizing the computational result. Having said that, it may be expected that by not considering all flooding as a priori progressive, the conclusion of some computations may switch from 'capsized or sunk' to 'survived'. In any case, combined with an efficient non-zonal computation method to determine the probability of damage  $p_i$ , results of the probabilistic damage stability assessment will be more in line with reality.

Perhaps, some day after the mentioned extensions have been implemented, we could make some comparative computations with and without Consecutive Flooding, with realistic specimen of ship designs. On the other hand, that would be mere examples, with little generic value. Just examples, while contemporary literature in our profession is already littered with examples of specific computations applied to specific ships. The new software presented in this paper is so easy to use that users will be able to create their own examples.

## ABSTRACT

*Conventionally, ship design and engineering are segregated activities, carried out with different software packages that thus each have their own place, qualities and tools. And consequently, a different data model. As a report on ongoing work to bridge that gap, this paper first explores existing neutral data models and standards employed or considered in maritime applications and concludes that none of these is directly applicable. It continues with describing the requirements and derived abstract data model of the SEUS project and its design and engineering applications. A graph database is identified as a potentially useful tool for SEUS data modelling, and a hands-on experiment confirms this presumption.*

## KEY WORDS

Ship design methodology; Data models; Digital transition.

## INTRODUCTION

In the ship design process, the transition from early conceptualisation to detailed design marks a critical juncture — a “tipping point” that involves a change of stakeholders. Early design models emphasize the vessel's fundamental characteristics, naval architectural and functional aspects. Detailed design and production design delve into the intricacies of layout and deal with the generation of production and construction data. This dichotomy in focus leads to disparities in the tools employed and necessitates the alignment of data models.

This paper explores data standards in maritime applications, data models of two particular software systems — PIAS (by SARC) and CADMATIC — and the direction for integrating these models in the SEUS<sup>3</sup> project. SEUS aims at creating a high Technological Readiness Level solution to provide a set of computational tools for shipbuilding, incorporating data flows while the design matures and providing a comprehensive toolset for different stakeholders of the overall shipbuilding process, with access to a single source of true data. However, conventional neutral models or industry standards have not generally demonstrated their suitability for this task, so the research question addressed in this paper is to find a data model for shipbuilding which provides coherence of the data generated along the life cycle. Critical for SEUS are its anticipated impacts — such as a) platform solution for PLM, b) facilitation of digital transformation and c) integration of early design into the overall design process, see Gaspar et al. (2023) —many of which require software integration between design and engineering. However, it is not the first time in the history of mankind that such an endeavor is undertaken, so in the next section the applicability of existing maritime product data standards is investigated.

## DATA STANDARDS FOR MARITIME APPLICATION

The authors share a combined 100<sup>+</sup> years of experience in developing maritime software, where aspects of interfacing and (software) collaboration have played an important role, from time to time. In that context, we have regularly been surprised

by the surprise of others when we have been asked why we don't just use one of the many existing data exchange standards. By way of a (late) response, this will be addressed later in this section. First, however, a brief overview of potentially applicable standards is given, without seeking to be complete.

## An Outline of Potentially Applicable Neutral Models and Data Standards

The obvious idea of a neutral model is demonstrated in Figure 1, where without specific provisions the eight independent computer programs A..H need  $8 \times 7 = 56$  interfaces to share their data, while some kind of centralized format only requires eight interfaces.

**Figure 1: The neutral model saves on interfaces (from Gielingh (2008)).**

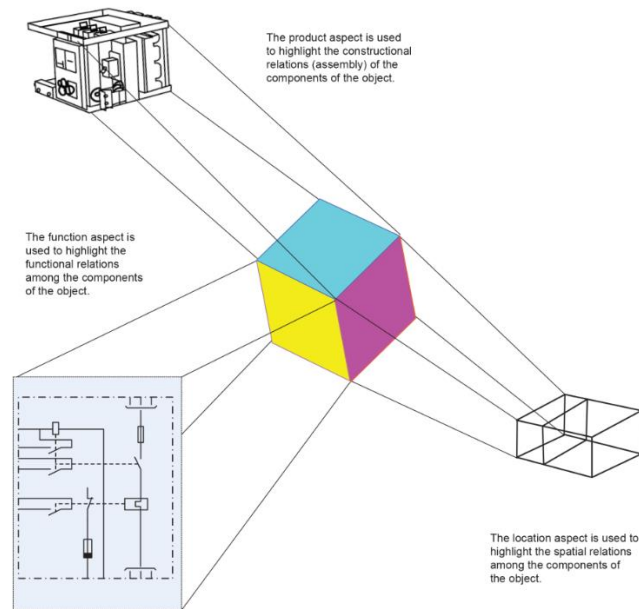

The paradigm of the neutral model is reflected in several neutral file formats which are used for this purpose. The search for a recent overview of the popularity of the various (file) standards for product information did not yield anything, so we fall back on the survey in Srinivasan (2008). The most frequently used data exchange standards appear to be DXF, IGES and ISO 10303 — commonly known as STEP, STandard for the Exchange of Product model data — with a combined utilization of 60%. The remaining 40% cannot be considered to be suitable for generic exchange of 3D data, for example PDF is listed, very useful, but ‘just’ a document format. Although quite widely used for data transfer, DXF is merely a drawing exchange and not specifically suitable for the exchange of product model data. IGES dates back to 1980, and, as its name suggests — Initial Graphics Exchange Specification — is more aimed at the exchange of 3D shape than of a product model. Although e.g. in Kirkwood and Sherwood (2020) STEP is recommended above IGES, the latter is still widely in use, for example for exchanging the shape of a ship hull in IGES types 126 or 128, which encode for NURBS curve or surface representation. This demonstrates a phenomenon that shall be encountered in a broader sense later: IGES contains a wide range of some hundred types, for all kinds of mathematical representations of shape, such as lines, curves, planes, surfaces and solids. So, the producer of a computer program that produces an IGES file is free to choose a few favorite representations, there is no need to support all (actually, nobody does).

This leaves STEP as perhaps the most viable alternative for product data exchange, a conclusion which is drawn in many papers, e.g. Kim et al. (2008) where it is proposed to use STEP not only for the exchange of 3D shapes, but to extend it to design intent (e.g. parameters, features, constraints and history). Furthermore, STEP specializes in specific areas of industry for so-called Application Protocols (APs), with maritime application AP215 (Ship Arrangement, see ISO (2004a)), AP216 (Ship Moulded Form, ISO (2003)) and AP218 (Ship Structures, ISO (2004b)). Incidentally, there is a short related anecdote to tell: when we ordered the STEP standard from the Netherlands Standardization Institute, a whole package arrived, but without AP215, 216 and 218. On enquiry, they maintained that these had since expired. Fortunately, the purchase could be made at ISO in Switzerland, but the exact status is now not entirely clear to us. Anyway, multiple researchers have formulated a preference for STEP for maritime application, e.g. Whitfield et al. (2011) and Shiplys (2019). Qin et al. (2017) report on some shortcomings of STEP, and they propose some improvement by combining it with Web Ontology Language (OWL) methods.

All these standards aim at a model for shape, with some ambition to grow towards product modelling. They have evolved into extensive books covering all kinds of pre-considered variations, more or less like a dictionary of a human language. Some considered that too limited, because life-cycle support, explicit semantics and relationships between entities are missing. This awareness has gradually led to a new standard, ISO-15926, see ISO (2005), from which a readable overview is presented on <https://15926.blog/>. The latter reports a twofold goal, a) global semantic interoperability and b) archiving, collecting and integrating plant life-cycle information. This terminology already reveals that this standard is leaning towards process plants, which might limit the applicability in the ship design area. Nevertheless, in the ship-borne integrated piping system as reported in Koelman (2024) the underlying data structure was inspired by ISO 15926. Another maritime

connection is that in a Dutch maritime research program from a decade ago, “Integraal Samenwerken”, a pilot with ISO 15926-11 (see ISO (2023)), was commenced — with the keywords “triple” and “Gellish” — but that did not proceed.

Another interesting industrial standard that has a wider scope than just the product and its shape, is ISO 81346, see ISO (2022). Here the multifacetedness of a product is addressed by assigning different *aspects* to a product, where each aspect can have its own hierarchy and taxonomy. An example is given in Figure 2, which shows three aspects: a) the constructional relations with the components, b) the functional relations and c) the spatial relations (e.g. the location). The application is not limited to these three; other aspects may also be considered, such as financial or logistical. As argued in Leclerc et al. (2022), this framework fits very well with a Systems Engineering approach, a method that is expected to enhance the productivity of the maritime sector (see the acronym *MBSE* in Maritiem Masterplan (2023)).

**Figure 2: Different aspects of an object (from ISO (2020)).**

The discussed standards relate to properties of a product in the design and construction phase. An emerging field is to include operational data as well, where a significant contribution is delivered by sensor data. This application is targeted by ISO 19848 (see ISO (2023)), which has been used by Fonseca et al. (2022) for an experiment with a digital twin of a scale model of a ship. Another emerging standard is the XML-based Open Class 3D Exchange (OCX) (see Zerbst (2023)), however, this is at the edge of our area of applicability, as expressed on <https://3docx.org/>: “The OCX is a vessel-specific standard addressing the information needs by the classification society”.

This ends a somewhat impressionistic overview of data standards and neutral data formats. A follow-up section discusses applicability and pitfalls, but first the data flow in a typical maritime project is outlined.

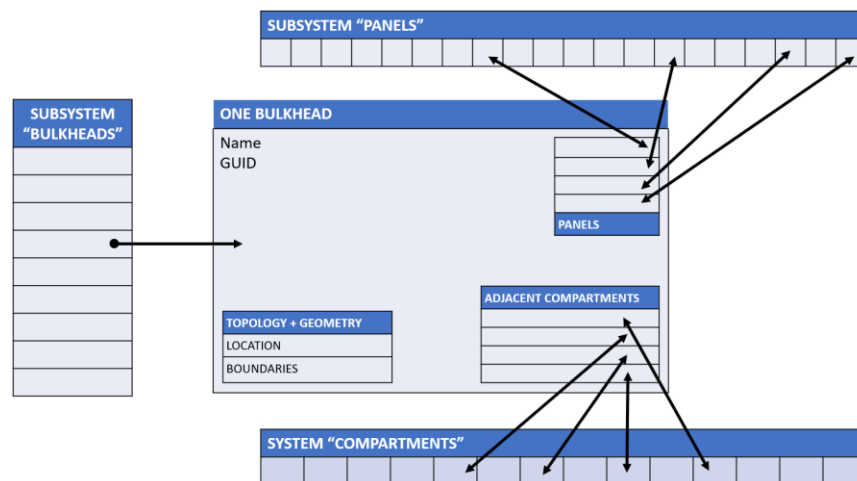

## Data Flow and Growth in a Typical Maritime Project

Kirkwood and Sherwood (2021) contains an interesting approach to simplify the sustained integration between CAD and CAE. This is motivated by the CAE application being a FEM analysis, and indeed such a representation may contain somewhat less detail than the original CAD model. However, in the maritime world CAE is predominantly seen as the precursor to production, which implies that data is becoming both more detailed and richer. For example, a watertight transverse bulkhead in a ship. In the first instance, this is just a line on a GA plan (or a plane in a 3D CAD model) with the intrinsic property that it is watertight, so it could act as a separator between tanks or compartments. This limited information is sufficient for producing tank capacity tables and damage stability computations. Later in the design process, this bulkhead data is extended with details of plate thicknesses, panels, beams, stiffeners, and perhaps paint details or manufacturing logistics; augmented with data that can be *derived*, such as weight, centroids and cost. And this all belongs to the bulkhead that started as a line in a GA plan. Consequently, when in a design update the bulkhead is shifted one frame position, some of

these properties have to change correspondingly. In a sense this issue is an instantiation of Figure 2, because functional, constructional, financial and logistical aspects are included, each with their own taxonomy and/or codification system. But it is also a matter of Level Of Detail (LOD), for example when at the stage of the General Construction Plan only the main structural elements are included, which are extended with brackets and welds in the final production preparation stage. If one would have the desire to shape such a system in a third generation (3G) programming language — only in RAM, without considering permanent storage and interfacing — a structure with arrays, classes and pointers connecting the different entities, could do the job. This is depicted in Figure 3, where:

- The bulkhead is part of subsystem “bulkheads” (which in turn could be part of the system “hull structure”).
- Each bulkhead contains a GUID<sup>4</sup>/UUID<sup>5</sup>, which acts as unique and permanent identifier (what is called a Virtual Persistent Identifier in Kirkwood and Sherwood (2021)). A unique identifier from another source (e.g. from a supporting data management system) might be an alternative for the GUID.
- Each bulkhead contains three types of subclassed information:
  1. Topology and geometry.
  2. References to compartments on both sides (in the system “compartments”).
  3. List of panels.
- The CAD system manages 1 and 2, never “sees” 3.
- The CAE system uses 1 and 2 and manages 3.

Please understand that this 3G solution is only presented to elucidate the process around and with the data. Practical considerations, such as the lack of a common 3G programming language, prevent its actual implementation.

**Figure 3: A class-based example of a data structure around a bulkhead, suitable for integrated CAD and CAE**

This example illustrates the continuously increasing completeness of information over the whole design and engineering process. This observation is somewhat contrary to the notion of design phases — concept, preliminary, contract and detail — of which it was once useful to distinguish between. The demise of the notion of distinct phases can be witnessed in practice, for example the typical ‘preliminary design’ requirement of sufficient damage stability is greatly influenced by the presence and position of pipes, valves and ventilation openings; details that are typically addressed in later moments of the design process. Also in literature this trend can be observed, for example a recent state-of-the-art report on ship’s design methodology, Erikstad and Lagemann (2022), counts zero entries of the words “design stage”. Yet, the title of the present paper addresses a gap, which is not a gap between design phases, but between models. The early design model is a bit more holistic — including non-material aspects such as simulation results — but smaller in size than the detailed model. Bridging the gap between models does imply that the connected tools should be unified for all design activities, indeed the objectives in the earliest stage of the ship design will differ from the later stages, as eloquently motivated in Andrews (2018).

Finally, there is the issue of bidirectional vs. unidirectional flow of data traffic. The ideal with a neutral model has always been that all connected applications are able to read and write from the central storage, as depicted by the bidirectional arrows in Figure 1, at the right. If the information involved is simple, such as an isolated number, then bidirectionality is easy to achieve. However, if complex logic or functionality is involved, then it can happen that not all applications are able to perform modelling changes. For example, the duality between compartments and bulkheads & decks can be managed by one

<sup>4</sup> <https://en.wiktionary.org/wiki/GUID>

<sup>5</sup> [https://en.wikipedia.org/wiki/Universally\\_unique\\_identifier](https://en.wikipedia.org/wiki/Universally_unique_identifier)

application only, while others can read and use that information without the need for specific tools to address that duality. Another example is hull shape modelling, where one parent application has the specific modelling tools, acting upon a parent representation, while other representations — such as STL, VRML, X3D and 3D-wireframe — at each design change are instantaneously derived and stored in neutral form. Ready to be used by other applications, without them having the tools for shape changes. If different applications are geographically dispersed then unidirectionality might be a bit awkward, but when two applications are open in two windows on the same monitor then it is neither unnatural nor time consuming that only one of the two can be used to make hull shape changes. It might even offer an advantage when an HVAC engineer is not able to change the shape of the bulbous bow.

## Applicability of Neutral Models and Data Standards in Ship Design and Engineering

At this point, the paper suffers from self-plagiarism, because what follows is an anecdote that one of the authors surely must have told hundreds of times over the past 20 years. As reported by Owen (1997), STEP has aimed at ‘completeness’, which led inevitably to ‘conversion’. This is illustrated by nine different representations of a circular arc in 2D, e.g. a) centre + radius + start angle + finish angle, b) center, radius, start point, end point, or c) polyline. If an application should want to support all these representations, and it uses one of them internally, then that implies eight conversion algorithms being required. From which item a) can be done with simple math, but item c) already requires some numerical analysis, which may result in round-off errors.

A similar example can be found in STEP AP 216, Ship Moulded Form, which supports three alternative representations: offset table, wireframe and surface. So, if a computer program internally applies a NURBS surface representation, and it receives a STEP file in offset tables, then it should be able to convert. Which is no trivial task in this example, see Koelman and Veelo (2013).

These are examples of the ‘variation in representations’, which are also addressed in the seminal paper by Gielingh (2008). There it is concluded that while we aimed for the nirvana of Figure 1, due to the large variation in representations, in practice only a subset is supported, leading to a situation of all kinds of ad hoc representation conversions, as depicted in Figure 4, regardless whether these representations are stored or communicated by DXF, IGES or STEP. This is the fate of any neutral model. One way or another underlying representations have to be converted, unless the world (or a workable subset of the world) decides to use a single representation for each and every entity.

**Figure 4: From theory (left) to practice (right); the neutral model doesn't really exist, from Gielingh (2008).**

Another issue with standards, such as IGES, DXF and conventional STEP, is that each only contains geometric data as stated by Qin et al. (2017): “A well-known problem of STEP AP 203/AP 214 neutral file-based exchange method is that this method is limited to exchange geometric data, where those nongeometric data related to design intent, such as construction history, parameter, constraint, and features, are completely lost after the exchange”. A practical issue of conventional neutral formats is that it does not always work properly, so that their usage may lead to errors and information loss, see Gielingh (2008) on STEP files read into an application and subsequently identified: “significant differences between these files were found: some entities disappeared, others appeared, and others were changed”. This observation was confirmed recently in Kurylo et al. (2023).

In particular STEP AP 215 is quite extensive, but still does not cover everything:

- It supports a single permeability per compartment, while in practice intact and damaged permeabilities will differ.
- Three types of block coefficients are specified, but not the one based on the design waterline length, as required for Holtrop's resistance prediction. It is questioned why include such *derived* information as the block coefficient in a standard? Each application should be capable of dividing a volume by length, breadth and draught, specifically in the variant that is relevant for that particular application.

- The height of the sounding pipe is included, but not its shape.
- A tank total volume and corresponding Center of Gravity is included, but not its free surface or a complete tank table provided. Again, here the question is why is easily derivable information stored?
- Although some relationships between entities are supported, there is no generic support for explicit dependencies and relationships between entities.

So, it can be concluded that STEP AP 215 is on the one hand too extensive, while on the other hand not complete. Probably, that will be the fate of any global neutral model. Furthermore, it can be considered to be a dictionary, not an ontology. Nevertheless, a lot of effort has been put into developing this standard, and many parameters and entities have been given a name and meaning, so why not use it, at least as inspiration?

The attractive feature of ISO 81346 (ISO, 2022) is that it addresses the multifacetedness of an object explicitly, but it defines a framework more than that it provides an implementable solution. Furthermore, it includes a standard on the coding of the location of objects, however, this is tailored to modeling buildings and is not directly applicable to ships.

Building Information Modelling (BIM) standards have not been discussed in the section on neutral models, because of the large volume, complexity and diversity of standards, national and international. The authors have not studied BIM in detail, yet BIM ISO standards 23386 and 19650 appear to be quite high-level, providing more of the general structure than relevant details. It seems that for many different fields of application this is further elaborated on a national or regional scale, (see [www.etim-international.com/](http://www.etim-international.com/), which contains article codings, for example: electrotechnical, HVAC and plumbing components). Although these components are vital in the ship's outfitting phase, their relationship with the design and engineering activities is relatively limited.

## TOWARDS THE SEUS DATA MODEL

At this point the conclusion is that of all the existing models and standards, none is directly usable for our purposes. Although, precise purposes have not so far been explicitly formulated, and thus this is addressed in the next subsection.

### Requirements for the SEUS Purpose

Minimum requirements can be derived from the analysis and discussion above, and consist of:

- A dictionary of the names and implicit relationships between entities. Although it is perhaps a bit premature to mention a solution at this stage, STEP AP215 provides a useful basis for this, without necessarily needing to adopt everything in it, and with the knowledge that it will need to be extended here and there.
- Support for explicit relationships between entities.
- Support for variations in representations. Since these are uni-directional an object may be defined by one parent application, which derives from each design change other child representations, which are read-only for the other applications of the system.
- Support for multifacetedness, so an entity can be part of multiple taxonomies or other data structures.

Furthermore, there is a feature that, very strictly speaking, is not minimally required, but which could be extremely useful in practice: that of support for *functions*, in addition to *data*. A function is a procedure, a subroutine, a piece of processing software that can be called by all connected applications, implemented as DLL, API or Remote Procedure Call (RPC<sup>6</sup>). The advantage of such a tool has been discussed in Koelman et al. (2015), under the name "request/reply".

Finally, there are some desirable features that are not strictly necessary, but could prove to be useful:

- A tool for documenting the essence and properties of entities and relations. This may be done in a common text editor, typically Word, however, that is not the most user-friendly tool, and for the tabular and reference work at hand, its usefulness is even less. Preferably, the documentation tool is integrated with the data management tool because they both deal with data, structures and relations, either to be understood by a human or by the computer.
- Explicit support for data integrity and authorisation.
- Aspects of system performance, such as processing speed and limits in data sizes. However, this is considered to be self-evident, and it is a bit premature to start quantifying it at this point, but it should not be forgotten in the end.

The ambition of the SEUS project extends beyond the design and engineering phases, which means another similar endeavour to find the data model links for operational data and engineering. This phase is not included in the present paper

---

<sup>6</sup> [https://en.wikipedia.org/wiki/Remote\\_procedure\\_call](https://en.wikipedia.org/wiki/Remote_procedure_call)

although the approach can be applied to it in later stages of the project. In PDM terms, the focus of this paper extends to linking “as designed” and “as engineered” data models, with a potential to extend to “as build” and “as in operation”. Hence focusing now on the data models links, means applying later on a similar approach to digital twin platform solutions where different applications can form digital threads.

## A First Experiment with Graph Databases

Although it is possible to implement a shared data format that can represent the relations depicted in Figure 3 on the basis of XML or JSON, that would be a laborious undertaking, because every element would need its own GUID and relations would need to be expressed in those terms. It would require a lot of cooperation, extensive formal specifications as well as data validation. The resulting text files would be very substantial and difficult to interpret by human designers, so the advantage of it being in natural language text would diminish. An alternative to sharing data in files is to share a database.

A traditional relational database consists of tables of rows and columns, where each row represents one data entry, and each property of that entry sits in its dedicated column. This enforces the need for the data to be structured: each column contains only data of a particular type and meaning, and each entry in the table has the same number and types of properties. Relations between entries are encoded as a property containing a reference to another row, possibly in another table; this is called a foreign key. An example would be a table of users and a table of orders, where each order has a reference to a user that placed the order. This encodes a “one to many” relation, where a user can place multiple orders. To collect all orders that were placed by a particular user, the entire column must be searched for matches with the user’s key. Because foreign keys are subjected to the rigid structure of this database format, relational databases aren’t very well suited to model systems with many relations or arbitrary relations, such as social networks and financial systems.

A different type of database has emerged that allows modeling completely unstructured data, the so-called graph databases. Different approaches exist, but common to them all is that a graph database describes nodes of information and how various nodes connect to each other. As such, the term “graph” refers to topology and discrete mathematics, not graphics. Depending on the application, a graph database can yield higher performance than can a relational database, it can be easier to query and it gives more freedom in conceptualising a system. Another aspect that is gaining relevance is that a graph may be easier to train using AI than a collection of tables, because semantics are expressed more clearly.

It is important to note that in the end there it is not necessary to use a graph database. A graph database gives the freedom and flexibility that is important for solution exploration. If the experiment is successful, this will to some extent demonstrate that it is implementable. Preferably, there is a concept that can be filled in by the PLM software of the SEUS consortium partner Contact Software.

In early 2024, the popularity ranking site db-engines.com had 41 graph database management systems (graph DBMS) in its ranking, and 13 additional DBMS capable of representing graphs as secondary model. Many of these build on open-source implementations, with some of them offering additional commercial services, which are seen to be more attractive than purely commercial solutions. Without the desire or need to do an exhaustive evaluation of all of these, the following graph DBMS have been considered: Neo4j, NebulaGraph, Memgraph, ArangoDB, Redis, GraphDB and Virtuoso. We have installed and programmed against both Neo4j and ArangoDB, after which the latter came out as the more appropriate DBMS. ArangoDB is performance oriented with features that allow some structuring of the data where that is desired. Nodes and edges in the graph are functionally equivalent to JSON documents, which can include arrays. Relations between nodes can be encoded as edges, which are just like nodes but with mandatory “from” and “to” properties containing node identifications. Edges allow the application of typical graph algorithms such as “shortest path” and facilitate validity guarantees that prevent dangling edges. Alternatively, relations may be encoded by having references as a property of the nodes themselves. In this way, ArangoDB offers a mix between graph database and document store.

Thus, an experiment has commenced representing the case depicted in Figure 3, using ArangoDB. The source code of the experiment is publicly available on GitHub<sup>7</sup>. Communication between the DBMS and the client program happens over HTTP. This allows the database and the client to be at different geographical locations, which is how the experiment was developed. Also included is an option to run the experiment in a Docker container, which simplifies reproduction and demonstrates that network overhead can be reduced when everything runs on the same hardware. In this case the reduction was 60 milliseconds, to under ten milliseconds per query. Evaluation of processing speed at scale is not part of this initial

---

<sup>7</sup> <https://github.com/seus-project/graphexperiment>

experiment, but increasing the size of the graph to one million nodes meant the slowdown was measurable but not significant. The VelocityPack binary transport<sup>8</sup> was not utilised, which has the potential to increase throughput.

The main question that this experiment tried to address is how the data of the design model can be sensibly organised in a graph database. It was noted that not all required functionality had to be covered by the database as such, because rules and logic in the governing applications can guarantee database consistency. As the database was not filled directly by an unauthorized system or human, nonsensical relations should in practice be prevented. Similarly, aspects of authorization can be handled by applications.

Figure 5: Bulkhead representation.

Considering the viewpoint of the applications, the ship model can be simplified by only considering bulkheads. For design software, a bulkhead primarily defines the partition of space and thereby determines the volumes of compartments. For engineering software, a bulkhead is primarily a structural object. The objective of the experiment was to allow both design and engineering software to work on the same bulkheads without getting in the way of each other. The approach that this experiment took (Figure 5) is to start with a node that represents the abstract concept of a bulkhead, by only containing its identity. Connected to it are separate nodes that represent specializations for design and engineering. This principle is scalable to additional systems, such as cost estimation, construction process logistics and maintenance.

Each specialisation contains properties that are specific to that specialization and can also extend the graph with nodes that are specific for that representation, as is shown in Figure 6.

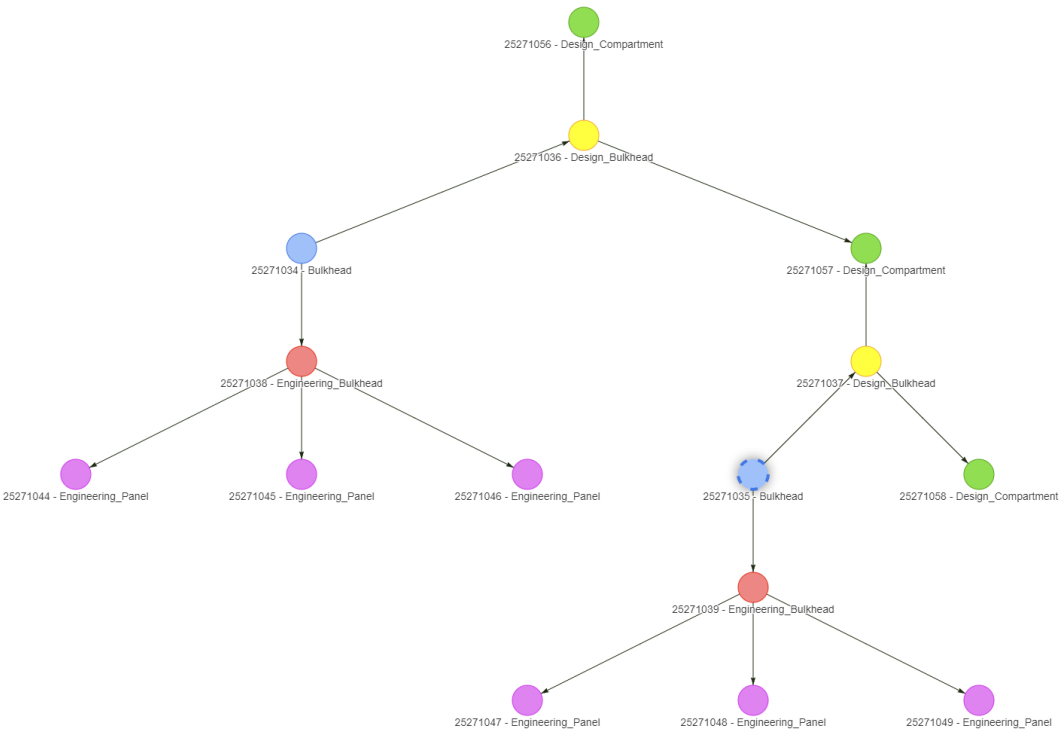

Figure 6: Automatically generated plot of a graph database with two bulkheads and three panels per bulkhead.

<sup>8</sup> <https://github.com/arangodb/velocystream>

The source code for the experiment contained a procedure<sup>9</sup> that synthetically generated data for a given number of bulkheads, where each bulkhead consists of a given number of panels on the engineering side of the graph, and on the design side of the graph the boundaries of compartments are defined. Figure 6 shows the nodes and connections for two bulkheads, three compartments and six panels. The connections are directional, but they can be traversed in any direction. The following lines of ArangoDB Query Language (AQL) are an excerpt of the source code that traverses the graph and lists the compartment names together with the positions of their bounding bulkheads:

```
FOR c IN Design_Compartment
  FOR db IN INBOUND c Design_BulkheadAdjacentCompartment
    RETURN [ c.name, db.position ]
```

The experiment demonstrated how the output changed when one of the bulkheads was moved to a new position.

In practice, the possibilities of extending the graph with additional information are endless. The design software could include constraints from the constraint management system (see De Koningh et al. (2011)), and any other model data that is currently stored in separate files. The engineering software can store the panel data, such as identification number, dimensions, and position in relation to the appropriate local coordinate system, and connections to other nodes representing other parts and production details. Even versioning can be implemented as part of the graph, where properties of nodes aren't simply updated, but a new version of the complete node is pushed on top of a stack of node versions, where edges between the versions contain the date of the change, approval by superior, etcetera.

In principle, the complete graph is traversable by both engineering client and design client. For example, when the engineering software needs the position of a bulkhead, it could locate the abstract bulkhead, traverse to the corresponding design bulkhead, and read out the position from there. But this requires the engineering software to have knowledge of the topology of the design side of the graph, and it also means that the developers of the design software cannot change their side of the graph without coordinating this with the developers of the engineering software. Interestingly, ArangoDB allows for the installation of so-called Foxx microservices, that can be used to provide a stable API for querying potentially dynamic subgraphs. A Foxx microservice is essentially a snippet of JavaScript that can be uploaded to the graph DBMS after which it can be accessed at a specific URL. When a client accesses that URL, the code in the microservice is executed inside of the DBMS, and the resulting data is returned. Among other things, a microservice can perform a graph query. This way, the developers of a particular system are free to change the layout of their side of the graph if they adapt their microservices accordingly, and other systems can continue using them without change, coordination, or synchronisation.

The experiment demonstrates that with 22 lines of JavaScript<sup>10</sup>, a microservice can be implemented by which the position of a bulkhead can be queried by name: thus, `http://localhost:8529/_db/seus/bulkhead_position/B1` produces the output `[10]`. ArangoDB's HTTP API follows the OpenAPI specification and is integrated with Swagger 2.0, meaning that the database server serves its own API documentation together with a web form where the API can be tested interactively. This functionality also covers the microservices. So, the microservice can include documentation that the returned value is the longitudinal distance in metres between the aft surface of the bulkhead and the aft perpendicular, with positive values meaning forward, and negative values aft, of the aft perpendicular.

A microservice can also contain additional logic. Thus the weight of a bulkhead does not need to be a discrete property stored in the engineering representation of a bulkhead, but a value that is determined dynamically, by a microservice. In an early stage of the design, the structure of a bulkhead might still be undetermined, meaning that there are no nodes connected to it that represent panels and stiffeners. In that case, the microservice could return an estimated weight, possibly with a low level of confidence. But as soon as panels have been defined, the plate thickness and dimensions known, the material known, and the stiffeners have been defined, then the weight can be calculated with a high level of confidence. When the weight of a module is requested, the microservice can recurse into all the parts that make up the module and accumulate the weights of the parts.

What is concluded from this experiment is that a graph database has great potential in the implementation of a shared data model. Flexibility and scalability is offered by a graph database, and the extensibility with microservices addresses to some degree the need for documentation (taxonomy) and RPCs. Whether the ship design department and the engineering department are working on the same model in different geographical locations, or all systems are run on the same computer, the HTTP interface of the DBMS means that it is applicable in either situation.

## SEUS' DATA MODELS

The purpose of this section is to conceptualise the model of data, relations and services from SEUS. Prior to that the existing data models of the design and engineering software suites are sketched out.

### The pre-existing data model of the design software

The basis of the ship design data model is formed by the hull shape, which can have two representations. The most complete is a solid model with closed curved surfaces, in proprietary H-Rep representation, see Koelman (2003). Another contains a wireframe, i.e. cross sections and stem/stern & deck contours, which is sufficient for all computations. The solid/surface model is convertible to PIAS' wireframe, and to IGES, NURBS surface and IGES/DXF 3D curves. The wireframe model can be converted to solid/surface, albeit with human assistance.

The space inside the hull is filled with constituting planes (bulkheads and decks) and compartments (tanks and other spaces), which form a duality: planes shape compartments, while spaces are bounded by planes. This duality is modelled by a proprietary method (see De Koningh et al. (2011)), which is based on Binary Space Partitioning (BSP). These constituting planes divide the internal of the ship hull into convex spaces, which are called subcompartments. Multiple subcompartments can be assigned to be part of a compartment. In this structure the spaces are 'logical' building blocks, while the compartments are physical, i.e. they are watertight. A finer subdivision may be obtained when non-constituting planes are also taken into account; these are not explicitly modelled, however their presence can be effectuated by modelling subcompartments by their corner vertices, typically, but not limited to, eight. These two compartment modelling methods can be mixed, and an average PIAS user applies the plane-based method for larger, systemic, subdivision planes, and the vertices-based method for smaller tanks or voids. Regardless which of the two modelling methods has been used, the final compartment shape is computed by an intersection with the ship's hull. Although this shape is the core property of a compartment, other properties are also stored, such as its name, permeability, design density, location and type of external openings, and location and shape of the sounding pipe(s).

From the viewpoint of hydrostatic and (damage) stability the connections from and to compartments — such as by pipes, internal openings and ducts — are as equally important as their shapes. This forms an integral part of PIAS' data model, but as this is already a topic of another paper on this conference, Koelman (2024), it is not discussed further here.

This comprises more or less the geometrical and topological ship design data, which are shared in many stages of design and engineering. However, an accurate prediction of all kinds of technical properties — such as draught, cargo capacity, power consumption, stability and strength — also depends on the ship's weight and its distribution. Obviously, PIAS supports this, basically with a long list of numbers of components, their weights, three spatial coordinates, and their aft and forward boundaries.

The 'design' software is not only applied during the ship design phase, but also to produce simulation and delivery documents. These include tables of tank capacity, assessment of (damage) stability, longitudinal strength and maneuvering characteristics. Such reports are currently exported to ASCII, XML or Word formats, although many of these computations can be offered in an RPC fashion.

Furthermore, all entities can be equipped with a Virtual Persistent Identifier, possibly a GUID, a concept that has attracted our attention before. This uniquely and permanently identifies an object, which facilitates tracking and processing changes.

### The pre-existing data model of the engineering software

The data model of CADMATIC Hull is based on relationships, which directly support the requirement that any change in shape or position will directly affect another element and provide a chain reaction to others. In addition, standards such as end shapes, holes, cutouts, lugs are included as a feature and not as their shape; and its form is recorded in a referenced library. The body and thickness directions are also assigned as a parameter of the object and therefore the CL and reversed frame have a direct influence on the final 2D and 3D presentations. A group of elements (plates and profiles) are recorded as a whole in a sub-database and this part is linked to a parameterised grid definition which also indicates the x, y and z directions or a plane definition defined as a surface. The whole (the ship) is a collection of these sub-databases, which can be flexibly exchanged, this approach facilitates simultaneous work in large models and possibility to replicate database of the project for several physical servers to provide seamless experience for remote work teams and users. This is the basis of the Hull application, from which all presentations are derived, such as 2D cross-sections, 3D views, derived information, such as

weight, length and material, and production data, such as cutting, robot and bending data. All objects have their unique GUIDs, which are used as a link for all relationships.

The CADMATIC applications are Hull, P&ID, Plant Modeller and Piping Isometrics & Spools. All the components, parts, symbols, and design instructions are stored and managed in Library & Project Databases. These databases also include the format control for sheets, listings, and reports. All applications use the same database, ensuring the information remains the same throughout the design project. Access is governed by the COS (CADMATIC Object Storage, see Figure 7) environment, where data is protected from being modified at multiple sites at the same time. Therefore, remote design teams can work in distributed projects using a common model database without conflicts. Projects are split into blocks, general project data, hull line subsets and 2D symbols, and these can all be saved to the COS server separately. In P&ID, the designer describes the process schematically in 2D format using predefined symbols and metadata information. In Plant Modeller and Piping Isometrics & Spools the process diagram is rebuilt in a 3D format to describe the ship in a realistic way using pipes, fittings, equipment, structural components, etc.

While different applications work in a slightly different way, depending on the discipline they serve, the overall project data is consolidated in the COS database. CADMATIC represents so called “intent-driven” CAD solution, which focuses primarily on the shipbuilding nature of the designer’s work, see Dush et al. (2017). Each application has their own API to serve the needs of particular integrations for design disciplines, while COS Web API serves the needs of integration with overall project data.

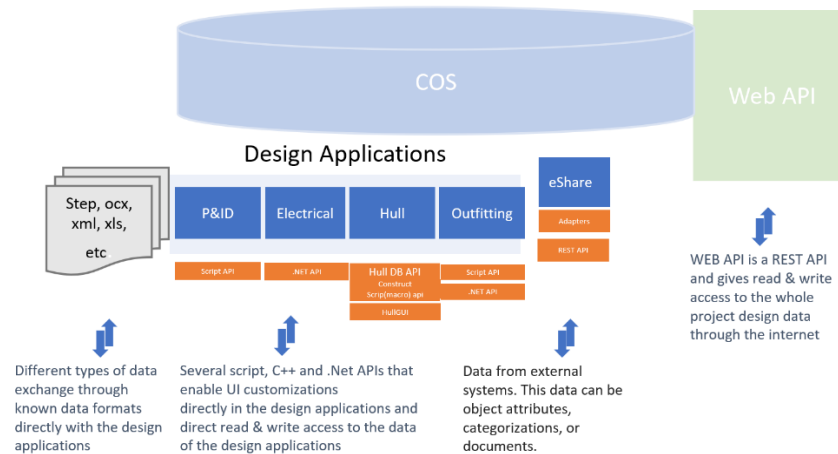

Figure 7: CADMATIC Object Storage structure.

## A sketch of the SEUS service warehouse

As a learned lesson, it is worth reflecting on a prior CADMATIC – PIAS interface, see Koelman et al. (2015), which comprised a) direct communication over TCP/IP instead of a shared database, b) data synchronisation on demand, rather than continuously and c) exchange of high-level data entities, based on STEP semantics, which means that in essence the deepest data representations were not shared. For example, both systems had a notion of *deck*, which was shared, while the underlying representation differed quite radically. As such, that software collaboration was impressive to see; with two windows open, showing the same model in the two distinct applications, with one press of a button the changes from one was transferred to the other. Nevertheless, the direct TCP/IP communication had one drawback: the lack of a central permanent storage; if one of the applications was not connected the *synchronisation actions* from the other vaporized. This conclusion, combined with the other analyses and experiments in this paper, led to an envisioned SEUS warehouse with the following functions and services:

1. Storage of data and their relationships are extendable, offering varying Levels of Detail, and multiple facets (i.e. the entities can be part of multiple taxonomies, each of a different kind and with a different purpose).
2. With data semantics based on the maritime STEP application protocols, extended where required.
3. Should this come down to a dictionary, then preferably some integrated documentation system for human use is required.
4. There is easy communication by API or RPC with this storage system, including systems of varying types, such as high-level programming languages and scripting tools.
5. It is extended with a set of system-wide services, among which there is conversion of data representations.
6. Control of access of the data is possible.

To underline that this is not limited to data, this is called a *service warehouse*, in analogy with a physical warehouse, where services are also provided, with or around the goods.

However, the world is littered with abstract plans and grand designs from the past, so how can the feasibility of this SEUS service warehouse be assessed? The first two items combined have been a bottleneck for many years, but the experiment described in this paper suggests that solutions exist. It is now time to sharpen this choice by also involving considerations around SEUS project strategy, involved effort, costs and other aspects of licencing of supporting software. At present how existing software solutions can satisfy the third and fourth requirement is being investigated.

Finally, a word on the *modus operandi* with this service warehouse. It will be obvious that the design and engineering programmes will not be using the service warehouse, so synchronisation between the internal representations and the service warehouse will be required from time to time. The question as to whether this is done automatically (at certain time intervals), or at the instigation of the user, or even restricted to authorised users, is a practical one that it is considered can be answered later. There may be a setting for this if necessary.

## CONCLUSIONS

In this paper the background, requirements and desires for the integration of design and engineering shipbuilding program suites have been sketched. After a survey of maritime data standards, it was concluded that none of these are directly applicable for our purposes, mainly because they do not support the inherent multifacetedness of the design and engineering data. The recently emerged category of *graph databases* might perhaps fill this gap, and as a first investigation a practical implementation with a set of bulkheads and compartments has been created and evaluated. The results look quite promising, although non-technical aspects, such as licensing and costs, have not yet been considered. Anyway, these experiments, combined with an analysis of the existing data models of SEUS' design and engineering applications, led to a sketch design of SEUS' central *service warehouse*. The considerations and experiments have shown that viable tools and methods exist to solve significant software integration aspects. Future steps in the SEUS development are intended to be:

- Exploration of attractive alternatives for the functionality offered by graph databases.
- Addressing the integrated support for RPCs.
- The management of the (STEP-based) dictionary, or, alternatively, the integration of dictionary and warehouse software implementation.
- The development of a second demonstration case, with piping, associated components and their connections to equipment and compartments.

## ABSTRACT

*In this study, we developed a method to simplify the analysis of complex Piping and Instrumentation Diagrams (P&IDs) on ships. By converting P&IDs into a graph format, we extracted lines and symbols from the original DXF files, enabling easier identification of connections between ship systems. Utilizing the graph, we can intuitively understand complex P&ID and easily apply it to research such as pipe routing optimization. This approach enhances the understanding of ship systems and has potential applications in recommending similar systems within existing ships, streamlining the design and analysis process.*

## KEY WORDS

P&ID; Pattern Recognition; Deep Learning; Arrangement Design; Connection relationships Analysis

## INTRODUCTION

A piping and instrumentation diagram (P&ID) is a drawing that uses simple symbols to represent the connections of equipment and piping within systems on a ship. Understanding the connections within the P&ID is important for designers to comprehend the systems on the ship. However, this process is difficult because various systems on the ship are complexly connected. In addition, since the P&ID represents the connection relationships as a line, it is inconvenient to find and follow the connection lines between the equipment among many complex lines. Therefore, we proposed a method to analyze the existing P&ID by converting it into a graph. Lines and strings were extracted from the original P&ID in DXF (Drawing eXchange Format), and symbols were recognized using the connections between the extracted lines. We could identify their connections with the extracted lines and the recognized symbols and convert them into a graph. The converted graph can represent the complex connection relationships of P&ID in a simplified form. Using this, we can obtain connection relationships between equipment and utilize it for the pipe auto-routing. With the method proposed in this study, P&IDs can be automatically converted into a graph and utilized for various applications. This graph format is specialized for representing connection relationships; it can help with topological analysis, such as recommending similar systems within existing ships.

## THEORETICAL BACKGROUND

The P&ID targeted for recognition in this study has the form shown in Figure 1. There are various objects in a P&ID, such as pumps, valves, and instruments. Objects in the drawing are represented by symbols that briefly represent the characteristics of the equipment. These symbols are composed of basic elements such as lines and are difficult to recognize because they are relatively small compared to the large size of the drawing. Additionally, because the types of objects are very diverse and mixed

with strings containing information about the objects, it is not easy even for experts to check them. Therefore, research on recognizing or extracting specific objects from P&ID is being conducted in many fields. Table 1 shows a summary of related studies for recognizing various elements in drawings such as P&ID and the method proposed in this study.

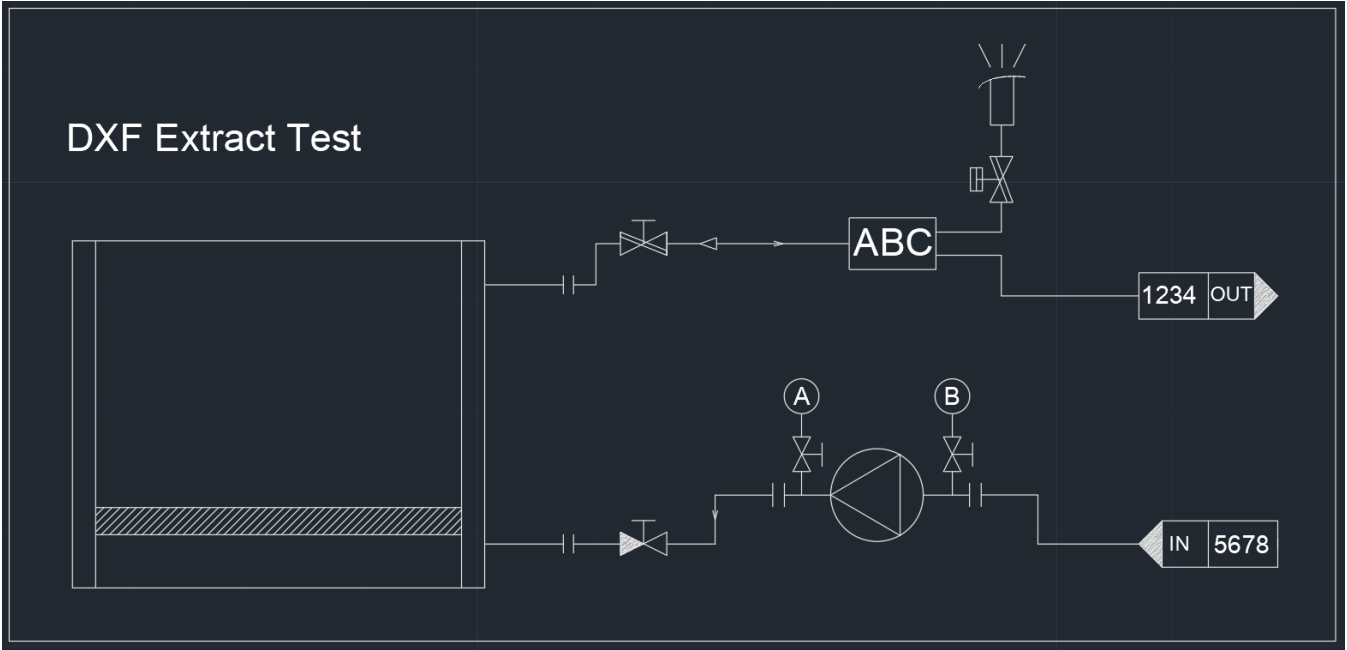

Figure 1: Example of P&ID (expressed briefly for security reasons)

Table 1: Summary of the related studies and comparison with this study

Studies	Application field	Recognition algorithms/model	Recognition target
Luo & Liu (2003)	Schematic	X	Schematic symbol
Yu et al. (2019)	P&ID	CNN (modified AlexNet)	P&ID symbol
Rahul et al. (2019)	P&ID	CPTN & FCN	P&ID symbol, text
WAN et al. (2019)	Mathematical formula	CNN	Math symbol
Kim et al. (2022)	P&ID	GFL, Tesseract	P&ID symbol, text
Moon et al. (2023)	P&ID	Modified hough transform	Line
This study	P&ID	Cascade R-CNN, DXF extraction tool	P&ID symbol, text, line, connection relation

As we can see from the table, there are two main ways to recognize objects in P&ID. The first method is to extract elements from a drawing and specify objects from their relationships. This method has the advantage of being able to accurately find an object under the condition that the drawing contains various information and can be extracted. Luo & Liu (2003) used a case-based recognition method to specify symbols from relationships such as points and lines. Additionally, Moon et al. (2023) used an image-based line recognition algorithm to find connecting lines in P&ID. Conversely, if the drawing is not created accurately and the creator makes a mistake when drawing some objects, there is a disadvantage in that the corresponding part cannot be found. In addition, the work process is complicated because users have to specify what the object looks like and find the corresponding characteristics.

The second method is a deep learning-based recognition method that has been popular recently. Convert the drawing into an image, and users directly label the objects they want to learn within the image. Afterward, a deep learning model for object recognition is built and trained to find objects in the image. Yu et al. (2019) and WAN et al. (2019) used a convolutional neural network (CNN) to recognize symbols in images. CNN is the most basic model among deep learning models for image recognition and is used to extract and classify image features using 2D images as input. Rahul et al. (2019) were able to extract more detailed features of equipment within P&ID by combining two deep learning-based object recognition models and text recognition models. In this method, because the deep learning model itself learns the characteristics of the object, there is a possibility of finding it well, even if there are slight errors or variations in the drawing. However, the disadvantage is that learning a deep learning model requires a large amount of data, and the user must label it. Therefore, it is crucial to understand the advantages and disadvantages of the two methods for recognizing objects within drawings in order to utilize them

appropriately. For example, Kim et al. (2022) were able to achieve more accurate recognition results by leveraging the strengths of both the Tesseract (Smith, 2007) model, which recognizes characters from extracted images in drawings, and a deep learning-based image recognition model. Therefore, in this study, these two methods were appropriately combined to select the optimal recognition method suited to the characteristics of objects in the drawing.

Another important piece of information that P&ID contains is the connection relationships. Objects in the drawing represent equipment, and the pipes connecting them are expressed as lines. Therefore, the user can check this and know how the equipment is connected by referring to the drawing. Humans can easily understand connections by following lines, but in order to automate this process, lines must be recognized accurately. There are many elements in a drawing that make it difficult to construct a recognition algorithm, such as lines representing objects and lines representing pipes being mixed and intersecting, with one line being cut off in the middle. In this study, information was extracted from a common drawing format called drawing interchange format (DXF), and connection lines were recognized through a preprocessing process.

If the equipment and connection relationships in the drawing are extracted through the above process, this information can be used to analyze the characteristics of the P&ID. In this study, the recognition results were converted into data using the concept of a graph. As shown in Figure 2, the graph is composed of nodes and edges, with nodes expressed as points and edges expressed as lines. We converted P&ID into a graph by representing equipment as nodes and connection relationships as edges. The converted graph is easy to analyze topology and connectivity because it excludes unnecessary elements and only has connections. Therefore, we proposed a method to convert P&ID into a graph automatically. As a result, this graph can be used for research, such as creating piping routes or analyzing similar systems.

Figure 2: Components of a graph

### APPLICATIONS

We used a deep learning model to recognize objects in P&ID. Deep learning allows us to find objects in drawings quickly; it is suitable for large-sized P&IDs. However, deep learning models require a large amount of training data. Because P&ID is large and contains various types of objects, the labeling process takes much time and labor. Therefore, we designed a model that can automatically generate training data. First, select an image that will become the background. At this time, several noises were added to the base image to increase the diversity of training data. Next, various objects are placed in random positions on the base. We called the placed objects as material. Material also went through the process of adding noise, such as rotation and scaling, to ensure diversity in the training data. The drawing created by this method is shown in Figure 3. Since we know where the materials are placed, we can automatically generate labeled data. Using this, we were able to generate a large amount of training data and train a deep-learning model for object recognition.

Figure 3: Example of the generated training data

Two-stage models generally showed better accuracy than one-stage models when recognizing objects in drawings (Kong et al., 2022). In this study, we used a two-stage CNN model called Cascade R-CNN (Cai & Vasconcelos, 2018) as a deep learning model to recognize objects. This model is known to have a high recognition rate for multiple overlapping objects. As shown in Table 2, we trained several two-stage models to find 26 types of objects and measured recognition accuracy on 11 actual drawings. Each model was trained using the same 120,000 pieces of virtually generated data. We trained the models using RTX 4070 Ti in a Windows 10 environment, and each parameter used the default values of each model. As a result, Cascade R-CNN showed the best performance among them. It took an average of 90 seconds to recognize each drawing, and most objects were recognized with F1-score=0.9863. Figure 4 shows some of the results of object recognition with the Cascade R-CNN model. We confirmed that the types, sizes, and locations of objects in the P&ID were accurately recognized.

**Table 2: Accuracy analysis between the detection models**

	Cascade R-CNN	Faster R-CNN	Sparse R-CNN
Elapsed time (s)	90	89	94
Precision (%)	99.29	97.19	96.06
Recall (%)	97.99	98.63	45.83
F1-score (%)	98.63	97.88	58.11

**Figure 4: Example of P&ID recognition results with Cascade R-CNN model (text blurred for security reasons)**

Deep learning models have the advantage of recognizing objects with distinct features, but they are known to have relative difficulty in recognizing simple elements such as lines. Therefore, we devised a method to extract lines directly from the drawing and preprocess them to find connecting lines between objects.

The DXF format converts drawings created with a computer-aided design (CAD) program into a highly compatible format. Elements that can be extracted from the DXF format include lines and strings. Figure 5 shows the types of elements that can be extracted from the DXF format. We analyzed the extractable elements and extracted only the lines representing the connecting lines. Lines extracted from the DXF format have both their start and end points. By using these, line elements in the object recognition results can be removed.

Furthermore, by sequentially linking the end points from the line connected to the object, a connecting line can be identified (Figure 6). Combining this result with the object recognition result is shown in Figure 7 (a). Since each extracted line has a starting point and an ending point, connecting lines between objects can be found by continuously extracting adjacent lines based on these points. As a result, it is possible to find all connections within the drawing, shown in Figure 7 (b). This result can again be expressed in graph form, as shown in Figure 7 (c).

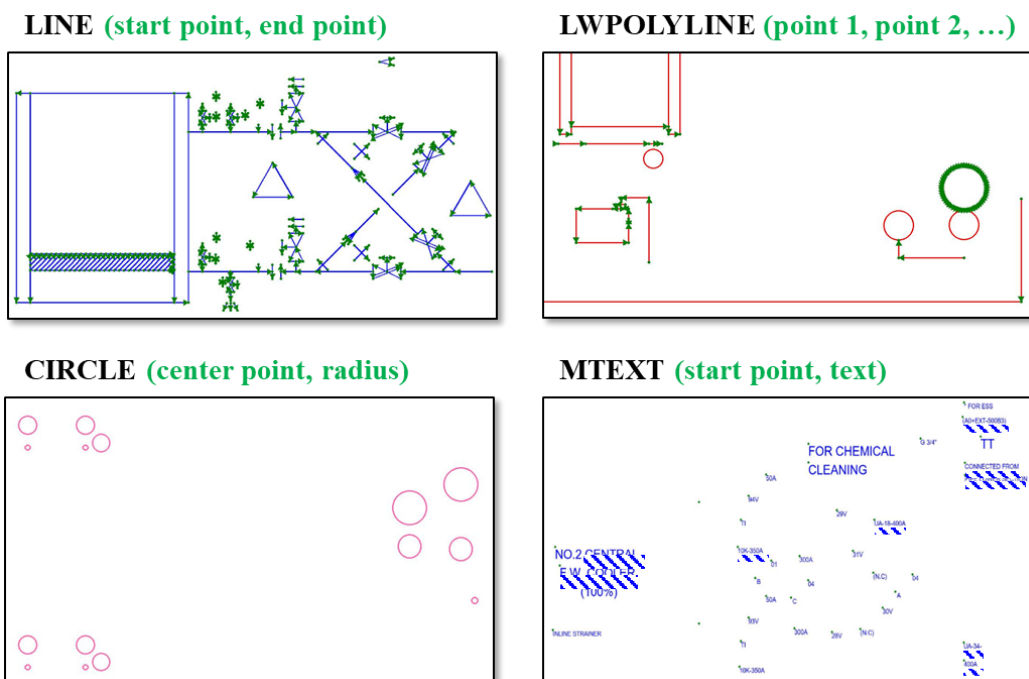

Figure 5: Examples of elements that can be extracted from files in the DXF format (text blurred for security reasons)

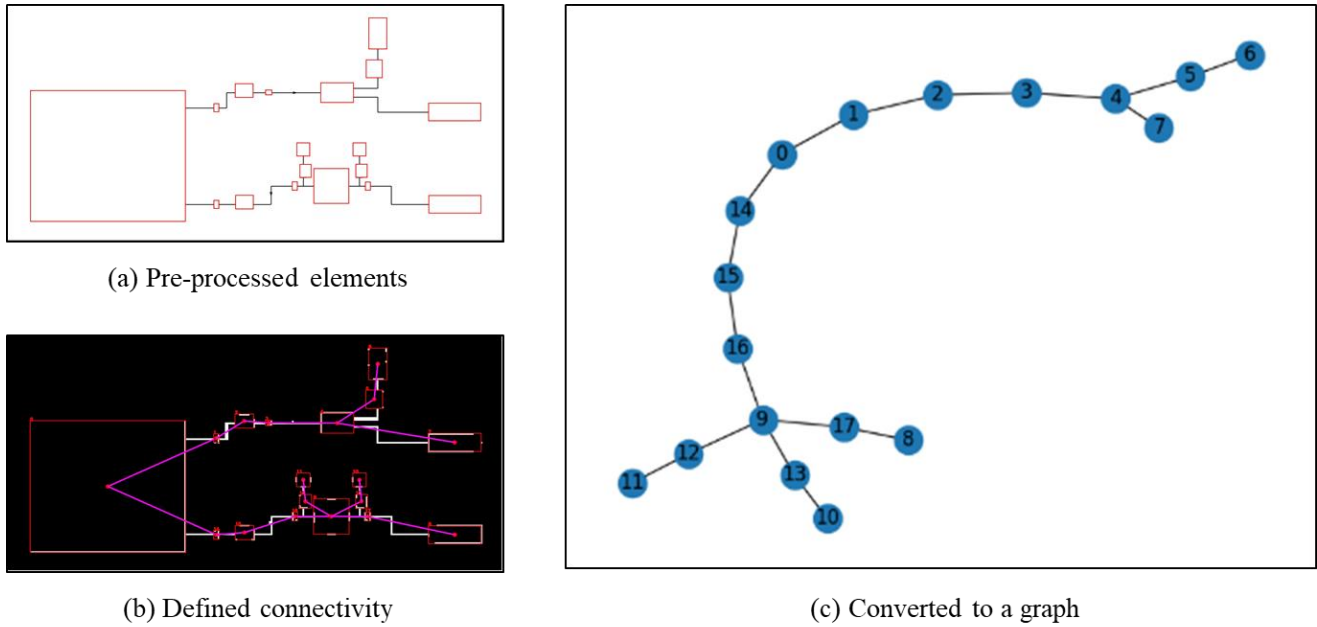

Figure 6: Process of obtaining connection relationships between objects using extracted line elements

**Figure 7: Conversion process of the P&ID to a graph (expressed briefly for security reasons)**

As mentioned above, P&ID represents the connection relationships between equipment in the form of a line. When the P&ID is converted into a graph form, we can use the connection relationships of the graph to check how the pipe is connected between each equipment. Each piece of equipment has a specific location for the part connected to the pipe, that is, the nozzle. Therefore, if we only determine the location of each equipment, we can automatically create pipes utilizing the graph. Even if they look like different P&IDs, if the recognized graph (so-called pattern) is the same, they can be considered the same system.

Ha et al. (2023) established measures for evaluating layouts of pipe by quantifying the expertise of professionals and, based on this, devised an algorithm to generate the optimal pipe routes. Utilizing this study, we designed a method that automatically creates pipes from the connection relationships of each piece of equipment. Figure 8 shows the results of creating pipe routes by adding the locations of equipment based on the graph extracted from P&ID. In the eyes of humans, the two results may appear as different systems, but from a graph perspective, they represent the same system. Therefore, an analysis from a graph perspective is necessary to recognize the patterns inherent in P&IDs.

**Figure 8: Results of creating different pipe routes from the same P&ID**

Moreover, through the proposed process, we can convert many P&IDs into a graph form and train a deep learning model on the graph structure itself. In the future, we can train a deep learning model with a graph neural net (GNN; Scarselli et al., 2009) structure and create a model that classifies which system the input graph is similar to the database. As a result, we plan to build an automated process that takes P&ID as input, finds objects, interprets connection relationships, converts them into a graph, and recommends the one most similar to the existing system.

## CONCLUSIONS

This study proposed an automated process for object recognition and connection relationships analysis targeting P&ID. P&ID consists of various objects such as pumps, valves, and instruments. So, precisely recognizing them is a difficult task. We trained the two-stage based CNN model with virtual images generated with our algorithm and were able to recognize objects in the drawing with high accuracy. Additionally, we extracted elements like lines or circles in the DXF format and obtained connection relationships between the recognized objects. We represented the results in a graph format. As a result, the proposed process could build an automated system. It receives P&ID as input, finds objects, and interprets the connection relationships. Then, it converts them into a graph and can be utilized in various studies. We applied the converted graph to the study for pipe auto-routing. Consequently, we confirmed that we could automatically place pipes by extracting the connection relationships between equipment from the P&ID. Due to the use of deep learning models and innovative application of training data generation methods, most objects were able to be recognized, and the characteristics of the system were successfully inferred through graph analysis.

We plan to convert more P&IDs into graphs and analyze additional features that can be learned from them. To confirm the practicality of the method proposed in this study, we must verify it on more diverse data. Additionally, the features of the converted graph must be labeled to train deep learning models in the future. We plan to research ways to create virtual data in DXF format, just as we created virtual data for object recognition. There are also many ways to utilize the graph, such as embedding the characteristics of each node and edge in addition to the characteristics of the structure itself used in this study. Therefore, we plan to investigate various possibilities that can be applied using the above process.

## ACKNOWLEDGEMENTS

This study is an extension of our previous study (Kong et al., 2023) and was partially supported by (a) HD Korea Shipbuilding & Offshore Engineering Co., Ltd., Republic of Korea, (b) BK21 Plus, Education & Research Center for Offshore Plant Engineers (COPE) of Seoul National University, Republic of Korea, and (c) Research Institute of Marine Systems Engineering of Seoul National University, Republic of Korea.

# System level simulation of the winter navigation in the Baltic Sea

Kujala Pentti<sup>1,2</sup>, Kulkarni Ketki<sup>1,3</sup>, Kondratenko Aleksandr<sup>1</sup>, Lu Liangliang<sup>1</sup>, Winberg Casper<sup>1</sup>, Li Fang<sup>4</sup>, and Musharraf Mashrura<sup>1</sup>

## ABSTRACT

*Efficient winter navigation has crucial importance for Finland as all Finnish harbors are icebound every winter. A winter navigation system level simulation tool has been developed to analyse the marine traffic in wintertime and to analyse the present and future need of icebreakers when both marine traffic patterns, ice-going ship characteristics and ice conditions will change. This paper summarises the basic principle of the tool and presents some recent applications together with the conducted verification and validation. The tool has been applied both in the northern part of the Baltic Sea and in the south to study the winter navigation system: on the Bay of Bothnia for Finnish marine traffic and the Gulf of Finland for Estonian marine traffic.*

## KEY WORDS

Maritime; Winter navigation; Simulation; System level; Icebreaking

## INTRODUCTION

The Baltic Sea holds significant socio-economic importance for the surrounding nations such as Finland, Estonia, and Sweden. It serves as a vital transportation route for goods, services, and passengers, while also supporting essential ecological systems. Ensuring the reliability and efficiency of maritime operations in this region is crucial. Particularly challenging is the winter season, when substantial portions of the northern Baltic Sea are covered with ice, a phenomenon that varies greatly from year to year in terms of extent. In response to these challenges and to facilitate safe and efficient navigation throughout the year, the Finnish-Swedish Winter Navigation System (FSWNS) has been implemented (Kulkarni et al., 2022, Trafi 2022).

Finland has more than 150 years' experience of winter navigation. The FSWNS system has been developed to guarantee safe and reliable shipping throughout the winter even though many of the Finnish harbours are ice-covered each winter. The system consists of three elements: ice-strengthened ships, icebreaker assistance, and traffic restrictions. The traffic restrictions ensure that only ships with some minimum size and ice class will get icebreaker assistance on the winter period and the harder the ice conditions the stricter will be the traffic restrictions. This is to guarantee that the icebreaker fleet is capable of offering the service required to keep the winter navigation operations safe and aiming for minimum waiting time for the merchant vessels. In order to ensure ships possess the necessary ice-going capabilities for safe and efficient operations, adherence to the Finnish–Swedish Ice Class Rules (FSICR) is imperative. (Trafi, 2022).

We have developed during the last 10 years a simulation tool to study the system level performance of the winter navigations in Finland (Lindeberg et al., 2015, 2018, Kulkarni et al., 2022a, Kulkarni et al., 2022b). The main aim of the tool development

has been to obtain a research-based prototype and decision-making aide that can be used to simulate the need of icebreakers as well as socio-economical and environmental impacts related to FSWNS in the future when both ice conditions, maritime traffic and characteristics of ice-strengthened ships will be under dynamic change. Climate change will affect the ice conditions so that the maximum ice thickness might decrease but the annual variations will be high and the ice movements can increase causing other type of challenges for the winter navigation system. Ship's size seems to increase and at the same time the new strict environment regulations will decrease the used engine power on ships. In efforts to curb Greenhouse Gas emissions from ships, the International Maritime Organization implemented the Energy Efficiency Design Index (EEDI) regulations in 2011 (EEDI, 2022). These regulations are geared towards promoting the adoption of highly energy-efficient solutions in maritime operations. While the focus is on reducing GHG emissions, the technical specifications of these regulations restrict the maximum propulsion power installed on ships and encourage the use of hull forms optimized for open water conditions. This will decrease dramatically the ice-going capabilities of these ships. All these aspects are included in the simulation tool.

The aim of this paper is to shortly describe the current status of the simulation tool. The main structure and elements of the tool will be described. In addition, some recent case studies with the tool will be summarized to demonstrate the extent of its application: a) Validation of the tool, b) Optimization of icebreaker assistance for sustainable shipping and c) Analysis of the icebreaker needs in Estonia.

## DESCRIPTION OF THE TOOL

### General description of the tool

The objective of the tool remains as described above: to simulate the FSWNS performance across a range of potential operating scenarios, aiding decision-making regarding its operation and development, including considerations like icebreaking resources and ice class regulations. To achieve this, the tool is designed to replicate winter traffic patterns under various operating conditions, incorporating elements such as icebreaker scheduling and directed pathway adjustments. Icebreaker scheduling involves determining the number of icebreakers available each day, their initial positions, and their designated operational areas. Additionally, mathematical modeling is employed at the ship level to capture individual vessel interactions with ice conditions and their impact on overall traffic flow. Vessel speeds under different ice conditions, such as convoys and towing, are calculated using closed-form expressions. The proposed tool enables users to assess how the FSWNS would perform under different hypothetical scenarios, enhancing understanding of the system's behavior. This project aims to combine the strengths of simulation modeling with the expertise of maritime professionals. Figure 1 illustrates a schematic block diagram of the simulation tool. (Kulkarni et al., 2022a)

**Figure 1: Simulation tool structure (Kulkarni et al., 2022a)**

The simulation tool incorporates a hybrid approach, utilizing discrete-event and agent-based simulation techniques along with process flow modeling. This selection of modeling methodologies enables the visualization of simulation processes and outcomes, as well as the integration of stochastic elements. Individual components within the FSWNS, e.g., merchant ships, icebreakers, and ports, are represented using an agent-based framework, which includes detailed decision-making processes. Each component, whether a merchant ships or icebreaker, faces numerous decisions throughout the winter season, responding to changing situations. The decision process for each component is governed by a series of rules presented in an if-then-else format, dictating adjustments to direction, speed, and operational mode according to system parameters. Moreover, an optimization logic is employed for icebreakers to determine the most effective ways for assisting vessels. (Kulkarni et al, 2022a).

The tool is designed to be utilized by domain experts, serving as a complement to their expertise rather than functioning as a standalone solution. Experts provide crucial details regarding resource availability (such as the available icebreakers and operational ports on a specific day) and other scenario specifics not available from existing data sources. The model inputs encompass vessel particulars, including dimensions of ships and coefficients of hv curve (abbreviation for the ice thickness vs ship's speed), traffic patterns, and ice conditions. The inputs are processed to derive formula for vessel and icebreaker speed variations, trip parameters (origin, destination, departure time), daily ice conditions, and dirway locations (dirway defines the ship path through ice). Traffic data are obtained through the processing of AIS (Automatic Identification System) data, which serves as essential input to the simulation model. At its core, the simulation engine incorporates agent-based models to replicate entity behaviors, discrete-event models to emulate both scheduled and random occurrences, and process flow models to depict the movements of vessels and icebreakers at sea and within ports. It also includes visualization functionalities, such as a color-coded scheme that illustrates different ice thicknesses, with darker hues of blue representing thicker ice layers. The primary simulation output is a visualization of traffic flows illustrating vessel movements across evolving dirways towards destinations see Figure 2. Vessel speeds adjust according to ice conditions along their routes, while icebreakers are observed assisting vessels unable to maintain speeds above a specified threshold. Following the simulation's completion, a Key Performance Index (KPI) referred to as the average waiting time is generated. These results are then presented to the domain expert, who serves as the decision-maker, for potential adjustments to future configurations. Subsequently, the expert offers feedback to enhance the simulation tool iteratively. (Kulkarni et al., 2022a).

**Figure 2: Visualization of ice fields, dirways and ships on the Bay of Bothnia (Kulkarni et al., 2022a)**

### Definition of ice conditions

To accurately depict the complexities of winter navigation, it is crucial to include ice conditions with precision. Ice data encompasses various aspects like thickness, concentration, and topography, typically sourced from Finnish Meteorological Institute (FMI) ice charts. However, this data originates from diverse sources, necessitating the integration of multiple file formats to compile a comprehensive view of ice conditions. Furthermore, ice data is dynamic, with updates available hourly for each geographical grid. To facilitate integration into the model, this information undergoes suitable aggregation to balance detail with computational efficiency.

In the simulation, vessels must be responsive to these dynamic ice conditions, adjusting speeds or halting. This necessitates that vessels can continually understand ice information and adapt behavior throughout a journey. To achieve this, concepts like equivalent ice thickness and HV curves are employed. Equivalent ice thickness utilizes a mathematical formula to derive a single value representing ice thickness, incorporating factors such as concentration, thickness, and topography. This approach enables vessels in the simulation to effectively gauge and respond to changing ice conditions as they navigate. The formula given by Lindeberg et al. (2018) is used in the model for obtaining the equivalent ice thickness (Kulkarni et al., 2022a).

Given that ice conditions can vary daily, they can significantly impact routing decisions. Actual ice data is employed to compute the equivalent ice thickness, which is derived from averaging the ice volume within a grid. These ice data sets are updated on a daily basis, but the frequency of updates can be adjusted as needed. The equivalent ice thickness definition may vary depending on the available ice data. In this study, equivalent ice thickness is calculated as the product of concentration and thickness to maintain volume equivalence based on NetCDF data (Milakovic et al., 2020). The equations are similar to those used in Lindberg et al. (2018). For more information, readers are pointed to Sormunen et al. (2018).

## Evaluation of ship performance in ice

The vessels simulated in the model must be responsive to fluctuations in ice conditions, adjusting their speeds accordingly or even halting when necessary. Each vessel is assigned an hv curve profile tailored to its dimensions, with Aker Arctic having developed numerous such curves for typical ice-capable ships as part of project Winmos I/Winmos II (2021). These hv curves are incorporated into the model as entity attributes, governing speed adjustments based on equivalent ice thickness. Each vessel is assigned an hv curve code. This code allows the vessel to reference the pertinent hv curve information during simulation runs. The expressions in level ice ( $v_l$ ) and in the convoy (travel at a distance following an icebreaker) condition ( $v_d$ ) to obtain ship speeds are provided in equations (1) and (2):

$$v_l = a_l h^3 + b_l h^2 + c_l h + v_{ow} \quad [1]$$

$$v_d = a_d h^3 + b_d h^2 + c_d h + v_{ow} \quad [2]$$

In the given equations, the symbol  $h$  represents the equivalent ice thickness, while the coefficients  $a$ ,  $b$ , and  $c$  denote the parameters defining the relevant ship speed in the ice condition, and  $w$  signifies the speed in open water. Table 1 illustrates a standard array of coefficients for an hv curve.

**Table 1: Example of hv curve coefficients**

Hv Ship	Vow [kn]	$a_l$	$b_l$	$c_l$	$a_d$	$b_d$	$c_d$
Example	15	-199.84	210.24	-87.997	-0.1658	1.5976	-7.4582

The polynomial expressions of two representative hv curves are depicted in Figure 3. It is notable from both plots that the open water speed is maintained at 15 kn. In Figure 3A, it is evident that the speed decreases swiftly with escalating ice thickness, approaching nearly 0 kn at approximately 0.4 m. Conversely, Figure 3B illustrates that speeds can be sustained up to 9 kn for ice thicknesses ranging from 0.4 m to 1 m when in convoy.

**Figure 3: Example of h-v curves. (A) Vessel in level ice; (B) Vessel in convoy. (Kulkarni et al., 2022a)**

The equivalent level ice thickness approach is used to make the simulation tool development systematic and easy to adapt. However, determination of equivalent level ice thickness is not straight forward process as various ice conditions require totally different approaches, as reviewed by Milaković et al., (2020). For ridged ice, one approach used is to estimate the relative increase of level ice thickness based on the density of the ridges. The values used in the model are as follows: rafted ice + 7.5%, slightly ridged ice + 22.5%, ridged ice + 60%, and heavily ridged ice + 105% increase (Lindeberg et al., 2018). For floe ice with varying concentration no good methods exist so far to determine the equivalent level ice thickness.

In Aalto University, the latest development has been related to the topic: how to evaluate the ship resistance and hv curves on two different important cases: 1) The effect of vessel breadth on the resistance during escort and 2) The effect of closing channel and compressive ice on the resistance. Li et al. (2021) conducted thorough investigations on the characteristics of the hv curves in what is termed a 'narrow ice channel.' In scenarios involving escort and convoy operations, an icebreaker creates a passageway while accompanying ships trail along this designated path. However, if the width of the assisted ship exceeds that of the channel formed by the icebreaker, the created pathway becomes insufficient for the assisted ship. Consequently, the assisted ship must independently break through some ice. This situation is denoted as navigation in a 'narrow ice channel.' To address this, a model-scale test was initially carried out, simulating a ship navigating through ice channels with varying widths

and ice thicknesses. Subsequently, numerical simulations of the model test scenarios were executed using an in-house simulation program specifically designed for ship operations in icy conditions. The simulation accurately captured the primary aspects of changes in ship resistance relative to channel width, validating its efficacy as a simulation tool. Further numerical simulations were then conducted with various other ships to gain comprehensive insights into ship performance in narrow ice channels. Emphasis was placed on evaluating the impact of channel width on ships' encountered resistance and achievable speed in icy conditions. Figure 4 illustrates an example of the obtained curves, with the parameter  $\gamma$  representing the relative breadth of the channel compared to the ship breadth. For instance,  $\gamma=0.25$  indicates that the channel width is 25% of the vessel breadth. When  $\gamma=0$ , the scenario corresponds to breaking level ice, and with  $\gamma=1.0$ , the ship navigates in a channel with a width equal to the ship's breadth. An illustrative example is the Agulhas II, a ship with ice class PC 5, constructed in RMC for South Africa to operate in Antarctica's icy conditions.

The other case stated above, i.e. the closing channel due to the moving ice, has been studied by Lu et al., (2023). The moving ice will close the channel in front of the ship causing increased resistance mainly due to increase of frictional forces at the straight midship part of the vessel. This will cause dramatic decrease of ship speed in ice, as shown in Figure 5. The curves represent various compressive ice conditions (different ice drift speeds). There are mainly three clusters. The first cluster follows the original level ice h-v trend. The second cluster is the ones drops quickest. The third is the ones between the two clusters. They show the transitions from no compression to compressive ice conditions, which can also be defined as 'critical ice speed'. After the 'critical ice speed' curve, the ship will totally follow the compressive ice clusters. In the critical ice speed, h-v curve also demonstrate 'up and down' feature which is affected by relative relationship between the broken ice cusps and ship speed. The ice movement is caused by the high wind and therefore the wind speed and direction on the navigation area should also be known before this can be included in our simulation tool and that development is still on-going.

**Figure 4: Example of h-v curves for narrow channel. Ice thickness is made non-dimensional by dividing it with the maximum level icebreaking capability of the ship and ship speed is relative to the open water speed. (Li et al. (2021))**

**Figure 5: Example of h-v curves for closing channel for MS Envik. Ship initial speed is 5 kn and  $v_i$  is the speed on the ice movement transversal to the ship movement. (Lu et al. (2023))**

## Icebreaker decision making

The pathways navigated by vessels, termed dirways, constitute an integral part of the model. Dirways are established by icebreakers in ice-laden regions and are susceptible to alterations due to factors like wind, pressure, and evolving ice conditions. Another critical consideration involves the transition between dirways. As vessels traverse ongoing journeys on existing dirways, new journeys are concurrently scheduled on updated dirways. Icebreakers must effectively coordinate between the two sets of dirways until all traffic seamlessly transitions to the new routes. This dynamic process also impacts convoy formation and can influence system waiting times.

Vessel speeds fluctuate in alignment with their respective hv curves. If a vessel's speed falls below a predefined threshold, icebreaker assistance is solicited. Depending on the vessel's location, an appropriate icebreaker from the available fleet is selected. Convoys may form when multiple vessels require assistance in the same direction. The simulation concludes once all vessels have completed their scheduled journeys within the specified time frame. The operational area is divided into distinct operating zones, delineated based on prevailing ice conditions, which may evolve dynamically throughout the simulation. Each zone is ensured to have at least one icebreaker available. Icebreakers possess specific ice-going capabilities, modeled using hv curves akin to those employed for assisted ships (refer to Figure 3), with examples of icebreaker hv curves provided by Lindberg et al. (2018).

Despite being assigned specific zones, icebreakers frequently collaborate to make sure the safe and efficient operation of the entire system. Vessels often require assistance across different zones. Usually, one icebreaker leads a vessel through its designated operating zone, leaving the vessel at a secure stopping point known as a waypoint. The next icebreaker assumes responsibility for guiding the vessel further along its journey from there. However, icebreakers have the flexibility to operate beyond their designated zones to alleviate traffic congestion or assist larger vessels requiring dual icebreaker support. Icebreakers must dynamically make decisions regarding prioritizing vessel assistance, coordinating with other icebreakers, selecting paths, and organizing convoys. When a vessel becomes stopped in ice, it sends a distress signal to the icebreaker control unit, which may consist of an icebreaker with a coordinating captain or a decision-making unit on land. A free IB can also "predict that point. The different merchant vessel threshold speed to start the assistance is an input parameter in the tool. The responsible icebreaker calculates the vessel's potential route based on its current position and destination, identifying one or more icebreaker zones through which the vessel must navigate to reach its destination. A schedule is then devised for the vessel, updated each time it completes a zone. The initial icebreaker assigned to assist the vessel is dispatched to guide it to the end of its assigned zone or port if the port falls within the zone. At the conclusion of each zone, the vessel's route is reassessed as necessary, and the subsequent icebreaker is tasked with guiding it onward. A comprehensive list of requests for each icebreaker is maintained and updated as the vessel progresses from one zone to another. Once the vessel reaches a port, it is removed from all lists. This coordinated approach ensures the efficient movement of vessels through ice-covered waters. More detail description of the IB decision making can be found from Kulkarni et al. (2022a, 2022b).

## VERIFICATION AND VALIDATION OF THE TOOL

To ensure the model reliability and instill confidence in its functionalities, both verification and validation processes are essential. Verification entails assessing whether the model behavior reflect the conceptual description and specifications. On the other hand, validation assesses the extent to which the modelling represent the real world from the perspective of end users. Essentially, verification addresses the question: "Is the model right?", while validation addresses the question: "Is this the right model?". Both processes can be conducted at both the individual ship level and the system level, as elaborated below.

Several challenges exist in the validation of this simulation tool. Firstly, despite the extensive AIS dataset, organizing and processing the data to suit the simulation is a complex task that demands dedicated attention. Secondly, the majority of data originate from a single common source, which was utilized to construct the model. Therefore, there are presently no additional data available solely for testing purposes. Thirdly, conducting trials of the tool alongside existing icebreaker management methods necessitates obtaining extensive permissions, undergoing checks, and adhering to regulations. Consequently, various validation approaches have been adopted for the simulation tool, detailed in the subsequent validation sections.

### Verification

Field experts attended the demonstrations where the model was operated at a discernible pace. The KPIs included in this case are summarised next. They monitored vessel speeds across a localized area characterized by high ice variability to ensure their adaptation to changing ice conditions. Dirway alterations were also closely observed, with an expectation of changes occurring weekly throughout the runtime. Experts also examined waiting time averages at various ports and for all vessels collectively. Some of these experts had prior involvement in field assistance during the same timeframe. They corroborated that the Key

Performance Indicators (KPIs) obtained fell within acceptable ranges for the winter season, meaning less than 10% deviations. Moreover, the assistance numbers provided by each icebreaker was recorded and compared with reality (Kulkarni et al., 2022a).

### **Validation on a ship level**

The validation on a ship level has been done by Sormunen et al. (2018). The main idea of the validation was to compare the speed variation on varying ice conditions for the Bay of Bothnia for one ice breaker and for the Gulf of Finland for one Ro-Ro vessel during winter 2010. The voyage length was few hours for both cases. The results indicate that the difference between AIS data and simulation model was less for the icebreaker (varying from -31 % to 41 %) than for the Ro-Ro (varying from -71 % to 61 %).

In a recent study by Kulkarni et al. (2024), a comprehensive approach to ship performance modeling is introduced, encompassing various parameters including ice conditions, power variations, and icebreaker assistance. This approach undergoes validation against real ship voyages. The h-v curves delineate the breaking capabilities of candidate ships against level ice, with the paper summarizing the methodologies employed for handling ice ridges, variable ice concentration, and ice floe sizes. Real-world ice fields often exhibit greater complexity than level ice, with variations in ice floe size and ice field concentration, as well as the formation of ice ridges under pressure. Equivalent ice thickness serves as a convenient means to streamline intricate ice fields into a single level-ice thickness, facilitating speed determination via the corresponding h-v curve. To validate the approach of ship performance modeling, real ship voyages documented by Kujala and Sundel (1991) are utilized as validation cases. These voyages were logged onboard corresponding ships during their visits to Finnish ports. Various parameters, like actual ship speed and power, are recorded, while ice parameters including level ice thickness, ice concentration, ridge sail height, and floe size are obtained by visual observation. Additionally, the operation modes (e.g., independent operation or assistance) are noted. This comprehensive dataset offers insights into the actual voyages, enabling ship speed estimations using the proposed approach, which can then be compared against the actual speeds observed during the voyages. In total, 12 ship voyages are included with 10 different vessels, with the typical duration of each voyage spanning a few hours. Comparing the average speed from the simulation tool and from the real observations, the relative difference is varying from -47,5 % to +7,2%.

### **Validation of the traffic system**

For the traffic system in the simulation model, three different types of validations have been conducted:

- 1) Ship waiting times,
- 2) Ship arrival times,
- 3) Time used for each voyage.

These are described in future details next. Ship waiting time was validated by Lindberg et al. (2018) using the previous version of the tool, a deterministic simulation tool developed to analyze the performance of the FSWNS regarding the cumulative waiting time for icebreaker assistance under predefined operating conditions. Validation of the tool using real-world data suggests its reasonable accuracy. One month period from 15 January to 15 February on winter 2011 was used for the validation. A 1.7% margin was obtained to the average real life port waiting times based on AIS data.

Kulkarni et al. (2022a) validated the ship arrival times including winter traffic from 15 January 2018 to 15 February 2018 on the Bay of Bothnia. A total of 115 vessels were incorporated into the study, and a total of 249 trips were analyzed. Only level ice thickness was used to define the prevailing ice conditions for the used hv curves. These vessels were categorized into 18 vessel types with similar hv curves. The historical dataset comprises arrival and departure timestamps at various ports, along with the duration of stay at each port. Port departure times are integrated into the model as inputs. The arrival of a vessel at its designated destination port hinges on several factors, including ice conditions, dirways, icebreaker availability, and the prioritization logic employed by icebreakers when handling assistance requests from multiple vessels. One approach to validating the model involves comparing the scheduled arrival times of vessels at different ports with their historical counterparts. Typically, the arrival times were within few hours error margins but also few exceptional cases were found with the error of several days showing the sensitivity of system on a number of parameters, which require further analysis.

The latest validation was done by Winberg (2023) in his master's thesis. Rather than validating for one winter, the model was studied on trip-level using three different historical winters, being 2011, 2018, and 2020 on the Bay of Bothnia. These represent the three different winter types of mild, average, and severe, classified by the Finnish Ice Service. One month period i.e. from mid-January to mid-February was used as the studied period. For the study, a trip-level validation is performed for the different winter classes (mild, average, severe). Trip-level validation is preferred, since that allows the individual trips

to be studied, and thus help find the root cause for the errors more easily than using a broader system-level overview. Therefore, comparing the trip durations from real-life to the results provided by the simulation, are chosen as the main method of the validation. Winberg (2023) made detail study of the AIS data and filtered out a remarkable number of voyages due to the errors on the data and thereafter the data resulted in 232, 599 and 408 trips for the winters of 2011, 2018 and 2020, respectively. In the study, 45 reference vessel hv curves were used for the studied ships, and only level ice thickness was used to define the prevailing ice conditions for the used hv curves. Vessel speed threshold to start assistance was 3kn and convoy maximum speed 6 kn. The trip distance was from the Northern Quark strait to the harbour on the Bay of Bothnia, so typical voyage length is from few hours to few days. The average difference between the trip durations was 72.7 %, -90.1 % and 40.2 % for the winters of 2011, 2018 and 2020, respectively. This is naturally a remarkable scatter as the results obtained from the three winters are very diverse. Winberg (2023) summarises on his conclusions the following possible error sources:

- There is possibility of errors in the AIS data
- The waypoints used by vessels for navigation in the area do not correspond to the routes used in real-life
- Icebreaker decision making is not optimized and do not follow the real-life procedures
- Winds and currents impact on the ice movement are not included
- The optimized utilization of ice channels is not included
- Only one speed threshold for the icebreaker assistance is included
- Inaccuracies may be present on the used h-v curves

## OPTIMIZATION OF ICEBREAKER ASSISTANCE FOR SUSTAINABLE SHIPPING

Kondratenko et al. (2023) employed the simulation tool to introduce a novel approach for decarbonizing shipping in icy conditions. This proposed method optimizes icebreaker support with a focus on both ecological and cost efficiency, thereby facilitating the implementation of more sustainable icebreaking strategies. While the fee of icebreaker assistance is not directly remitted to Finnish and Swedish organizations who provide such assistance, it is encompassed within the fairway fee collected by the government. This fee is contingent upon the ice class (only applicable to Finnish authorities) and the vessel size. As reported by Baltic Icebreaking Management (2020), the average total operational cost of one icebreaker during the 2019–2020 navigation season amounted to 4.91 million euros per month, with approximately 11 percent allocated to fuel expenses. The total amount of fuel needed by the assisted ships in ice is now known, but the simulation tool can be used to approximate this. The main research question is then what is the optimum number of icebreakers so that the total amount of fuel and emissions on the air can be minimized on the winter navigation system level. In other words, can we use some other KPIs as average waiting time in future, to account for both ecological and cost efficiency KPIs, supporting sustainable shipping in ice.

Kondratenko et al. (2023) expanded the model to incorporate an eco-efficiency Key Performance Indicator (KPI) by estimating the total CO<sub>2</sub> emissions (in tons) of the FSWNS encompassing all transport vessels and icebreakers simulated in the analysis. While port emissions are negligible and remain unaffected by icebreaking assistance, they are thus not factored into the calculations. The total CO<sub>2</sub> emissions are determined for the scheduled voyages of transport vessels and all simulated assistance operations conducted by the icebreakers. This can be done as the simulation tool knows the used engine power and voyage time and length for both icebreakers and assisted ships. Using standard approaches the fuel consumption as a function of engine power can be determined and conversion factor between fuel consumption and CO<sub>2</sub> emission exists as well. The fuel cost can then also be determined once we know the total amount of fuel. The other economic costs in the model are included using the time charter rate (USD/hour) of a transport vessel or an icebreaker. More details of the approach used can be found from the paper by Kondratenko et al. (2023).

The case studies are established based on historical AIS traffic data and ice data during an average winter from traffic and ice perspective (15 Jan - 15 Feb 2018). Freight rates for each vessel are estimated based on publicly available data, taking into account the vessel's purpose and capacity (measured in deadweight (DW) or twenty-foot equivalent unit (TEU)). Estimated daily freight rates vary significantly, ranging from 4900 USD/day for small transport vessels to 43,000 USD/day for large vehicle carriers, and 60,000 USD/day for icebreakers. The study systematically varies the number and size of icebreakers, determining CO<sub>2</sub> emissions and costs using the simulation tool. Findings indicate that current practices are close to optimal, but alternative operational strategies could potentially reduce greenhouse gas emissions by up to 7% or lower costs by up to 14.2%. Results suggest that the proposed approach holds promise in offering recommendations for environmental and economic policies aimed at decarbonizing Finnish-Swedish icebreaking assistance. Naturally, this is the first attempt to evaluate the other KPIs than average waiting time and the model needs improvements, but the study shows the strength of the tool to study also other KPIs.

## ANALYSIS OF THE ICEBREAKER NEEDS IN ESTONIA

The latest application of the developed simulation tools has been the evaluation of icebreaker needs for Estonia until the year 2025 (Tapaninen et al., 2023). Figure 6 shows the developed model layout for Estonian maritime traffic. The main objective of the study was to simulate the Estonian wintertime traffic and analyse how many icebreakers Estonia will need as described next in further detail.

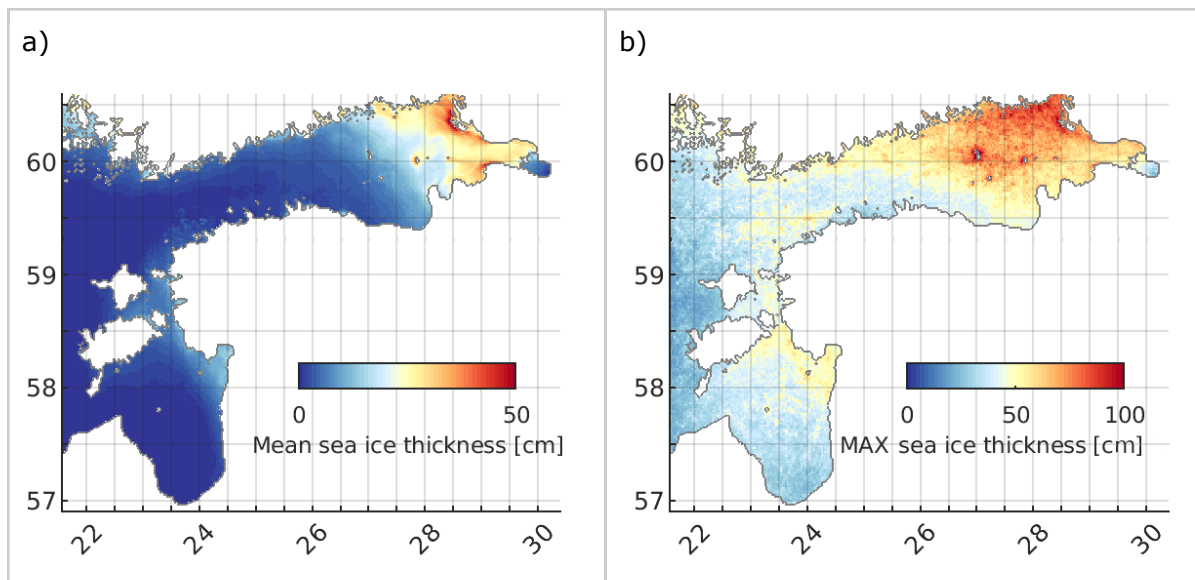

Figure 6: A demonstration of the Estonian Winter Navigation System model (Tapaninen et al., 2023)

### Evaluation of ice conditions

The ice conditions on the Estonian water were analysed by Taltech, Department of Marine Systems. Figure 7 illustrates the mean and maximum ice thickness on Estonian waters based on the long-term data. As can be seen that there are winters with very minor amount of ice, but also hard winters with extensive ice coverage on Estonian harbours. Over the years 1993–2022 about 20% winters have been severe, 60% have been average, and 20% have been mild winters. As temperatures are projected to increase in climate scenarios, a rise in occurrence of average and mild winters is anticipated. Consequently, severe winters are expected to become significantly less frequent. Nevertheless, under extreme weather conditions in warmer climate scenarios, there remains a possibility for severe winters to occur. Consequently, the simulation tool was used to analyse the winter navigation system on a mild, average, and hard winter.

**Figure 7: (a) Mean and (b) maximum of ice thickness. The values are retrieved from data between 1993 and 2021 (Tapaninen et al., 2023)**

### Simulated scenarios

In order to simulate the effects of the different combinations of icebreakers (IB), the scenarios given in Table 2 are used. Three of the used icebreakers are delegated to Gulf of Finland (GUF) and one to Gulf of Riga (GUR). IB scenario 1 includes two icebreakers, i.e. one in both areas and scenario 2 have three icebreakers, i.e. one in GUR and 2 in GUF, and scenario 3 activates all four icebreakers, i.e. one in GUR and 3 in GUF.

**Table 2: Icebreaker scenarios studied (Tapaninen et al., 2023)**

Icebreakers	Main Engine power [kW]	Shaft power [kW]	IB scenario 1	IB scenario 2	IB scenario 3
GUF, Primary IB	13000	10000	+	+	+
GUF, Secondary IB	9100	7000		+	+
GUF, Third IB	6250	5000			+
GUR, IB	5500	4400	+	+	+

### Obtained results

In the conducted simulation, the level of maritime traffic flows are kept same using historical AIS traffic data from 2018 Jan 15th to Feb 15th. The studied scenarios are given in Table 2. One of main KPIs for icebreaker assistance is average waiting time for each assisted ship, i.e., how much time is needed for merchant ships to wait for icebreaker assistance. Therefore, this will be one of the main outcomes. In addition to this, the icebreaker operation time used in winter navigation system and corresponding fuel consumption are also outputs from the modelling. Table 3 summarises the obtained results for the average waiting time KPI, indicating that on mild winter scenario 1 is satisfactory, on average winter scenario 2 is satisfactory and on hard winter scenario 3 is satisfactory when the average waiting time is kept less than 4 hours (240 mins).

Although the simulation results show reasonable trend for the scenarios, the modeling of the Estonian winter navigation system still has many limitations and simplifications comparing to the practical working system. The absolute values of the waiting time need to be referred to carefully. The icebreaker assistance logic still needs improvements, and the practical icebreaker assistance is affected number of additional parameters. The average waiting time is likely to decrease if the optimal home port or waiting location for IBs can be identified in further detail. Especially in IB Scenario 1, with only one icebreaker in Gulf of Finland and Gulf of Riga respectively, the waiting time is likely to reduce dramatically. In addition, near the coastline, there are possibilities for icebreaking assistance from tugs and channels can also be left open by other ships, which are not able to be

included in the simulation. These will also reduce the waiting time in practice. In general, further validation and comparisons with the practical cases are planned in future research for improving the accuracy and resilience of the model.

**Table 3: Summary of the main KPI-average waiting time (mins) for all scenarios (Tapaninen et al., 2023)**

Scenarios	Mild winter	Average winter	Severe winter
1	130	500	1000+
2	110	160	400
3	110	140	150

## DISCUSSION

The developed simulation tool aims to capture all the main elements of the winter navigations system: ice-going ships, icebreakers, varying ice conditions and varying situations for assisting ships in ice. All these elements are challenging to simulate. Ice conditions are dynamic with great variations even for one day. In addition, the idea of using the equivalent level ice thickness to describe various ice conditions with one value aiming to simulate reliably the ship average speed on these ice condition causes a number of challenges. This is due to the fact that evaluation of the equivalent ice thickness needs accurate physics-based models to determine ship performance in varying ice conditions. Historically, ship performance in level ice has been the dominating research area to develop analytical formulation for ship resistance. The other ice conditions, such as ridges, dynamic moving ice, and ice floes with varying concentrations have obtained less attention. Consequently, the methods used to evaluate the equivalent ice thickness for these ice conditions needs further research as well how to link the equivalent ice thickness calculation methods to the main particulars of the ice-going ships.

Another important area for further development is how to simulate the decision-making process of icebreaker captains coordinating the whole maritime operations during wintertime. This has crucial effect on the efficiency of the winter navigation system. This decision-making process should include knowledge of a number of parameters like: summary of the ships and their ice-going performance being or approaching the studied area, most probable development ice conditions in near future, available ice-breakers on the area and their location and duties in near future etc. On the present form the tool is using mainly the maximum waiting time for ice-going ships as the main decision-making criteria, which is naturally too simple.

However, the first results of applying the system level simulation tool are promising even though of the prevailing challenges describe above. This is unique tool worldwide trying to simulate all the main elements of the winter navigation system. On system level the average waiting time for ships have been obtained with less than 10 % accuracy. Comparing the ship arrival time to harbors the scatter has been much wider caused mainly by the limitations on the factors: Icebreaker decision making, winds and currents impact on the ice movement not included, optimized utilization of ice channels not included, only one speed threshold for the icebreaker assistance is included and inaccuracies on the used hv curves. All these topics will need further development in near future.

## CONCLUSIONS

We have developed during the last 10 years a simulation tool to study in the system level the performance of our winter navigation activities. The main aim of the tool development has been to develop a research-based prototype that can be used to simulate the need of icebreakers in the future when both ice conditions, maritime traffic and characteristics of ice-strengthened ships will be under dynamic change. In this paper, the current status of the simulation tool is shortly described together with the main structure and elements of the tool. Some recent case studies with the tool are also summarised: Validation of the tool, optimization of icebreaker assistance for sustainable shipping and analysis of the icebreaker needs in Estonia.

The tool has been applied with success to analyse the wintertime marine traffic both on the Bay of Bothnia for Finnish marine transport and for Gulf of Finland for Estonian marine transport. On system level the accuracy (e.g., the average waiting time of ice-going ships) has been found adequate, but create variation can take place on the voyage based comparisons. The validation of the simulation tool with AIS data to determine the arrival times to harbors shows extensive scatter as the used methods to determine equivalent ice thickness with a reliable link to the used hv curves as well the ice-breaker decision making needs further development.

## ABSTRACT

*Ship design is a creative process serving a defined objective. This is normally an iterative process with the design being corrected and adjusted many times until it satisfies this objective. Ship design is taking place in a broader business context consisting of stakeholders providing necessary resources and information to enable the realization of a vessel newbuilding project. Activities performed by different actors, such as customers, suppliers and brokers, are organized by and integrated into a ship design firm. This paper addresses and discusses different ways of organizing integrated design-related activities to deliver on the firm's value proposition. A value proposition denotes the promised value to a selected customer, and through its value proposition, a ship design firm provides "superior" solutions to a customer's needs. To enable this solution, a design firm draws on its current resources, including its past knowledge and experiences, and uses these resources in different types of processes, and – in different ways of collaborating with internal and external actors and specialists.*

*In this paper, we draw on approaches from the field of business strategy to understand implications and trade-offs in different logics of value creation processes, how they can be applied in ship design firms, and their implications.*

# 1 INTRODUCTION

Ship design has traditionally been executed by naval architects and marine engineers (Andrews, 2010) with an integrating role for specific disciplines involved in the process. In the past, this activity was mostly done by integrated shipyards, while more recently the ship design role – particularly during the vessel concept ship design phase – has been decoupled from yards and, in the merchant shipping world, is done mostly by firms that are specialized in ship design activities (Semini, Sjøbakk, & Alfnes, 2013; Semini, et al., 2023).

Shipbuilding is still considered, by most parties, as comprising the design of the vessels, the erection of the ships, and finally, the production of all main systems and equipment onboard to eventually constitute an operable floating ship. Shipbuilding, including ship design activities, is a highly competitive global industry. Over the past decades, European shipyards have lost a considerable part of their market share to East-Asian shipyards, especially within the conventional and high-volume cargo-carrying segments, such as tankers, bulkers, and container vessels. In these segments, European shipyards now play a marginal role – a market share of less than 10% of the worldwide annual orderbook (Brett, Gaspar, Ebrahimi, & Garcia Agis, 2018; Semini, et al., 2023). In Europe, and Norway in particular, shipyards and their affiliated or independent ship design firms have focused on a limited set of specialized vessels, but still stand for a good portion of the worldwide orderbook value within passenger vessels, fishing and aquaculture vessels, service vessels, including both the offshore oil & gas service vessels as well as ships for the offshore wind industry. Yet, for most of the European ship design firms the European shipbuilding market is not sufficient, and they also provide ship design services to other international yards. Projects with the European shipyards are typically one-of-a-kind rather than series of ships, which is the case in the Far East. Typically, European ship design firms deliver few, but novel design packages with high degree of innovation – complex and expensive designs.

With the past and current low levels of demand and ordering of ships, yards and ship design firms have been and still are struggling to make sufficient profit margins out of meager order books and falling market shares. Competitiveness is dwindling too. To regain competitiveness – despite other parts of the world benefitting from lower wages, lower material costs, more favorable financial support, more lenient laws, and regulations – there is a critical need for European shipbuilders and independent ship design firms to improve their understanding of why this long-term market trend is happening, what affects their performances and how it can be improved. It is argued by this article that for regaining competitiveness in the ship design firm business segment, a much deeper and broader insight into how value creation and extra profits can be achieved is paramount. Further, it is argued that competitiveness is among other factors, particularly interlinked to the choice and application of strategy models for value creation in that business segment. Therefore, this article looks for ways to improve competitiveness by better understanding the basis for applying one or a mix of the generic strategy models for effective value creation (Fjeldstad & Lunnan, 2022).

This paper is rooted in the DREAMS research project, which has researched these challenges for a couple of years with the goal of improving the competitiveness of Norwegian ship design companies. The project was introduced to the IMDC participants at the Vancouver IMDC 2022 conference (Brett, Asbjørnslett, Garcia Agis, & Erikstad, 2022). In this paper, we would like to share and discuss some of the preliminary findings. The study and this paper take a broader view, stressing that such a study must take a comprehensive approach to competitiveness – with the purpose of the ship design activity to make money and not only produce better and innovative design solutions.

Previous papers at IMDC have discussed many technical aspects and considerations around the ship design process as well as design methodologies (Andrews, et al., 1997; Andrews, Keane, Lamb, Sen, & Vassalos, 2006; Andrews, Papanikolaou, Erichsen, & Vasudevan, 2009; Ulstein & Brett, 2012; Andrews & Erikstad, 2015; Andrews, Kana, Hopman, & Romanoff, 2018; Erikstad & Lagemann, 2022). Little emphasis has been placed on the organization of human resources in performing design activities. However, in several IMDC papers it has been stated that naval architects and marine engineers as well as ship design firms must expand their knowledge, expertise, and skills to be able to handle future ship design challenges from a commercial, operational, and technological standpoint (Ulstein & Brett, 2012; Brett, Garcia Agis, Ebrahimi, Erikstad, & Asbjørnslett, 2022).

This paper discusses ship design activities from an organizational and business perspective by discussing strategic aspects around the design team composition. We hope this opens a relevant discussion on how ship design is performed in practice and how a ship design firm can create value for its customers. This has important implications for the type of people employed, their competence and skills and consequently also demands for academic education (Asbjørnslett, Erikstad, Lagemann, & Brett, 2022).

Our paper is structured as follows: Subsections 1.1 to 1.3 introduce the topic and important concepts and definitions. Section 2 presents four strategic models for value creation. Section 3 describes how the two most common strategic models can be applied

to ship design firms, supplemented by two empirical cases. Section 4 compares and discusses the two models, and Section 5 concludes the paper.

### 1.1 Definition of a ship design firm

Design is a decision-making process that results in the specification of an artifact (Goel & Pirolli, 1989; Simon, 1996). The ship design process can be categorized as a special variant of the design of physically large and complex systems (Andrews, 1998; Garcia Agis, et al., 2019; Ebrahimi, Brett, & Garcia Agis, 2018). The ship design process is typically executed by a team of naval architects and marine engineers, with support and expertise from various other disciplines such as sales, interior design, electrical engineering, and suppliers. If this team is part of a business entity<sup>1</sup>, can this organization be termed a ‘ship design firm’? In other words, are all organizations that conduct some ship design activities called a ‘ship design firm’? To our understanding, the answer to this question is ‘no’.

Figure 1 indicates the general ship design process timeline and several relevant stakeholders involved. Each of these stakeholders may employ naval architects, marine engineers, and other experts, and each may engage in the ship design process in one way or another. Yet, we would not call all of these stakeholders ‘ship design firms’. Instead, for this paper, we suggest the definition of a ship design firm as ‘a business entity where ship design constitutes the primary value activity and where a significant integration effort takes place’. To be more precise, we consider only firms that sell the specification and drawings of a ship to be a ship design firm. In other words: If you cannot buy a ship design from it (i.e., a specification, class-approved drawing package and supporting analyses), that firm does not count as a ship design firm for the purpose of this paper. This definition aligns with the idea that systems architecture is at the core of early-stage ship design (Andrews, 2003; Andrews, 2015).

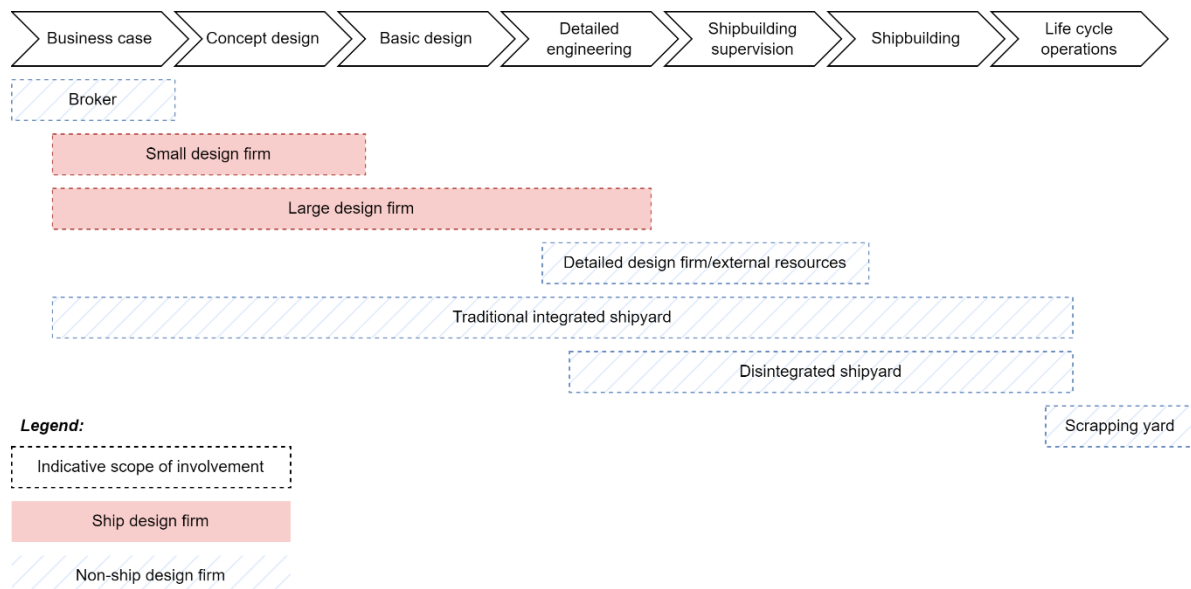

Figure 1: Different actors in the ship life cycle

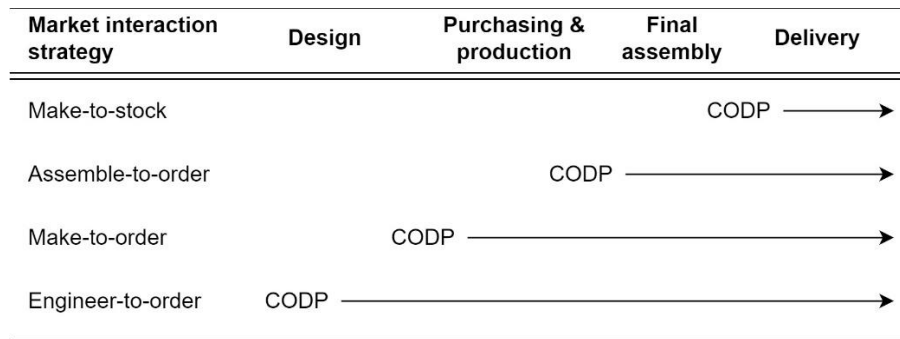

It should be noted that formerly, ship design was mainly executed at what is here called ‘traditional integrated shipyards’, spanning the whole value chain from early-stage ship design to shipbuilding, maintenance and repair of ships. While this is still common practice in some instances and many countries (Cho & Porter, 1986), diversification and specialization have taken place in many locations. More firms are entering the market that focus their main activities on ship design. These firms’ main activities are design, not shipbuilding. This is especially true for the Norwegian market, where yard activities and market share have been declining over many years (Menon Economics, 2023), but we see independent ship design companies are generally growing by number, revenue and employees – albeit growth was halted after 2015 (inhouse compilation based on data from Proff (2023)). While the Norwegian ship design firms’ global market share is around 3 to 5%, ship designers provide important design and integration competence to Norwegian yards, the maritime cluster (Menon Economics, 2022), and to customers (owners, operators, and yards) abroad. The labels ‘small design firm’ and ‘large design firm’ in Figure 1 relate to the firms’ scope of involvement (concept, basic or detail) in the design process, not directly to their size in terms of turnover or employees

<sup>1</sup> The Oxford English Dictionary (2023) defines a firm as “generally: a commercial enterprise, business, or company”.

as such. A ‘disintegrated shipyard’ (ship factory), in this paper, shall denote a yard that does not undertake substantial design activities itself, but instead focuses on ship production and repair.

## 1.2 Standardized and customized design and market interaction strategies

Shipyards typically follow different product portfolio strategies with respect to standardization and customization and sometimes a mix of the two. In most cases, customer strategies are then linked to market interaction strategies and the value creation strategy of the company. Ship designers may certainly, also employ such different strategies. One element of this strategy concerns activities covered and their customization. Semini et al. (2014) discuss four different approaches. First, make-to-stock, where products are manufactured to and sold from stock. Second, assemble-to-order, with components produced to stock and awaiting the final assembly to an order. Third, make-to-order, with all components and assembly waiting until an order is placed. Fourth, engineer-to-order (EtO), where the design is completely customized to an order. The four different approaches and their relation to the customer order decoupling point (CODP) are illustrated in Figure 2. The choice of approach has profound implications for what a ship design firm is, its organization, and how it operates.

**Figure 2: Market interaction strategies and customer order decoupling point (CODP), adapted from Semini et al. (2014) and based on Olhager (2003).**

The make-to-order (customize existing design concepts) and engineer-to-order (design solution from scratch) strategies are the most relevant in this context, as they involve design activities as opposed to production and assembly activities (shipbuilding) only. On the surface, there may seem to be a certain overlap with Andrews’ (1986) different degrees of novelty in ship design, i.e., adapting existing designs versus developing radically new technology and system solutions. The difference between the two is that a market interaction strategy describes a designer’s approach towards a customer, whereas Andrews’ degrees of novelty describe the following internal design processes. In this paper, we explore the importance of a fit between a market strategy towards the customer, the novelty of the design solution, and the organization of the ship design process and the role of the team.

## 1.3 Different types of customer interactions

Closely linked to the market interaction strategies, different types of customer interactions exist. In Table 1, we outline five customer interaction types that are commonly exercised in commercial merchant ship design processes.

**Table 1: Customer interaction types**

#	Customer interaction	Archetypical request	Typically initiated by	Solution response strategy	Competition
1	Customer design inquiry	“I want to have this ship”	Ship owner	New/existing	Unknown
2	Broker inquiry	“Do you have a solution that can do...?”	Broker or ship owner	Existing	Unknown
3	Tender inquiry	“Can you help us respond to this tender?”	Ship owner	New/existing	Usually known
4	Customer project inquiry	“Can we develop this together with your expertise/knowledge?”	Various	New	None
5	Project-making	“We have an interesting business proposition to offer you - do you want to be part of the initiative?”	Ship designer	New/existing	None

The market interaction strategies are closely linked through the ‘solution response strategy’ indicated in Table 1. A ‘project-making’ customer approach is normally combined with a standardize-to-order market interaction strategy. Thus, a standardized technical solution (StO) is developed, most often, without a customer involvement in the early phases of the project, but one or more takers (customers) may be involved at a later stage in the finalization of the new building project realization. While this inquiry approach is not so common, more often make-to-order strategies (configuration-based design or variant design; CtO) are experienced in the interrelationship with the customers. Interesting to note for our discussion are the differences between re-using existing designs, simple adaptations of these, and designing a complete novel ship from scratch.

In addition to the customer interaction strategy chosen, the overall value creation activities in a ship design firm, i.e., the ship design activities and resources’ organization, may be arranged and performed according to a set of different value creating logics. It is argued in this article, therefore, that these logics have profound implications on the way activities are organized and executed, and what people, knowledge, experience, and tools are needed. The next section presents and analyzes ship design activities considering these models. We will particularly focus on two strategic models for value chain creation: the ‘value chain’ and the ‘value shop’.

## 2 STRATEGIC MODELS FOR VALUE CREATION

A firm’s strategy can be described as a plan or pattern to attain overall goals (Nag, Hambrick, & Chen, 2007). Reaching strategic decisions, the firm must make three consistent choices (Miles & Snow, 2003):

- i) What products and services to deliver in which markets;
- ii) What activities and resources to utilize to deliver these products and services;
- iii) How to acquire, develop and organize these resources and activities to balance efficient operations and innovation.

These choices are partly interdependent. That is, to offer a low-priced product or service, for example, the firm must pursue low-cost resources and activities, whereas costly technology development may be needed for novel and unique designs. It should also be noted that the competitive advantage is only temporal (McGrath, 2013) and a firm needs to continuously monitor and critically evaluate its choices with respect to aspects i) to iii).

To examine, study, and understand activity systems and the drivers of cost and customer value, Porter (1985) introduced the value chain, outlining a “manufacturing” logic, focusing on economies of scale, capacity utilization, and activity linkages as core cost and value drivers. This configuration framework was later expanded by Stabell and Fjeldstad (1998), introducing the “value shop” and the “value network”, building on the long-linked, intensive, and mediating technologies topology by Thompson (1967). Furthermore, Fjeldstad & Lunnan (2022) introduce “value access” as a fourth value creation model. Value access means appropriating value by offering customers access to shared resources, e.g., cloud computing or “management for hire”. Each of these models focuses on different sets of activities, different dynamics between these, and different drivers of cost and value. Table 2 provides an overview and comparison of the different value creation models.

**Table 2: Value creation models**

	<b>Value chain</b>	<b>Value shop</b>	<b>Value network</b>	<b>Value access</b>
<b>Business problem<sup>1</sup></b>	Transforming inputs into products (production-based) <sup>1</sup>	(Re)solving customer problems (Problem solving-based) <sup>1</sup>	Linking customers directly and indirectly (Network-based) <sup>1</sup>	Providing access to resources <sup>3</sup>
<b>Deliverables created<sup>1</sup></b>	Products <sup>1</sup>	Solutions <sup>1</sup>	Services <sup>1</sup>	Access to resources <sup>3</sup>
<b>Business-logic method<sup>1</sup></b>	Sequential <sup>1</sup>	Cyclical, spiraling <sup>1</sup>	Simultaneous, parallel <sup>1</sup>	Continuous <sup>3</sup>
<b>Value creation strategy<sup>1</sup></b>	Achieve scale and focus on efficient linkages between activities <sup>1</sup>	Make optimal use of human capital and reputation <sup>1</sup>	Create superior connectivity and ability to carry products and services <sup>1</sup>	Secure resources and their quality <sup>3</sup>
<b>Activities<sup>1</sup></b>	Inbound logistics Operations Outbound logistics Sales and marketing Service <sup>1</sup>	Problem finding Problem solving Solution choice Execution Control/evaluation <sup>1</sup>	Network promotion Contract management Service provisioning Network infrastructure <sup>1</sup>	Acquiring resources Managing resources Manage customer interface <sup>3</sup>
<b>Frequent activity tradeoffs<sup>2</sup></b>	Differentiation vs. cost leadership Integration our outsourcing <sup>2</sup>	Knowledge depth and scope <sup>2</sup>	Open source vs. walled garden. Broad vs. specialized <sup>2</sup>	Focused vs. Specialized <sup>3</sup>

In ship design activities, the ‘value chain’ and ‘value shop’ appear to be the most common value creation models and will be examined and exemplified in the following section. The ‘value network’ and ‘value access’ configurations are less common as explicit and individual strategies for ship design activities as such, but for some appear as complimentary value creation strategies for supporting, additional products and service deliveries. Maritime examples for these two models do exist, however: Broker activities are typical instances of a ‘value network’ configuration. DNV’s Veracity platform (DNV, 2023) may be seen as an example of ‘value access’, with elements of a ‘value network’ as it enables third-party app developers to link with customers. Moreover, a ‘project-making’ type of customer interaction in ship design shares many elements with a ‘value network’ logic.

### 3 VALUE CHAIN AND VALUE SHOP EXAMPLES OF DESIGN FIRM STRATEGIES

In this section, we will first outline the two value configuration logics of a ‘value chain’ and a ‘value shop’ and illustrate these two logics with examples from two different ship design firms. One of the ship design firms more often uses the logic of a ‘value chain’, whereas the other one uses the logic of a ‘value shop’. The description of the illustrative cases is based on a total of 17 interviews with employees from the two firms. The semi-structured interview setup covered a pre-defined set of topics, while giving the interviewees the opportunity to elaborate. The interviews were conducted mostly by one interviewer, who asked questions and simultaneously took notes to document the interviewees answers. After the interview, the answers were analyzed and condensed by the interviewer into one summarizing document.

The activities of firm A and B can to some extent be described by one of the two value creation logics. In practice, however, both firms do adapt and mix the logics to a certain extent, dependent upon the type of customer inquiry received. Such a mix can be observed within and across projects. That is, within one project, a firm may predominantly follow a ‘value chain’ logic for instance, while still employing elements of the ‘value shop’ logic to a limited extent. Across projects, the firms may also switch between strategic approaches and in that sense adapt their value creation logic to the nature of the project and customer inquiry and thereby, mix the two whenever meaningful.

#### 3.1 Design firm A – example of the applied value chain logic

In a typical value chain framework, the ship design firm follows a sequential logic, which often relies on standardization. The design processes can be portrayed as a chain of interlinked and linearly organized activities, where the work performed in one activity builds on the work done in the prior activity. The work is done by separate units, and specialized. In principle, there should be no need for feedback loops, the process is one-directional. This type of design firm is akin to an assembly line and is therefore also called a 'project factory' approach, in this paper.

At the initiation of each project, the project manager divides the project into specific parts identified by discipline. The project manager oversees the combination and coordination – the linkages between – these parts and information exchange. Ideally, the boundaries between disciplines are as clear-cut and as specific as possible, following a seamless handover between different disciplines. Each discipline is handled by a group of specialists, who do not necessarily need to know what other specialists do, if the interfaces between the parts of the design are clear, well-specified, and structured. The design process can follow a sequential and established logic, where each part is done according to allocated time and clear specifications. The customer, normally, takes no part in the execution of the design work processes, as the various tasks are clear and well understood by the naval architects, marine engineers and other specialists involved. Therefore, this process only works well if the project-specific expectations and requirements are clearly defined, documented, communicated, and understood prior to the design process execution and the naval architects and marine engineers are well trained and experienced in their work disciplines.

This logic can be illustrated by design firm A. Design firm A employs about 40 people directly engaged in the design activities, many of them with a specific discipline training and experience and/or shop floor background from a shipyard. The firm engages normally in projects with a concept and basic design scope. To engage in the latter one, a "winning" or an accepted customer concept design is a prerequisite. For both design phases – concept and basic – the firm's activities can be described with a value chain logic (similar to a project factory): In concept design, the project team usually consists of seven people with different roles. Two out of seven have an integrating function, and five out of seven work within their specific discipline. Each discipline uses its own specialized set of tools. Although employees are located on the same floor, they typically have separate offices combined with separate meeting rooms and more informal social areas. In the basic design phase, the design team is typically enlarged, and each discipline follows its own pre-defined and specific workflow. This work process triggers a lot of coordination meetings and mini seminars.

Design firm A has a long tradition in the design of complex vessels of medium size. Most of these vessels can be classified as service vessels. Examples in the most recent past are service offshore wind vessels (SOV), expedition cruise vessels, fishing and aquaculture vessels, or cable laying vessels. Common for all these vessels is that they have complex operational patterns and systems to integrate on a small to medium-sized vessel, typically up to 160m. The vessels are typically built as one-offs or in small series. Design firm A makes use of all five types of customer interactions (Table 1). Over time, a considerable design portfolio has been built up. The firm proactively develops this portfolio/catalog, both to strengthen inhouse knowledge and to be able to offer standardized, but customizable solutions to certain customers, such as for customer approach #2 (Broker inquiry: "Do you have a solution that can do...?"). To cut response time in a tender process, catalog solutions may serve as a starting point for most customization or adaptation work.

### **3.2 Design firm B – Example of the applied value shop logic**

In a typical value shop framework, the design firm follows a logic of problem-solving. The design a customer demands is unique and does not currently exist. Every new project starts a creative process, where the main idea is to match customer preferences with the design in a novel way. Customers may have non-standard requests that cause ripple effects among different disciplines involved in design, and initially, the main elements of these must be identified. At times, the customer may not be clear on her exact demands and needs to explore the feasibility of these together with the design firm. The interaction between the customer and the design firm is normally handled by the most senior experts in the firm. These seniors have deep and broad knowledge of the major disciplines and have skills in customer communication. In this process, important stakeholders, such as customers and major suppliers are involved in early discussions and in offering comments to early design suggestions, promoting an interactive (as opposed to the sequential value chain logic) value creation logic. The process is characterized by feedback loops and trials until the main elements of the design are settled. Then, the detailed work may be handed over to specific disciplines and sometimes junior engineers (yet, with deep knowledge in one discipline). In such a value creation logic strategy, it is important to stop the process and revert back to start if surmountable problems occur and incorporate more deliberate customer and expert feedback along the way.

Design firm B consists of about 20 people directly engaged in design activities. Most of these have a master-level education in naval architecture, resulting in a workforce with consistently high and homogenous academic training. All naval architects are trained on a small set of tools. These tools partly consist of commercial software, and partly of special in-house developments.

In concept design, the project team typically consists of three to five people in total, with one senior naval architect as a project leader. Due to their relatively homogenous skills, one person can have different roles in different projects. To promote and further develop this versatile and homogeneous skillset, it is common practice to rotate the roles among employees over time. All people work on the same floor and in open plan office facilities.

Firm B is an established designer for large, offshore energy vessels applied in segments such as wind turbine installation vessels (WTIVs) or foundation installation vessels (FIVs), and heavy lift and other specialized vessels (HLVs) for the offshore oil & gas industry. These vessels are typically somewhat larger in size, more expensive and tailor-made one-offs. Firm B is usually contacted by customers to develop tailor-made solutions. While the firm also maintains its own design portfolio, the firm's target segment is characterized by tailor-made, one-off solutions as opposed to potentially small series. Vessels in this segment are, on average, more expensive and the engineering hours – particularly concept design hours – amount to a smaller proportion of the overall costs of the vessel.

## 4 DISCUSSION

The two value creation logics we have outlined may both provide competitive value propositions to customers. A 'project factory' model is normally more cost- and time-efficient on known designs and when market conditions are good – many inquiries that need quick turnaround time for response – much dependence on continual high production throughputs, whereas the 'value shop' model offers highly customized designs for special missions and is less sensitive to consequences of good and bad market conditions. The project factory approach is also less demanding w.r.t the qualifications of the engineers involved – a few well-seasoned naval architects can handle several less trained engineers. On the other hand, it requires more organizational structure and management – more formalism. The value shop model requires more experienced and fuller-fledged naval architects and marine engineers, i.e., project managers being capable of both handling the upstream sales interaction and the downstream managing the project efforts until delivery of the design package.

If we consider our two examples of solutions (firm A and B), both operate on a project basis. That is, a temporary project team is assembled individually for each project – whether paid for or not, and whether a concept or basic design scope – from the pool of available employees within each company (relatively constant over time). The skillset and composition of this human resource pool differs between the two design firms, and this is reflected in the project team composition. Firm A employs specialists in each discipline that focus on a specific part of the design process. For firm A, it is vital to have a clear overview of the design project, and design the interfaces where activities are handed over to the next discipline. Firm B's work force is less discipline-specific and has a more versatile background. Their skillsets, tools, and collaborative shared workspace facilitate a more problem-oriented working style in line with the value shop logic.

The main challenge of a 'value shop' type of logic is to as quickly as possible come up with a concept design solution that is agreeable to the customer and feasible for all other stakeholders. This implies that the initiation of a value shop project is crucial, and that handling and coordinating initiatives from all stakeholders finding a solution is the key (Brett, Gaspar, Ebrahimi, & Garcia Agis, 2018; Garcia Agis, et al., 2019). Our illustrative example shows that firm B has succeeded with this collaborative and less streamlined working style in the conceptual phase, reporting good experience and high satisfaction with this value configuration logic. Firm A's more streamlined 'project factory', in turn, showed more variety in terms resource consumption and deviated more often from its original plan in the conceptual design phase. A possible explanation for this is that the conceptual design phase can be more successfully approached by 'architecting' (Brooks, 1995; Maier, 1996; Maier & Rechtin, 2000; Andrews, 2012; Andrews, 2018) instead of a streamlined 'engineering' approach, as the V-model and others suggest.

Fjeldstad & Lunnan (2022) suggest that the chosen value creation model must fit the other strategic choices, e.g., resources and market positioning, of a firm, in addition to factors such as culture and practice. This is also suggested by Porter (1996) as the notion of "strategic fit" between different activities. Thus, when discussing the two firms' value creation logics in the conceptual design phase, the relation and fit to its other activities, its market positioning (target segment and customer interaction types), and its resources must not be neglected. Neither should general time-dependent circumstances be forgotten: In periods with high market activity, firm A reported good experience with the 'project factory' value creation logic. This was possibly due to a high level of similarity between different designs and high project turnaround, which enabled an efficient utilization of personnel and expertise. In this situation it was much easier to divide tasks and standardize interfaces, simply based on prior experiences. Thus, there was much less need for an initial consultation with the customer because the task was assumed clear. In periods with lower market activity and higher demand for unique designs, firm A has been forced to expand into other market segments in order to keep the business going and utilize its personnel. Under such circumstances, the firm lacks the experience needed to standardize the workflow and may also enter projects where the customer wants a unique design. In this situation, the 'project factory' is more problematic.

## 5 CONCLUSIONS

In this paper, we have characterized a ‘ship design firm’ as ‘a business entity where ship design constitutes the primary value activity and where a significant integration effort takes place’. By this definition, the ship design firm is thus fundamentally different to a shipyard, where ship erection constitutes the primary value generation activity. We have shown that the difference between the two can – in certain cases – also be seen in the value creation logic, i.e., the internal configuration of the firm’s activities and personnel: The value creation logic at a shipyard, with relatively well-defined and sequential tasks, can almost always be described as a ‘value chain’ logic. In contrast, ship design firms – in particular in the concept phase – often operate with less streamlined, iterative problem-solving activities that can be described as a ‘value shop’ logic. Our two example firms have shown that a seemingly streamlined ‘value chain’ logic creates friction in the conceptual design phase. A likely reason is that the nature of the problem (Andrews (2011) “wicked”; Pettersen et al. (2018) “ill-structured”) conflicts with well-defined and streamlined processes in a ‘value chain’. The ‘value chain’ does, however, work well in ship design when project turnover is high, as it enables an efficient utilization of resources. To exploit these scale effects, it seems to be necessary to have well-defined tasks with clear interfaces. This can be achieved by strategically focusing on projects with a high similarity in the conceptual design phase, or by a higher share of activities in the more well-defined basic design phase.

Our illustrative examples and the discussion are based on the comparison of only two firms. To strengthen or discard our illustrations, a larger number of case studies as well as a quantitative study would seem useful. Moreover, our analysis has primarily focused on the conceptual design phase in both firms. For both firms, a successful concept design is seen as necessary to win projects with a basic design scope. Both firms adapt their value creation logic to the different demand of such projects. However, successfully employing different value creation logics within the same firm and with potentially the same people may pose challenges. The explicit switch between the two logics within the same firm should therefore be further investigated. Finally, we have described the ‘as-is’ state of two design firms as examples of the two most common value creation logics. In order to improve competitiveness and develop ‘to-be’ states, the application of the remaining logics ‘value network’ and ‘value access’ should be critically examined (Sjåvåg, 2022).

## ACKNOWLEDGMENTS

We would like to thank all interviewees for their willingness and openness to share information with the DREAMS project. Moreover, we acknowledge the funding support from the Research Council of Norway under the KSP DREAMS, project number 327047.

## ABSTRACT

*The energy transition from fossil fuels to sustainable alternatives makes the design of future-proof ships even more important. In the design phase of a ship, it is uncertain how many and which fuels it will use in the future due to many external factors. In fact, a ship typically sails for decades, increasing the likelihood that it will use different fuels during its lifetime. Pipe route design is expensive and time-consuming, mainly done by hand. Motivated by this, in previous research, we have proposed a mathematical optimization framework for automatic pipe routing under uncertainty of the energy transition. In this paper, we build on the state-of-the-art by implementing design constraints in mathematical models based on discussions with maritime design experts. Additionally, we apply these models to realistic, complex situations of a commercial ship design company. Our experiments show that location-dependent installation costs, which reflect reality, increase the usefulness of stochastic optimization compared to deterministic and robust optimization. Additionally, to prepare for a possible transition to more sustainable fuels, we recommend installing suitable pipes near the engine room upfront to prevent expensive retrofits in the future.*

## KEY WORDS

Pipe routing; Ship design; Mathematical optimization; Energy transition; Design automation

## INTRODUCTION

The maritime industry is responsible for 2-3% of global carbon emissions (International Maritime Organization, 2020). Therefore, new regulations from the IMO and UN state that net zero should be reached by 2050 (International Maritime Organization, 2023). Consequently, ship designers want to consider these measures when designing a new ship. However, Pruyn (2017) states that this is not the case, as most ship owners optimize their ships for the economic situation at the beginning of construction. As a result, ships are not future-proof upon delivery, leading to expensive retrofits in the future.

For sustainability and financial reasons, ship designers must consider future alternative fuels already in the design phase to prevent these retrofits. Using a new fuel typically impacts three essential aspects of a ship: the engine (or the prime mover), the fuel storage, and the pipe routes between them. Although the academic literature elaborately describes the first two aspects (Lindstad et al., 2021; Zwaginga and Pruyn, 2022), the role of pipe routing is not often considered in the academic literature according to Blokland et al. (2023). Automated pipe routing can save time and costs as it is done mainly manually and, consequently, requires over half of the total detail-design labor hours (Park and Storch, 2002). This effort is expected to increase as pipe routing constraints largely depend on the fuel used (Lloyd's Register, 2023).

In Markhorst et al. (2023), we have proposed a mathematical optimization framework consisting of three models: deterministic, robust, and stochastic optimization. These models route pipes such that they minimize the sum of the installation and retrofit costs while adhering to (some of) the pipe routing rules from Lloyd's Register (2023). In the following, we explain how we have built these models on the current state-of-the-art and what our academic and practical contributions are.

**Literature** Two extensive works extensively describe the literature on pipe routing (Asmara, 2013; Blokland et al., 2023). They almost exclusively mention works that do not consider any form of uncertainty. More specifically, in their conclusion, Blokland et al. (2023) suggests to include the energy transition uncertainty in pipe routing models. For this, we can model the problem of connecting multiple tank(s) and engine room(s) in a ship as a Steiner Tree Problem (STP); see Ljubić (2021) for a survey. A stochastic version of this problem is called the Stochastic Steiner Tree Problem (SSTP), for which Bomze et al. (2010); Zey (2016); Leitner et al. (2018) have elaborately described exact solution methods. In Markhorst et al. (2023), we consider a generalization of the SSTP called the Stochastic Steiner Forest Problem (SSFP), which connects multiple independent groups of terminals (i.e., tanks and engine rooms). We have built on Schmidt et al. (2021), who describe exact solution methods for the Steiner Forest Problem (SFP).

**Our contributions** In this work, we build on the state-of-the-art by implementing design constraints in mathematical models based on discussions with maritime design experts. One of the main conclusions from discussions with these experts is that installation costs largely depend on the location in the ship. We apply the models to realistic, complex situations of a commercial ship design company and study different versions of location-dependent costs, which reflect reality, and their impact on the pipe routes and costs. This work aims to show the power of mathematical optimization in the maritime pipe routing domain.

**Outline** The rest of this paper is structured as follows. First, we describe the three different models using an illustrative example. Then, we describe the data, the experiments, and the corresponding results. Finally, we formulate our conclusions and sketch directions for future research.

## METHODOLOGY

In this section, we formally describe the deterministic and stochastic problem formulation of our pipe routing problem in mathematical terms. To this end, we start with an example that will later show the characteristics of the different models. Then, we continue with the deterministic optimization model and explain why this is a naive benchmark. Finally, we elaborate on the value of adding uncertainty to our models, after which the robust and stochastic optimization models follow. We only sketch the general idea behind the models and refer to Markhorst et al. (2023) for further details.

### The translation from maritime design to mathematics

For this work, we consider a ship that sails on diesel but *could* transition to methanol in the future. In the following simplistic example, we assume that the methanol and diesel tanks are placed on the starboard side of the ship and that the engine room is placed on the port side. Schematically, we represent this ship, where each room may contain one or more engines or fuel tanks, as a graph; see Figure 1. For simplicity, we only consider rooms A, B, C, and D in the corresponding graph representation. Additionally, we assume that installing a pipe between adjacent rooms costs €1, except for the connection between room A and E, which costs €0.5, hence an installation cost of €1.5 for the connection between A and D. The undirected graph  $G = (\mathcal{V}, \mathcal{E})$  consists of a set of vertices  $\mathcal{V}$  (the rooms in a ship) and a set of edges  $\mathcal{E}$  (the possible connections between the rooms). Later, we will assume that the ship's graph representation  $G$  remains the same when considering future scenarios.

(a) Simplistic top-down view of a ship.

(b) Graph with the first stage installation costs.

**Figure 1:** Example of the mathematical representation of a ship with 8 rooms. The icons in Figure 1a indicate the function of a room: A denotes the engine room, while C, E, F, and G represent voids, and vertices B and D denote the methanol and diesel tanks, respectively. For simplicity, we only consider rooms A, B, C, and D in the graph representation. The arrows indicate possible pipes and the black square denotes a room through which we cannot route any pipes.

In our problem, we want to connect the fuel tank(s) with the engine room(s). Because we consider different fuel types, we must route according to different rules for pipe routing. For example, diesel pipes cannot be routed through rooms adjacent to water due to regulations from, for example, Lloyd’s Register (2023). Consequently, we consider two different terminal groups. One group corresponds to diesel, whereas the other corresponds to methanol. For now, we assume that we only need to connect the diesel tank with the engine room. To do so, we can use a set of types  $\mathcal{P}$  denoting the set of feasible pipes for diesel, which are single and double walled pipes in this case. Introducing these sets of pipes allows us to consider different fuel types in the future. The installation cost of a pipe  $p$  at a particular edge  $(u, v)$  is given by  $\gamma_{puv} > 0$ .

Due to regulations from Lloyd’s Register (2023), we cannot route some dangerous fuel types through certain areas in a ship. For instance, we cannot route diesel through rooms adjacent to the waterside. To model this, we introduce the set of admissible edges, which contains the edges that can be used for the installation of pipes to connect the tank(s) and engine room(s) for the fuel type under consideration. This model choice enables us to consider different fuel types in the future.

Our problem consists of three components: (i) a graph consisting of vertices and (feasible) edges; (ii) a set of (feasible) pipes, which depends on the fuel type under consideration; and (iii) the cost parameters for the installation of a pipe on an edge. A feasible solution connects each terminal group’s tank(s) and engine room(s), only uses feasible pipes and edges, and can install pipes in advance that might be redundant for now but may become useful in the future.

## Deterministic optimization: a naive benchmark model

Deterministic optimization aims to connect the terminal group’s tanks(s) and engine room(s) while only using feasible pipes and edges with as little installation costs as possible. Mathematically, we can formulate the deterministic mathematical optimization problem as

$$(\text{DO}) \quad \min_{\mathbf{S} \in \mathcal{M}(I)} F(I, \mathbf{S}_0, \mathbf{S}) = \min_{\mathbf{S} \in \mathcal{M}(I)} \sum_{(p, (u, v)) \in \mathbf{S} \setminus \mathbf{S}_0} \gamma_{puv}. \quad (1)$$

We denote our problem by  $I$  and the set of all feasible solutions by  $\mathcal{M}(I)$ . We introduce the set  $\mathbf{S}_0$  of pipe-edge pairs that describe which pipes already exist on which edge to consider previous stages in time. For example,  $(p, (u, v)) \in \mathbf{S}_0$  represents pipe  $p$  which is installed at edge  $(u, v)$ . We denote the cost of solution  $\mathbf{S} \in \mathcal{M}(I)$  for instance  $I$  when pipe-edge pairs  $\mathbf{S}_0$  are present by  $F(I, \mathbf{S}_0, \mathbf{S})$ . In (1), we find the feasible solution with the lowest installation costs that are required to connect each terminal group’s tank(s) with the engine room(s). We compute these costs per feasible solution by summing the installation costs of all the pipe-edge pairs that we have to install except for the ones that are already “pre-installed”. For deterministic optimization, it holds that  $\mathbf{S}_0 = \emptyset$  as no pipes have been pre-installed.

We cannot directly solve the problem described in (1) with (commercial) solvers, but we need the corresponding Integer

**Figure 2:** Optimal pipe routes for Figure 1b according to the three mathematical models. The red solid and dotted lines represent the pipes we installed in the first and second stages, respectively. Note that for simplicity, we have not yet distinguished between single- and double-walled pipes. In Figure 2c,  $p_2$  denotes the probability that the methanol tank must be connected to the engine room. We will discuss these probabilities later.

Linear Optimization (ILO) model. If we apply this model to the pipe routing problem sketched in Figure 1b, we install a pipe on the edge between vertices A and D, as shown in Figure 2a. However, a possible retrofit to methanol would be expensive, especially when installation costs increase, which is typically the case in the maritime industry. Our deterministic optimization model is naive as it does not consider any other (future) scenario than the present. Throughout the rest of this work, this model will mainly serve as a benchmark to compare with the other two models, which will be explained in the following section.

### Adding uncertainty is useful for future-proof design

Pruyn (2017) states that ship owners typically design their ships for the current economic situation, leading to future sub-optimality. Retrofitting a ship is not preferable as it comes with considerable costs due to its downtime and complex maintenance. To prevent these high costs, ship designers must consider alternative fuels in the design phase.

In practice, however, we do not yet know which alternative fuel will be used in the future as this depends on external factors, such as technology improvements, availability, and future costs (Prussi et al., 2021). To capture this uncertainty over time, we consider two time periods in our framework: the present (i.e., first stage) and the future (i.e., second stage). Figure 3 shows these two stages, of which we know the possible outcomes. For instance, we know the fuel a ship will sail on in the present, typically diesel. However, in the future, this could change to a sustainable alternative, such as green methanol, which has different pipe route requirements than diesel. For instance, it can be routed through rooms next to the waterside and requires double-walled pipes. At each stage, we can install pipes to connect the engine room(s) and the fuel tank(s). Unfortunately, the future outcome is unknown due to uncertainty, adding another layer of complexity to the problem.

**Figure 3:** Two-stage scenario tree which describes our problem setting: we start with the diesel scenario in the present, but it is unknown which scenario will take place in the future. We assume that we can install pipes in the first- and second-stage and that we know the probabilities of each future scenario, i.e.,  $p_1$  corresponds to the probability of a future diesel scenario. This work only considers two future scenarios, diesel and methanol, which are colored black in the scenario tree. The other scenarios are not studied in this work and are therefore colored gray.

To illustrate the value of considering future scenarios, we use the example from Figures 1 and 2. In the first stage, the ship sails on diesel, whereas in the second stage, it is uncertain whether a transition to methanol is required. As Figure 2a shows, the deterministic optimization model suggests installing a pipe on the edge between the diesel tank (vertex A) and the en-

gine room (vertex D), leading to high second-stage costs in case a transition to methanol takes place. To prevent this situation, we can prepare for the transition by connecting both the diesel and methanol tank (vertices B and D) to the engine room (vertex A), as shown in Figure 2b. We call this way of modeling robust optimization, which is rather expensive and might yield redundant pipes. The route in Figure 2c lies between deterministic and robust optimization. The pipe installation between the void (vertex C) and the methanol tank depends on the probability of the methanol scenario and the installation costs on that edge. This way of modeling is a form of the stochastic optimization model. Although this route seems inefficient for the diesel scenario, it prepares the ship for a possible transition to methanol in the future and balances current and (expected) future costs.

**Figure 4:** Expected costs of the three routes shown in Figure 2 and the stochastic optimization model (3). As (3) considers the probabilities of the future scenarios, it follows the minimum of the expected costs of the three routes shown in Figure 2.

Figure 4 shows the expected costs of the three pipe routing options for our example on the y-axis and the probability of the methanol scenario on the x-axis. Here, we assume that installing a pipe on an edge in the second stage is twice as expensive as the corresponding first-stage costs. Hence, we can compute the route costs shown in Figure 2a with  $1.5 + 4p_2$  where  $p_2 \in [0, 1]$  represents the probability of the methanol scenario. In contrast, the robust route costs shown in Figure 2b yield a horizontal line at €3 as the costs do not depend on any probability. Finally, we can compute the costs from the route of Figure 2c with  $2 + 2p_2$ . The grey dashed area indicates where stochastic optimization outperforms deterministic and robust optimization. Hence, this toy example illustrates that the only way to make the best pipe routing decisions is to explicitly include uncertainty in our mathematical models.

## Extending the deterministic model: robust and stochastic optimization

As discussed, we want to include uncertainty in our models. Stochastic optimization (SO) and robust optimization (RO) consider uncertainties and variability in real-world optimization problems, but each follows a different approach. While SO requires distribution information and, in our case, optimizes the *average* case, RO uses the support of the uncertain parameters and optimizes the *worst* case. We refer the reader to Birge and Louveaux (2011); Klein Haneveld et al. (2020) and Ben-Tal et al. (2009); Gorissen et al. (2015) for extensive discussions on SO and RO, respectively. Their application in the context of ship pipe routing is novel.

To model different future scenarios, we introduce a set of second-stage scenarios  $s \in \mathcal{S}$ , where each scenario corresponds to one fuel type. We can almost exactly reuse the notation for the deterministic optimization model: we only introduce a superscript ( $s$ ) for scenario  $s$ . For example,  $I^{(s)}$  denotes a pipe routing problem in scenario  $s$  and  $\mathbf{S}^{(s)}$  represents the decisions taken in scenario  $s$ . The installation costs of a pipe  $p$  at a particular edge  $(u, v)$  is given by  $\gamma_{puv}^{(s)} = \gamma_{puv} \cdot \nu_{uv}$  where  $\nu_{uv} \geq 1$  is the increase rate.

**Robust Optimization** We formulate the robust optimization model in which we anticipate the *worst-case* future scenario as follows:

(RO)

$$\min_{\mathbf{s} \in \mathcal{M}(I)} \left( F(I, \emptyset, \mathbf{S}) + \max_{s \in \mathcal{S}} \min_{\mathbf{s}^{(s)} \in \mathcal{M}(I^{(s)})} \left( F(I^{(s)}, \mathbf{S}, \mathbf{s}^{(s)}) \right) \right) \quad (2a)$$

$$= \min_{\mathbf{s} \in \mathcal{M}(I)} \left( \underbrace{\sum_{(p,(u,v)) \in \mathbf{S} \setminus \mathbf{S}_0} \gamma_{puv}}_{\text{First stage costs}} + \underbrace{\max_{s \in \mathcal{S}} \min_{\mathbf{s}^{(s)} \in \mathcal{M}(I^{(s)})} \sum_{(p,(u,v)) \in \mathbf{S}^{(s)} \setminus \mathbf{S}} \gamma_{puv}^{(s)}}_{\text{Second stage (retrofit) costs}} \right). \quad (2b)$$

The minimization in (2b) depends on the first- and second-stage costs. For the first-stage costs, we do not have to consider the pipe-edge pairs from the set  $\mathbf{S}_0$  as these are pre-installed. For the second-stage costs, we minimize the total installation costs of the worst-case scenario, hence the combination of minimization and maximization. The pipe-edge pairs installed in the first stage can be considered as “pre-installed” in the second stage and do not have to be considered when computing the second-stage costs.

**Stochastic Optimization** The stochastic optimization problem (SO), which aims to minimize the *sum of expected costs*, can be formulated as:

(SO)

$$\min_{\mathbf{s} \in \mathcal{M}(I)} \left( F(I, \emptyset, \mathbf{S}) + \mathbb{E}_{\mathbb{S}} \left[ \min_{\mathbf{s}' \in \mathcal{M}(I^{\mathbb{S}})} \left( F(I^{\mathbb{S}}, \mathbf{S}, \mathbf{s}') \right) \right] \right) \quad (3a)$$

$$= \min_{\mathbf{s} \in \mathcal{M}(I)} \left( \underbrace{\sum_{(p,(u,v)) \in \mathbf{S} \setminus \mathbf{S}_0} \gamma_{puv}}_{\text{First stage costs}} + \underbrace{\mathbb{E}_{\mathbb{S}} \left[ \min_{\mathbf{s}' \in \mathcal{M}(I^{\mathbb{S}})} \sum_{(p,(u,v)) \in \mathbf{S}^{(s)} \setminus \mathbf{S}} \gamma_{puv}^{(s)} \right]}_{\text{Second stage (retrofit) costs}} \right), \quad (3b)$$

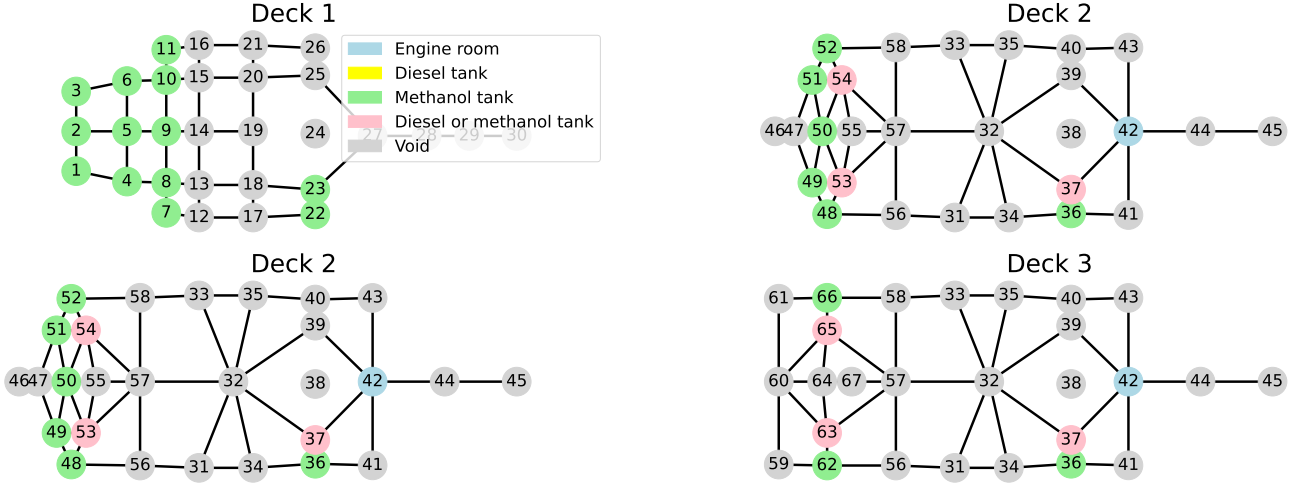

where  $\mathbb{E}$  denotes the expectation and  $\mathbb{S}$  represents a discrete random variable for the future scenario with a known distribution, i.e.,  $\Pr(\mathbb{S} = s)$  is known for all  $s \in \mathcal{S}$ . The minimization from (3b) differs from (2b) in the second-stage costs. Instead of minimizing the costs of the worst-case scenario, the expected costs over the future scenarios are computed.

## RESULTS

We concluded from discussions with maritime experts that pipe installation costs largely depend on the location in the ship. Therefore, we study the impact of a location-dependent cost increase on the pipe route and the corresponding costs. In the following, we elaborate on the used data and then explain the experimental setup. After this, we provide the results of our numerical experiments, including a discussion and analysis of the value for considering uncertainty. To solve the models from (1), (2), and (3) with (commercial) solvers, we use the corresponding ILO formulations.

### Ship modelling and data

For this work, we have collaborated with a commercial shipyard company that provided us with data from a state-of-the-art ship consisting of four decks. As it is not trivial to visualize the original data, a 3D network of 75 compartments on the ship and 156 edges, we use four 2D graphs. Figure 5 shows the result, where the vertex colors indicate whether a room contains an engine, a fuel tank, or a void. We have data on the location of diesel and methanol tanks due to the work of Minderhoud (2023). We chose this specific ship as it contains a moonpool, which makes pipe routing more complex as it restricts routes.

**Figure 5:** Four 2D graphs representing the data we obtained from the shipyard and Minderhoud (2023). The vertex colors indicate whether a room contains an engine or tank or can be seen as a void, and indicate that there are rooms that can be both diesel and methanol tanks. Note that there are no rooms that can only contain diesel (and no methanol) tanks, hence no vertex is colored yellow. The lines indicate the edges on which we can install pipes. Vertices 24, 38, and 70 correspond to the moonpool.

Similarly to the example in Figure 2, we assume that we start with diesel in the first stage and might transition to diesel or methanol in the second stage. The locations of the diesel and methanol tanks and the engine room are shown in Figure 5. We cannot route diesel pipes through the double bottom or rooms adjacent to the water. Furthermore, we can use single- or double-walled pipes for diesel, but only double-walled pipes for methanol.

## Experimental setup

We carried out numerical experiments to study the impact of the cost increase from single- to double-walled pipes ( $\eta$ ) and the cost increase from first to second stage ( $\nu_{uv}$ ) on the pipe route and the corresponding costs. First, we use the Manhattan distance between the vertices for the costs  $\gamma_{1uv}$  of installing a single-walled pipe in the first stage, or mathematically:  $\gamma_{1uv} = d(u, v)$ , where  $d(u, v)$  denotes the Manhattan distance between the vertices  $u$  and  $v$ . We chose this distance measure because it reflects the natural distance a pipe travels. Next, we assume that double-walled pipes are more expensive than single-walled:

$$\gamma_{2uv} = \eta \cdot \gamma_{1uv},$$

where typically  $\eta = 2$ . However, in our experiments, we will study the impact of  $\eta$  on the pipe route and its corresponding costs. We introduce  $\nu_{uv}$ , which is the increase rate from first- to second-stage costs for installing a pipe on edge  $(u, v) \in \mathcal{E}$ :

$$\gamma_{puv}^{(s)} = \nu_{uv} \cdot \gamma_{puv}.$$

The simplest parameter definition for  $\nu_{uv}$  is a homogeneous cost increase rate, which we assume to be equal to 2 for now

$$\nu_{uv} = 2, \forall (u, v) \in \mathcal{E}, \quad (4)$$

In other words, the increase rate from the first- to the second-stage costs is the same for each pipe-edge pair. As suggested by the maritime experts, it is more realistic to make  $\nu_{uv}$  dependent on the location in the ship. For example, they suggested that retrofitting the pipe network might be more expensive in rooms adjacent to the engine room or tanks than in a void.

We have incorporated this intuition into two parameter definitions, one only depends on the distance to the engine room whereas the other depends on the function of the rooms. We chose these definitions to study the difference in impact on pipe routes and the costs. First definition looks as follows

$$\nu_{uv} = \frac{\max_{(a,b) \in \mathcal{E}} \{d(a, \text{ER}) + d(b, \text{ER})\}}{d(u, \text{ER}) + d(v, \text{ER})}, \quad (5)$$

where ER denotes the vertex representing the engine room. In (5), the value of  $\nu_{uv}$  decreases as the distance between ER and the vertices  $u$  and  $v$  increases. Note that  $\nu_{uv}$  is always bigger than or equal to 1 for all edges. The intuition behind (5) is that the further an edge lies from the engine room, the lower the complexity of the retrofit and hence the lower the increase rate for the second stage costs. The second definition for  $\nu_{uv}$  looks as follows:

$$\nu_{uv} = \begin{cases} 6 & \text{if } u \text{ or } v \text{ is ER,} \\ 3 & \text{if } u \text{ or } v \text{ is a tank,} \\ 2 & \text{otherwise.} \end{cases} \quad (6)$$

The intuition behind (6) is that retrofits near the engine room are the most expensive, as many essential elements of the ship are close to each other in a narrow space. Additionally, retrofitting through a tank is expensive as additional safety measures are required for the pipe routing. Finally, routing through a void is cheaper but still relatively expensive, as we should consider the costs of not sailing and the complexity of the installation.

Finally, all experiments are executed on a laptop with four cores and CPU 1.2GHz using the Gurobi solver Gurobi Optimization, LLC (2023) for our Python code, which is available upon request.

### Numerical experiments: studying the impact of two cost increase rates ( $\nu_{uv}$ and $\eta$ )

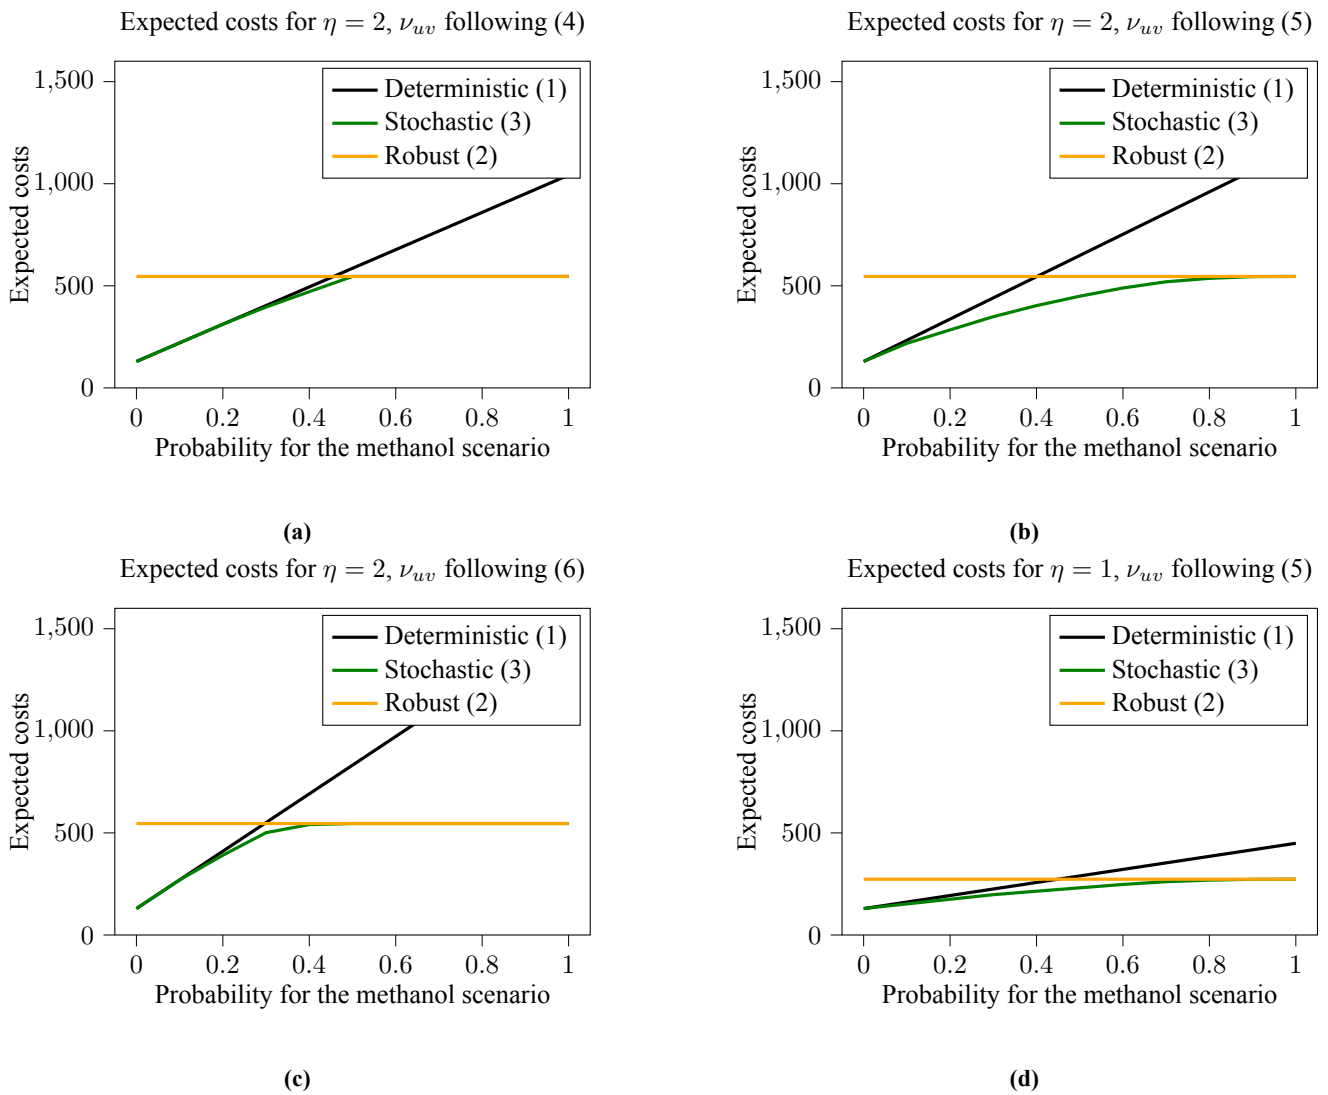

In the following, we will divide our numerical experiments, which consist of a parameter study, into two parts: the impact of  $\nu_{uv}$  and  $\eta$  on the pipe route and the corresponding costs.

**Figure 6:** Distribution of the  $\nu_{uv}$ -values under the two parameter definitions (5) and (6).

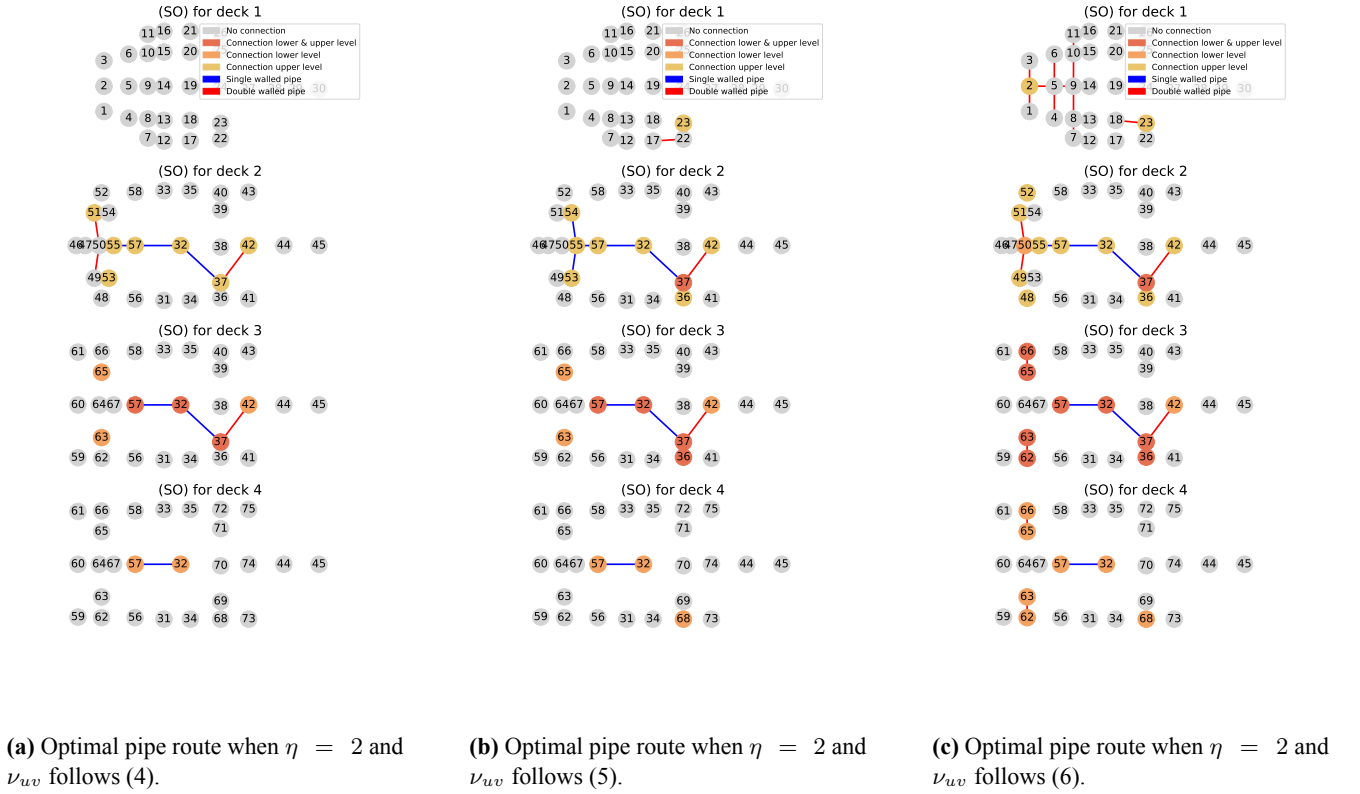

**Increase rate from first- to second-stage costs ( $\nu_{uv}$ )** The two proposed parameter definitions (5) and (6) yield considerably different distributions for  $\nu_{uv}$  as shown in Figure 6. In Figure 6a, which displays the values of  $\nu_{uv}$  on the x-axis and the frequency on the y-axis, we see a skewed distribution, which indicates that most edges have relatively low increase rates, whereas only a few yield extreme values. In Figure 6b, which is a pie chart of the  $\nu_{uv}$ -values, we see a small number of edges connected to the engine room and many edges connected to a fuel tank.

Recall that we use three parameter definitions for  $\nu_{uv}$ : (4), (5), and (6). A consequence of these different definitions is a difference in expected costs between the mathematical models as shown in Figure 7, where  $\eta = 2$ . The three figures display the probability of the methanol scenario on the x-axis, the expected costs on the y-axis, and the three mathematical models colored by different colors. Figure 7a shows that the stochastic optimization model slightly outperforms the deterministic and robust optimization model in a small range of probability values. This gap becomes larger in Figure 7c and even larger in Figure 7b, which shows that the heterogeneity of  $\nu_{uv}$  yields more cost efficiencies for the stochastic optimization models than for the deterministic and robust optimization models. Hence, we conclude that the value of stochastic optimization is enhanced by heterogeneous cost increase rates.

**Figure 7:** Expected costs of the three mathematical models under different parameter settings. It shows that more heterogeneous cost rates lead to more cost efficiencies for the stochastic optimization models than the deterministic and robust optimization models.

Besides the expected costs of the three models, we are also interested in how the corresponding optimal pipe route looks. Figure 8 shows the result of stochastic optimization with equal probabilities for each future scenario using the parameter settings  $\eta = 2$  and  $\nu_{uv}$  according to (4), (5), and (6). The blue and red lines indicate an installation of a single- or double-walled pipe on the corresponding edge, respectively. The vertex colors tell if a vertex is connected to a lower and/or upper deck via a pipe. We see that the pipes go via the ship's starboard side due to rooms 22, 23, 36, and 37 that contain fuel tanks. We make two observations in Figure 8. First, Figure 8a contains the least pipes and second, does not contain many double-walled pipes. On the other hand, Figure 8c contains the most pipes and already installs double-walled pipes in the double-bottom to prepare for the methanol scenario. In other words, we see that Figure 8b and Figure 8c prepare better for a possible methanol scenario than Figure 8a as shown in the first decks. As Figure 8a is based on homogeneous cost increase rates, they do not differ between edges based on their location in the ship. We already installed double-walled pipes between vertices 17, 22, and 23 in Figure 8b as these are close to the engine room and are relatively expensive to install in the second stage. Additionally, we see a difference in the pipe routes between Figure 8b and Figure 8c. We explain this result using the difference between Figure 6a and Figure 6b, where (5) mostly yields considerably smaller values for  $\nu_{uv}$  than (6) despite the fact that the outliers from (5) are considerably higher than the highest value for  $\nu_{uv}$  in (6). Consequently, the second stage becomes more expensive for (6), and stochastic optimization will install more pipes in the first stage to prevent expensive retrofits.

**Figure 8:** Optimal pipe routes based on (3) under different parameter settings with equal probabilities for the two future scenarios. Figure 8a contains the least pipes, whereas Figure 8c contains the most.

**Increase rate from single- to double walled pipes ( $\eta$ )** To illustrate the findings of the numerical experiments, we compare Figures 7b and 7d, which correspond to  $\nu_{uv}$  following (5) with  $\eta = 2$  and  $\eta = 1$ , respectively. These values were chosen for simplicity reasons. We see that  $\eta$  positively correlates with the expected costs because it directly impacts both first- and second-stage costs. For example, the costs for robust optimization are considerably higher for  $\eta = 2$  in Figure 7b

than for  $\eta = 1$  in Figure 7b. Additionally,  $\eta$  influences the relative cost behavior: stochastic optimization still outperforms deterministic and robust optimization, but the range of probabilities under which this happens changes with  $\eta$ . Figures 7b and 7d a larger probability range for  $\eta = 1$  than for  $\eta = 2$ . In other words, when the installation costs of double- and single-walled pipes become more similar, which is realistic, the stochastic solution becomes more powerful compared to deterministic and robust optimization.

## CONCLUSION

Motivated by ship pipe routing under the uncertainty of the energy transition, we have applied the mathematical framework to realistic, complex situations of realistic ship data from a commercial ship designer. In collaboration with maritime design experts we have implemented design constraints in these models: deterministic, robust, and stochastic optimization models. Using these models, we analyzed the impact of realistic location-dependent costs for installing pipes on the pipe route and the corresponding costs. For a more elaborate overview of the different models, we refer the reader to Markhorst et al. (2023).

We find that realistic, heterogeneous cost increase rates depending on the location in the ship enforce the usefulness of stochastic optimization compared to deterministic and robust optimization. More specifically, in our experiments, this effect also depends on the relation between double- and single-walled pipe costs. We see this difference in the corresponding optimal pipe routes as well because the rooms containing an engine or tank get considerably more expensive for retrofits in the future. Consequently, we install most pipes near these sensitive areas in the first stage. Our results show the value of considering uncertainty in ship pipe routing for which our models can be used. Discussions with the maritime experts show that our methods can lead to cost reduction and decreased (financial) risk for ship owners. Additionally, our methods allow the engineers to consider various degrees of preparation for the energy transition with limited effort in the early design stage.

Future research could focus on methods that solve larger instances of the SSFP, which enable ship designers to include even more details in the (graph-)data. Furthermore, we could include more constraints from Lloyd's Register (2023), allow multiple fuel types (i.e., hybrid solutions) in one scenario, and include multiple decision stages over time to make the models more realistic. Finally, we could add other piping and cable infrastructure that may interact with the fuel piping system to our optimization models, to further reduce both costs and risks.

## ABSTRACT

*The design process of motor yachts mainly relies on the experience of designers, who have confidence in the knowledge acquired from designing units with similar hull-form characteristics. However, once a new concept needs to be developed, the acquired experience on a standard platform is no longer sufficient to achieve in a short time a successful design. The design of a motor yacht implies considering multiple aspects of ship hydrodynamics: resistance, propulsion, seakeeping, and manoeuvring. Such factors have been widely discussed individually on different kinds of ships, but an appropriate joint investigation of hulls like motor yachts is missing in the open literature. Therefore, the present paper intends to cover this gap, providing guidelines for the design of motor yachts in a length range between 20 and 40 meters. As a preliminary study, a series of 15 yacht hulls has been developed, starting from a reference hull form. Seakeeping, manoeuvring, and propulsive performances have been evaluated at a reference environmental condition and speeds according to the ISO 22834:2022 guidelines. Such calculations allow for developing response surfaces of the hydrodynamic properties for the series of yachts as a function of the hull's main dimensions. As a final result, the obtained responses allow for identifying the best compromise solutions for the main dimension selection of a new motor yacht in the length range of 20-40 meters.*

## KEY WORDS

Large-yacht; ship design; multi-attribute design; hydrodynamic performances

## INTRODUCTION

Designing a motor yacht involves several key considerations, including the size of the yacht, its intended use, materials, propulsion system, interior layout, and aesthetic features. More precisely, it is necessary to identify since the beginning of the project the primary use of the vessel (cruising, entertaining, fishing or a combination of them) to evaluate the operative profile of the large yacht, the estimation of crew and passengers and a preliminary definition of the internal spaces (number of cabins, living rooms, etc.). Afterwards, a crucial part of the design process concerns the estimation of the vessel's size and style. The sizing focuses on the selection of the main dimensions of the unit (length, breadth, draught, and a preliminary estimate of displacement), the style is the design theme of the yacht, which means, as an example, if it is a conventional bow, vertical bow, a sport yacht or an explorer unit (Ansaloni et al, 2024). Subsequently, all the decisions concerning the propulsion system (conventional, podded or hybrid electric solutions) and the definitive hull design need to be taken, before considering the definitive internal layout and the aesthetic of the external shape and interiors (Mancuso & Tumino, 2022, Mauro et al. 2021a). However, for the specific case of concept design, the most essential part is to determine the sizing of the vessel, which means choosing the best combination of hull dimensions leading to a given displacement and granting the achievement of some performance criteria concerning relevant attributes for the vessel (Papanikolaou, 2014, Papanikolaou et al., 2022).

The design is generally based on the designers' confidence in the knowledge acquired from the design of units with the same hull-form characteristics. This approach is worthy once sister units must be built but is not advisable for the development of a new concept. Therefore, general guidelines are needed to achieve a successful new design in a short time.

The design of a motor yacht implies considering multiple aspects of ship hydrodynamics: resistance, propulsion, seakeeping, and manoeuvring, respectively. Such factors have been widely discussed individually on different kinds of ships (Tonelli et al., 2015), but an appropriate joint investigation of small hulls like motor yachts is missing in the open literature. The only guidelines available in the recent literature concern solely the vertical motions in waves (Ivanova & Gyurov, 2022, Begovic et al. 2023a, Begovic et al. 2020) or dedicated studies on the hybrid-electric propulsion (Geertsma et al., 2017, Bucci et al. 2020, Coppola et al. 2022, Begovic et al. 2022) or dynamic positioning of such units (Mauro et al. 2021b). A comprehensive analysis of the effect of different hull forms on the overall hydrodynamic performances of a motor yacht is not yet available, also considering that the relations between hull form parameters and hydrodynamic performance may lead to counteracting solutions while considering, as an example, propulsion or seakeeping characteristics.

To fill the gap between designers' needs and what the actual literature offers, this work presents a preliminary investigation of the effect of main dimensions on the hydrodynamic performance of a motor yacht. The study covers the estimation of some peculiar hydrodynamic attributes of a motor yacht, concerning resistance, seakeeping and manoeuvring characteristics. To this end, it is necessary to build a design space, starting from a reference hull and changing parametrically the main dimensions; here the variations are limited to the length, the breadth and the immersion, keeping the hull form coefficients constant. With this approach, a design space has been built with the design of experiment techniques, applying a central composite design. From the process, 14 hulls have been derived from the initial hull form, by systematically changing the length, the breadth and the draught. For all hulls, resistance, seakeeping and manoeuvring calculations have been carried out for speed and heading conditions derived from the ISO 22834:2022 guidelines. More precisely, resistance parameters have been calculated with viscous flow CFD calculations. Seakeeping performances have been assessed with a linear 2D strip theory code and manoeuvring performances with rigid-body time domain simulations. The results formed a database of hydrodynamic attributes that can be analysed with multiple linear regression techniques and finally regressions of the attributes as exclusive functions of the main dimension of the vessel have been performed.

The present paper describes in the first section the definition of the design space. Section 2 describes the hydrodynamic calculations performed on the 15 hulls composing the design space. Section 3 reports the multiple linear regression analysis and, finally, section 4 reports an example of the applicability of the obtained regression to identify the effect of hull forms on the hydrodynamic performances of the large-yacht.

The results reported in this paper are promising for the definition of hydrodynamic performances in the early design stage of a motor yacht and encourage future studies on a wider range of hull form variations, including also hull form coefficients.

## THE DESIGN SPACE

The present study investigates the hydrodynamic performances of motor yachts for optimal dimension investigations during the concept design phase of a new unit. To this end, it is necessary to develop mathematical instruments, like response surfaces, for capturing the variations of relevant hydrodynamic quantities with the vessels' main dimensions. In this sense, it is necessary to select a reference vessel and a set of geometrical transformations for the main parameters (applying the design of experiments) to form a design space suitable for regression analyses. In the following sections, the reference hull form is described, together with the parametric variations leading to the definition of the 15 hull forms composing the database.

### Parent hull form

The reference hull form has been designed specifically for the present study. The main dimensions of the parent hull have been determined based on a preliminary analysis of the yacht database available at MARIN. The main particulars of the hull are listed in Table 1, while the transversal sections of the vessel are given in Figure 1.

**Table 1: Reference hull main particulars**

Quantity	Value	Quantity	Value
Length between perpendiculars (m)	30.00	Block coefficient (-)	0.563
Length on waterline (m)	29.99	Midship coefficient (-)	0.846
Breadth (m)	7.5	Prismatic coefficient (-)	0.665
Draught (m)	1.625	Waterline coefficient (-)	0.817
Volume (m <sup>3</sup> )	205.768	Vertical prismatic coefficient (-)	0.689

**Figure 1: Body sections of the reference hull form.**

**Table 2: Hull form variations starting from the original hull form.**

Hull Number	$L_{BP}$ (m)	$B$ (m)	$T$ (m)	Volume (m <sup>3</sup> )
HULL 1	20.0	6.0	1.250	84.418
HULL 2	20.0	6.0	2.000	135.068
HULL 3	20.0	9.0	1.250	126.626
HULL 4	20.0	9.0	2.000	202.602
HULL 5	40.0	6.0	1.250	168.835
HULL 6	40.0	6.0	2.000	270.137
HULL 7	40.0	9.0	1.250	253.253
HULL 8	40.0	9.0	2.000	405.205
HULL 9	20.0	7.5	1.625	137.179
HULL 10	40.0	7.5	1.625	274.357
HULL 11	30.0	6.0	1.625	164.614
HULL 12	30.0	9.0	1.625	246.922
HULL 13	30.0	7.5	1.250	158.283
HULL 14	30.0	7.5	2.000	253.253
HULL 15 (original)	30.0	7.5	1.625	205.768

The initial hull represents an example of a yacht that can be used to study parametric variations of the main dimensions ranging from a length of 20 to 40 metres. In the following section, more details are given about the ranges and transformations performed on the reference hull form.

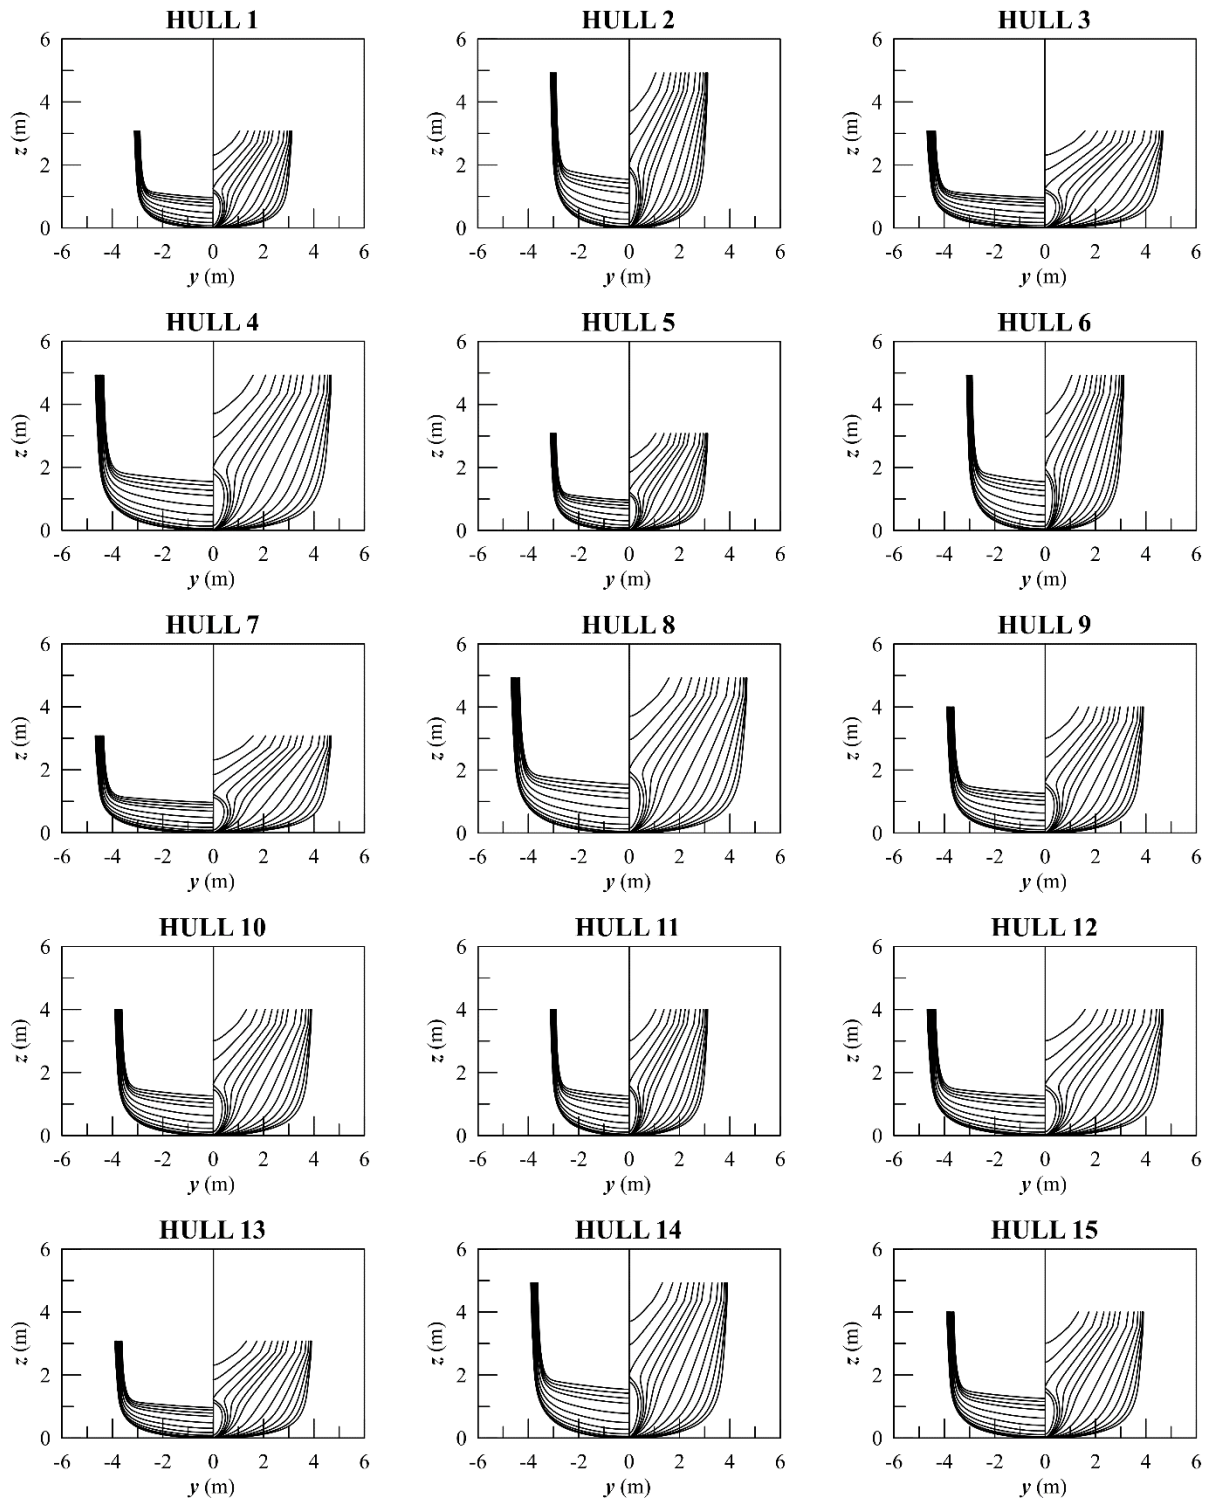

### Hull form variations

Starting from the parent hull form, a set of 15 hull forms has been developed by systematically changing the main dimensions. As a simplification, the hull form coefficients have been kept constant and equal to the parent hull, as reported in Table 1. Then, by applying the design of experiment techniques (DoE) (Chang, 2008, Myers et al. 2008), a Central Composite Design (CCD) has been chosen to represent the 15 design variations (Beaver et al, 1977, Montgomery, 2009). The main dimensions of the resulting matrix of hull forms are reported in Table 2 and in Figure 2. The variations performed on the original hull forms led to the following range of main dimensions:

$$\begin{aligned}
 20.0 < L_{BP} < 40.0 \\
 6.0 < B < 9.0 \\
 1.25 < T < 2.00
 \end{aligned}
 \tag{1}$$

This is an approximation that may affect the final results, as coefficients may influence the hydrodynamic performances. From a manoeuvring point of view, the choice of keeping the coefficients constant is in line with typical preliminary studies, as for instance, Clarke's diagram (1977) that shows the dynamic stability boundaries per block coefficient as a function of the length

to breadth  $L/B$  and breadth to draught  $B/T$  ratio. However, this is a starting point to develop a methodology for the preliminary design stage that may be improved with time by adding more hull form variations considering also changes in the hull form coefficients.

**Figure 2: Body sections of the 15 hull forms.**

The choice of a CCD design has a consequence on the type of analysis that can be carried out on the resulting hull series. In fact, any attribute relevant to a single hull can be described with at most a full quadratic model. Therefore, having in mind to derive multiple linear regressions on the resulting datasets, such a limitation should be taken into strict consideration as a bound for the research.

## HYDRODYNAMIC CALCULATIONS

The crucial part of building design instruments for the preliminary design of a new vessel concerns the reliability of the initial dataset used to form the tools themselves. As such, the modern methodologies employed for the numerical estimation of hydrodynamic performances grant reaching high level of reliability, enhancing the accuracy of initial prediction. In the open literature, it is not common to find methods aiming at preliminary design relying on first-principle calculations

The main aspects to focus on for this study, concerning the hydrodynamics of large yachts, relate to the behaviour of the vessel while sailing in calm water, in waves and during a manoeuvre. Different tools have been used to evaluate the hydrodynamic performances for the specific characteristics needed to describe the behaviour of the vessel. In the specific, for the behaviour in calm water, i.e. resistance and dynamic trim, viscous flow CFD (Computational Fluid Dynamics) calculations have been performed. The behaviour of the vessel in waves has been assessed through strip-theory calculations, with a focus on the comfort characteristics of the yacht. Concerning the manoeuvring, time-domain simulations have been carried out to determine the yaw, checking turning ability of the vessel. In the following sections, a more detailed description of the performed calculations is given together with the parameters selected as principal attributes for the hydrodynamic description of a yacht.

### Resistance Calculations

Resistance calculations have been carried out with the MARIN's in-house CFD (package ReFRESKO (<https://www.marin.nl/en/facilities-and-tools/software/refresco>)). ReFRESKO is a community-based, open-access CFD code for the maritime sector. It solves multiphase unsteady incompressible viscous flows using the Navier-Stokes equations, complemented with turbulence models, and volume-fraction transport equations for different phases. The equations are discretised using a finite-volume approach with cell-centred collocated variables. A pressure-correction equation based on the SIMPLE algorithm is used to ensure mass conservation. Time integration is performed implicitly with second-order backward schemes. ReFRESKO is currently being developed, verified and its several applications validated at MARIN in collaboration with several worldwide known non-profit organisations.

The computational grids used in this study were generated using the software Hexpress. Surface refinements were used on the ship hull itself to provide space resolution to resolve the near-wall flow. The surface refinement was then complemented with three groups of boxes, defined to further improve space resolution in the near and far-field flow. The computations were performed at full scale and the computational domain size was chosen sufficiently large to ensure that the influence of the boundary conditions on the flow solution was negligible

For the specific case study, CFD simulations have been carried out in calm water, at a speed of 12 knots and results are presented in terms of total resistance (Larson and Raven, 2010) and dynamic trim. Resistance results include a correlation allowance ( $C_A$ ) which incorporates the drag due to hull roughness, still-air drag of the hull and superstructures. For the dynamic trim, positive values indicate a bow-down trim, while negative values indicate a stern-down trim.

### Seakeeping Calculations

To evaluate the seakeeping characteristics of the developed series of yachts, the new regulation ISO 22834:2022 has been applied to estimate the global comfort level. ISO 22834:2022 considers the Effective Gravity Angle (EGA) and the Motion Sickness Incidence (MSI) as key performance indicators for global comfort, which is afterwards translated into a star rating system ranging from one star (poor) to five stars (excellent). The assessment is performed by evaluating the EGA and MSI, at a reference heading of 135 deg and for speeds of 0 and 12 knots, across five locations along the yacht: the beach club (BC), the crew area (CA), the dining area (DA), the owners' cabin (OC), and the wheelhouse (WH).

The coordinates of the locations onboard the 15 vessels have been assumed according to the reference used by the authors in previous publications (Begovic, et al. 2023a, Mauro et al 2021). Table 3 reports the coordinates used for the calculation in non-dimensional form, as a function of the length between perpendicular  $L_{BP}$ , the breadth  $B$  and the draught  $T$ .

**Table 3: Nondimensional coordinates for considered locations.**

	BC	CA	DA	OC	WH
<b>x/LBP</b>	0.06	0.90	0.43	0.83	0.73
<b>y/B</b>	0.00	0.00	0.00	0.00	-0.23
<b>z/T</b>	1.81	1.09	2.54	3.26	3.99

For all the hulls, the longitudinal position of the centre of gravity has been set to have a zero-trim condition at rest. The vertical position of the centre of gravity has been calculated by taking the transverse metacentric height equal to 10% of the breadth at the waterline, to guarantee a uniform application of seakeeping calculations.

The evaluation of EGA and MSI for each location and speed requires knowledge of the Response Amplitude Operators (RAOs) of the ship motions for the 5 locations at a heading of 135 deg and the speeds of 0 and 12 knots. For this purpose, use has been made of the software ShipX, based on the strip theory as developed by Salvesen et al. (1970).

For each vessel the comfort level has been evaluated according to a number from 0 to 100, reflecting the percentage scale of the star system reported in the ISO rules. The final level of comfort is then assessed with the following weighted sum:

$$ISO_{TOT} = \sum_{i=1}^2 \sum_{j=1}^{N_l} \sum_{k=1}^{N_{T_z}} w_{v_i} w_{l_j} w_{T_{z_k}} I_{ijk} \quad [2]$$

Where  $w_v$ ,  $w_l$  and  $w_{T_z}$  are the weights for speed, locations and wave periods, respectively.  $I$  is the functional that accounts for the satisfaction of the criteria imposed by ISO 22834:2022. The functional is equal to 1 when both EGA and MSI are under the given thresholds (2 deg for EGA and 10% in one hour of exposure time for MSI). The functional is equal to 0 if at least one criterion is not fulfilled.

To have a more detailed description of the trends in EGA and MSI in different locations, the assessment can be performed also at a local level, considering each location individually and for each sea state, reducing equation (2) to just a summation of the weights for the reference wave periods. Alternatively, the comfort can be assessed globally per each speed, reducing equation (2) to the some of weights for locations and wave periods.

In this study, the global evaluation of comfort given by equation (2) has been considered for the calculations.

## Manoeuvring Calculations

To predict the dynamic variation of the motion of a ship, specific manoeuvring simulations have been carried out employing the software ANYSIM XMF. The software computes the motion of a ship resulting from non-linear hydrodynamic and mechanic loading. Ship-specific results from model-test, semi-empirical methods (such as slender body and cross-flow drag theory), and linear frequency domain tools are used for modelling hydrodynamics. Other elements such as rudders, propellers, thrusters, etc. are modelled in the time domain. The equations of motion are integrated through a fourth-order Runge-Kutta method with a fixed time step of 0.1 s. Such a time step is sufficient to have a converged solution. The software can handle the use of both propellers and rudder or pod for the manoeuvring of the vessel.

The simulations need the definition of a linearised stiffness matrix composed of terms derived by the hydrostatics of each one of the 15 hull forms. Besides, the simulations require the definition of a resistance curve or in general a resistance value for the speed of interest. For the specific case of this study, the speed of 12 knots is the target speed for the simulation and the resistance used for the simulation derives directly from the ReFRESCO simulations described in the previous sections. Hydrodynamic forces (damping and added mass) are then computed according to the sectional approach employed in the slender body theory and cross-flow drag theory (Toxopeus, 2006, Hooft, 1994).

The propeller model is based on the B-series, employing for all the hulls the same wake fraction ( $w=0.05$ ) and thrust deduction ( $t=0.15$ ). This is a reasonable approximation for the determination of general guidelines for the preliminary design stage.

Simulations performed include speed runs, zig-zag manoeuvres (both 10-10 and 20-20, i.e. the steering-yaw checking angles) and turning circles. The simulation process has been performed in two steps, employing a tuning process for the yaw moment calculated by the slender body theory. The tuning process employs empirical coefficients derived from the correlation between simulations, model tests and sea trials available at MARIN.

From manoeuvring simulations, there are a lot of parameters that can be used as a main attribute for ship design purposes. Between them, particular attention should be given to the initial turning ability and the yaw checking ability. The initial turning ability, also called course-changing ability, describes the responsiveness of the ship to initiate a turn with a moderate helm. The yaw-checking ability is a measure of the ship reaction to counter steering. It is identified by the response delay when reversing the helm angle of a turning ship. The most relevant manoeuvring characteristics related to these abilities are the overshoot angles and the initial turning distance. The overshoot angle is the heading deviation from the moment the steering device is

reversed to the moment the heading rate of turn is zero. The initial turning distance is the distance travelled in the direction of the original course by the ship from the moment the first steering order of, e.g., 20° is given (first execute) to the moment the heading has changed 20° from its original course.

## Parameter Selection

The simulations performed to determine the hydrodynamic characteristics of the hulls can define multiple attributes as an output of the simulations. However, to proceed with the definition of the design guidelines for the large-yacht in the preliminary design stage, it has been decided to select a reduced number of attributes. Such a decision aims to give a more focused overview of global attributes for the preliminary design, instead of going too much into capillary details in a phase where most of the final details of the project are not defined yet. In any case, the procedure that will be shown in the next section can be applied to all possible attributes derived from hydrodynamic analyses.

The following attributes have been then selected to proceed with the multiple linear regression analysis:

- Resistance at 12 knots, (kN)
- Trim at 12 knots, (deg)
- Global  $ISO_{TOT}$  index for comfort, (-)
- Initial turning ability (from a 20-20 zig-zag manoeuvre), (-)
- Yaw checking ability (from a 20-20 zig-zag manoeuvre), (-)

This set of preliminary attributes grants a comprehensive vision of the operational profile of a motor yacht of small dimensions, capturing issues related to resistance, comfort and manoeuvring. Therefore, the regression analysis has been conducted on the sets of data describing such attributes, by employing a process that will be described in the following section.

## MULTIPLE LINEAR REGRESSION ANALYSIS

In the field of engineering, the Design Of Experiments (DoE) is frequently used to analyse the response of a certain variable as a function of others by reducing the number of observations necessary to describe the variations. This results in a lower effort for experimentation or calculation work. In parallel, Response Surface Methodology (RSM) quantifies the relationship between the controllable input parameters and the obtained response variables. To this end, the following working principle should be pursued:

- Design a set of experiments for an adequate and reliable measurement of the analysed response.
- Develop a mathematical model of the response surface by applying a best-fitting technique.
- Represent the direct and interactive effects of processed parameters through multidimensional plots.

The first step has been already tackled by the definition of the design space of the motor yachts, which is choosing a CCD design for the 15 hulls developed in this study. Therefore, it is necessary to better define the mathematical models employed to identify the response surface for the selected parameters for the hydrodynamic properties of the yachts.

A response surface of a generally measurable variable can be identified by the following equation:

$$y = f(x_1, \dots, x_n) \quad [3]$$

where  $y$  is the output of the process and  $x_i$  are the  $n$  variables of the problem to describe. Under the assumption that the independent variables are continuous and adherent to experiments with negligible errors, a suitable approximation for the relationship between the independent and the independent variables should be found. Adopting a CCD design, it is possible to use a complete second-order model to describe the surface response, following the subsequent general regression model:

$$y = \beta_{0,0} + \sum_{i=1}^n \beta_{i,0} x_i + \sum_{i=1}^{n-1} \sum_{j=i+1}^n \beta_{i,j} x_i x_j + \sum_{i=1}^n \beta_{i,i} x_i^2 + \varepsilon \quad [4]$$

Where  $\beta_{i,j}$  are the unknown parameters and  $\varepsilon$  is the regression error. In the literature, there are several methods available to evaluate the unknown parameters. However, in the specific case of relatively simple models, it is convenient to employ a least square method. Then, equation (4) can be written in the following matrix form:

$$\mathbf{Y} = \mathbf{bX} + \varepsilon \quad [5]$$

Where  $\mathbf{Y}$  is the matrix of the measured values and  $\mathbf{X}$  is the matrix of the independent values. The matrix of independent variables includes not only the variables themselves but also their combinations up to the second order. The matrices  $\mathbf{b}$  and  $\varepsilon$

are the regression coefficients and the errors, respectively. Adopting this matrix formulation, the coefficients matrix can be determined by applying the least square method technique, deriving in the following expression:

$$\mathbf{b} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{Y} \quad [6]$$

Where  $\mathbf{X}^T$  is the transpose matrix of  $\mathbf{X}$  and  $(\mathbf{X}^T \mathbf{X})^{-1}$  is the inverse matrix of  $\mathbf{X}^T \mathbf{X}$ .

For performing the multiple linear regression analysis on the selected dataset of hydrodynamic parameters, use has been made of a stepwise selection process (Harrell, 2001). In the initial step, all the variables are included in the complete second-order model. Afterwards, at each step, a different variable is removed from the equation changing its status (from removed to inserted and vice-versa). For each variable whose status changes, the change in the sum of squared error (SSE) is evaluated and the variable is consequently removed or added to the final model. The process continues automatically until there is no more variable changing the SSE over a given threshold. Moreover, to keep the same threshold in SSE throughout the study, all the dependent and independent variables have been normalised in  $[-1,1]$  before starting the regression procedure. Then the threshold is set to 0.06. To judge the quality of the regression, a key performance indicator has to be selected. Here use has been made of the determination coefficient  $R^2$  and the adjusted determination coefficient  $R^2_{adj}$ . The coefficients are defined as:

$$R^2 = 1 - \frac{SSE}{SS_{tot}} \quad [7]$$

$$R^2_{adj} = 1 - (1 - R^2) \frac{n-1}{n-p-1} \quad [8]$$

where  $n$  is the number of points to fit,  $p$  is the number of variables included in the model (after executing the stepwise procedure) and:

$$SSE = \sum_{i=1}^n (y_i - y_i^*)^2 \quad [9]$$

$$SS_{tot} = \sum_{i=1}^n (y_i - y_M)^2 \quad [10]$$

Being  $y_i$  the datapoint to fit,  $y_M$  the mean value of datapoint and  $y_i^*$  the fitted values derived from the application of regressions. The following section reports in graphical and tabular form the regression performed on the hydrodynamic attributes according to the process that has been here described.

## Surface responses

The procedure for determining multiple linear regression and the associated surface responses described in the previous section has been applied to the data processing of the main attributes defined beforehand.

Table 4 reports the results of the regression analysis, reporting the coefficients together with the quality of the regression assessed through the performance indicators described by equations (7) and (8).

From the results reported in Table 4, it is evident that the general quality of the regression is high. All the values for the  $R^2$  are above 0.9 and the unbiased estimator of  $R^2$ , the  $R^2_{adj}$ , is also high except for the dynamic trim regression. It is interesting to observe that none of the final regressions employ all the estimators of a full quadratic model. Such a matter is the effect of the stepwise iterative procedure used to develop the regression models, which automatically excludes the non-significant terms.

Analysing in detail the individual regressions, for the resistance, it is interesting to observe that the dependence from the vessel length is only linear, no significant higher order, coupled terms are present. Higher order dependency is observed only for the breadth and draught. For the dynamic trim, coupled terms became significant for the length, but still, the higher order is not present. Changing hydrodynamic quantity and going for the analysis of comfort, the regression for the ISO comfort considers all the coupled terms but is missing higher order terms for the length and breadth. The same situation is for the initial turning ability, while for the yawing ability the coupled term between breadth and draught is missing together with all the higher order terms. Such a trend in the significant coefficients does not have a direct explanation for the resulting hydrodynamic properties as the selection of coefficients is purely associated with the automatic selection procedure described in the previous section. It could be possible that with a different dataset as an input to the process, the resulting coefficients would be different, resulting in other conclusions. In fact, even though the multiple linear regression analysis can be classified as a white-box model, the relationship between the data remains difficult to directly analyse the effect of main dimensions on the hydrodynamic properties.

On the other hand, having an instrument like the regressions allows for visualising the behaviour of the dependent variables (i.e. the attributes) as a function of the dependent ones (i.e. the ship's main dimensions). Therefore, a particular set of diagrams can be derived to observe the variations of the attributes for a particular set of hull forms. The design space considers hull form variations that keep the coefficients constant. Then, all the hulls having the same volume can be plotted as a single surface in a diagram having *L*, *B* and *T* as principal axes. On this surface, it is possible to visualize in the form of a contour plot the value of a single attribute, highlighting the areas where the main dimensions have a good value for the reference attribute or not. Here, these graphs have been reported for the 5 main hydrodynamic attributes selected for the analysis, using as a reference a project constraint that imposes a reference volume of 225 m<sup>3</sup>. The selection of this volume is purely arbitrary and is just a value that allows a good visualisation of the variations of the hydrodynamic properties along with the vessel main dimensions. The response surfaces are reported in Figures from 3 to 7. Figure 3 shows the response surface for the resistance, highlighting the area most favourable for hulls having main dimensions with a length of around 40 metres, breadth of 6.0 metres and draughts ranging between 1.6 and 1.8 metres. Such a combination of values is expected as the slender the ship is the lower is resistance. Figure 4 shows the behaviour of the dynamic trim. Here the behaviour of the data is different compared to the case of resistance, as not only one minimum or maximum are identified. In any case, for the trim the most preferable value for designers is the achievement of a neutral trim; therefore, for the reported surface, the best combinations refer to the saddle points populating the central part of the surface.

Figure 5 shows the response surface for the *ISO<sub>TOT</sub>* comfort index. In this case, a maximum of the function is clearly identifiable for combinations of *L*, *B* and *T* around 30-35, 8.5-9.0 and 1.2-1.5 metres, respectively. This area is different compared to the area of minimum for the resistance, confirming that attributes for hydrodynamic characteristics are sometimes antithetic between each other.

Figure 6 highlights the variations of the initial turning ability. Also in this case the most favourable is for the attribute to be clearly identifiable, with a maximum for long and slender ships and a minimum for short slender ships. Such a behaviour is totally opposite to the description of the yaw-checking ability shown in Figure 7. It is interesting to notice that the two attributes related to manoeuvring have antithetic behaviour, that in both cases do not match between optimal regions for resistance or comfort. This would apply even to the turning ability from the turning circle test. This is in fact most likely antithetic to the yaw-checking ability from zig-zag manoeuvres

From this qualitative analysis, it is evident that a designer can make his decisions based on empiricism by just interpreting the graphs with the associated surfaces. However, the adoption of more advanced mathematical techniques can give more quantitative help to designers. In fact, the obtained surfaces can be employed to feed a Multi-Attribute Decision Method (MADM) in order to find the best compromise solution between the given attributes, providing also weightings according to the desiderata of the designer. The following section reports the description and the application of this technique on a reference yacht size.

## APPLICATION TO CONCEPT DESIGN

The concept design of a new vessel implies the handling of different knowledge in Naval Architecture and Marine Engineering, ranging from resistance determination up to the estimation of the structural loads on a ship. As such, the designer should face a multi-criteria environment to find a proper design solution. Due to the complexity of the environment, a proper methodology needs to be applied in the early stages of design. In this respect, Multi-Attribute Decision Making (MADM) stands as an valuable tool for decision-makers facing complex and multifaced choices (Trincas, 2001, Kumar, 2010). In fact, by systematically considering multiple criteria and employing rigorous analysis techniques, MADM enhances the decision-making process, leading to more informed and effective choices in a complex environment as the design of a vessel.

Several methodologies can be employed to select the weighting attribute criteria, the decision matrix and the scoring of the best solutions. The Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS) is one of the possible methodologies that can be applied to the early design of ships as it has been recognised to be simple and effective for the problem (Behzadian et al. 2012).

TOPSIS is based on the concept that the best alternative is the one closest to the positive best ideal solution and the farthest from the negative ideal solution; where the maximum positive represents the best quality for all criteria and the negative the lowest quality. By calculating the proximity of these alternatives to the ideal solutions, TOPSIS assigns a score to each alternative, providing a rank among different solutions. To proficiently work, the TOPSIS procedure needs to go through the following steps:

1. Attribute definition: identifying the project attributes relevant to the design process.
2. Weight assignment: assign relative weights to each attribute according to the designer's preference.
3. Determination of Decision Matrix: normalise all the attributes and multiply them according to the given weights.
4. Determine the Positive and Negative ideal: find the best and worst case according to given weights
5. Rank the solutions: identify through Euclidean distance the closeness of each solution to the ideal and rank the solution accordingly.

The process is quite straightforward and allows for easily determining the rank among different solutions with sufficient flexibility for incorporating the desiderata weights for each attribute in a complex scenario.

While MADM offers valuable insights into complex decision scenarios, it has also a large number of challenges. These may include the data uncertainties, the susceptibility in criteria weighting, and the difficulties in capturing the dynamic nature of the decision environments. Therefore, also the application of these techniques requires an iterative approach and training before defining and refining the best decision model.

The adoption of first-principle tools for the definition of the main hydrodynamic attributes aims at reducing the uncertainties due to the methods employed to generate the initial database. However, even though the regressions show a high accuracy level, the resulting responses are still an approximation of the process and, therefore, the results should be interpreted by the designers with caution. Nonetheless, the implementation of the calculation process, automating the calculations and providing a graphical representation of the output help in streamlining the decision-making process and consequently enhance the efficiency.

In the present section, the TOPSIS process is applied to the example of the large yachts, employing the response surfaces described in the previous sections as an input to generate multiple design solutions for a given design space. For demonstration purposes, the design target is a large yacht with a displacement of 225 m<sup>3</sup>. According to the definition of the TOPSIS process, it is necessary to assign weights to the different attributes, to incorporate designers' preferences into the project. For this initial calculation, the weights have been hypothesised to be evenly distributed among the attributes, afterwards they have been arbitrarily changed to reflect different kinds of design strategies. Table 5 reports the weights employed and the results for the main dimension obtained by applying the TOPSIS procedure on a dataset of 10,000 randomly generated projects.

**Table 5: Example of TOPSIS procedure for different weighting factors.**

Project	Weights [ $R_T, \tau, ISO_{TOT}, Init, Yaw$ ]	L [m]	B [m]	T [m]
P1	[0.20;0.20;0.20;0.20;0.20]	39.446	7.857	1.303
P2	[0.20;0.10;0.50;0.10;0.10]	32.107	7.609	1.678
P3	[0.50;0.10;0.20;0.10;0.10]	30.161	7.645	1.725
P4	[0.10;0.10;0.10;0.35;0.35]	37.053	7.007	1.503
P5	[0.60;0.10;0.10;0.10;0.10]	33.595	6.003	1.968

From Table 5, it is evident how different weights identify different main dimensions for the same target displacement of the yacht. It has to be underlined that weights are arbitrary and do not reflect any design strategy derived from yacht designers but they have been used to reflect possible design strategies that favour more attributes related to resistance, comfort or manoeuvrability.

Even though the present method considers only the main dimensions of the yacht, the methodology proposed allows potential designers to make decisions on the main dimensions of a new project intrinsically considering attributes related to resistance, comfort and manoeuvring. Therefore, by adding further hull form variations to the initial dataset it would be possible to increase the flexibility of the current set of regression, by including also hull form parameters variations. In manoeuvring and seakeeping, only the main dimensions are often looked at, considering moreover large variations, and local modifications to the hull are often considered negligible. However, local modifications on the hull lines in the stern could produce different manoeuvring performance. Future studies as described in this paper could bring better insight.

## CONCLUSIONS

The present study investigates the possibility of generating response surfaces for ship design purposes on a set of large-yacht hulls. An initial database of 15 hulls has been generated by parametrically changing the main dimensions in a specific range of values and by keeping constant the hull form coefficients. The changes have been performed according to a CCD design. On the resulting set of hull forms, CFD resistance calculations, strip theory seakeeping calculations and time-domain manoeuvring simulations have been carried out to evaluate the hydrodynamic performances of the yachts. Afterwards, multiple linear regression analyses were performed to determine the surface responses of all the hydrodynamic characteristics previously derived by first-principles calculations. Thanks to this process, the resulting responses can be employed in a MADM approach to find the best combination of main dimensions for a yacht having a predetermined target displacement, considering the weighting of attributes.

The resulting response surfaces from the first-principles calculations show the behaviour of the hydrodynamic attributes along with the changes in the main dimension, highlighting the antithetical nature of certain attributes. The developed graphs including the variations of hull form parameters for specific hull displacements could provide help to designers, in identifying the areas where the best solutions for each attribute are located. Besides, the development of response surfaces allows the application of such instruments to the selection process of main parameters through the application of MADM approaches. This allows for identifying the best tuple of dimensions taking into account also different weights among the attributes.

The process developed in this study is just a starting point for subsequent developments, since modifying only the main dimension is not sufficient to have a thorough understanding of the changes of hull forms on the hydrodynamic performances. The hull form coefficients strongly influence the hydrodynamic performances, and, in this case, they are kept constant as a preliminary assumption. Furthermore, progress can be made in the methodologies applied for the determination of the hydrodynamic coefficients, which means applying CFD also for manoeuvring purposes and 3D diffraction codes for seakeeping. Nonetheless, the methodology developed for this study can easily be implemented to a wider dataset that may become available by increasing the number of changes in the hull form generation.

In any case, the findings of this study are the first step to initiate a series of studies oriented to identifying response surface for the hydrodynamic performances of small and large yachts, taking finally into consideration all the aspects of ship hydrodynamics (i.e. resistance/propulsion, seakeeping and manoeuvring) plus additional attributes that are nowadays not included at all in the preliminary design of yachts like the Dynamic Positioning. The present work shows that this path can be pursued by employing the tools and methods described in the paper, ensuring promising results for the following research.

# Operational Matrix Framework for Energy Balance Analysis for Early Stage Design of Complex Vessels

M. H. Mukti<sup>1,\*</sup>, R. J. Pawling<sup>1</sup>, D. J. Andrews<sup>1</sup>

## ABSTRACT

*Considering vital ship systems or distributed ship service systems at the early stage of complex vessels is a challenging task. The recent UCL Network Block Approach aimed to enable ship designer to address ship systems design synthesis simultaneously as a logical network using MATLAB with a CPLEX Toolbox in MATLAB and representative piping, cabling, and trunking routings on the physical description of the ship using a proven CASD tool PARAMARINE-SURFCON. This was possible due to adopting a set of frameworks, as part of this comprehensive approach. The paper presents one of the frameworks: the Operational Matrix, to formulate distributed ship service systems network in the early stage design of complex vessels. The application of the framework could take on many forms and can be manipulated to suit a specific distributed ship service system's design. In this paper, a tutorial is given, leading from the simplest application of the Operational Matrix Framework to an example of a complex Operational Matrix application for the 3D multiplex submarine systems problem. The use of the proposed Operational Matrix Framework is shown to reveal the relationship between objective functions, constraints, bounds, and solutions of that linear programming formulation. The Operational Matrix Framework can enable the solvers (CPLEX Toolbox in MATLAB) to be very efficient in advancing early stage ship design applications. The Framework could be developed further for investigating the analysis of energy balances for new systems to achieve net zero energy demands for future naval vessels.*

Distributed Ship Service Systems, Network Theory, Early Stage Ship Design.

## NOMENCLATURE

Symbol	Description
$\alpha$	Coefficient of the objective function for a cable type A
$a$	The set of all arcs
$\beta$	Coefficient of the objective function for a cable type B
$b_i$	Specific amount of commodity at a node $i$
$c_{i,j}$	Generic "cost" coefficient in an objective function
$\delta_{i,j}$	Binary variable of an arc $i, j$
$e$	Energy coefficient
$\gamma_h$	Power flow produced by a hub/path/intermediate node
$\gamma_s$	Power flow produced by a source node
$\gamma_t$	Power flow produced by a sink/target node
$H_{sub}$	Hotel load submerged for a submerged submarine
$i \in n$	A node $i$ as a subset of a set of nodes $n$
$(i, j) \in a$	An arc $i, j$ as a subset of a set of arcs $a$
$j \in n$	A node $n$ as a subset of a set of nodes $n$
$k \in K$	An operating scenario index $k$ as a subset of scenarios $K$
$\lambda_{i,j}$	Power to volume ratio of an arc $i, j$

$L(i, j)$	Distance between nodes $i$ and $j$
$\mu_{i,j}$	Coefficient of the objective function of an arc $i,j$
$m \in M$	Indexed damage scenario $m$ as a subset of scenarios $M$
$k \in K$	Indexed operating condition $k$ as a subset of scenarios $K$
$n$	The set of all nodes
$OF_{i,j}$	Objective function value of an arc $i,j$
$P_{i,j}$	Power of an arc $i, j$
$u_{i,j}$	Flow capacity/variable of an arc $i, j$
$U_{i,j}$	Flow capacity of an arc $i, j$
$x_{i,j}/x_{j,i}$	Flowpath or flow variable of an arc $i, j$ or arc $j, i$
$x_{i,n}$	Flow variable from a node $i$ to node $n$
$x_{n,j}$	Flow variable from a node $n$ to node $j$
$Y_s$	Power flow capacity of a source node
$Y_t$	Power flow capacity of a target node

## 1. INTRODUCTION

In the initial sizing of complex vessels, where recourse to type ship design can be overly restrictive, the estimation of the weight and space demands of vital distributed ship service systems has traditionally been poorly addressed (Andrews, 2018). The UCL Network Block Approach (Mukti, 2022) can help the concept designer to consider the impact of different configurations for the distributed ship systems in concept design with more inputs than a parametric approach but fewer assumptions than detailed systems design. This is possible because the UCL Network Block approach combines the use of an architecturally driven ship synthesis approach (Andrews, 2018), and the use of network tool called SUB/RFLOW: SUBFLOW for submarine (Mukti et al., 2021) or SURFLOW for surface ships (Mukti et al., 2024).

SUB/RFLOW was originally derived from the Architecture Flow Optimisation (AFO) (Brown, 2020) and Non-Simultaneous Multi Commodity Flow (NSMCF) (Trapp, 2015). Compared to this previous research, the SUB/RFLOW process is integrated with a 3D CASD tool (Paramarine (Qinetiq, 2019)) for designing ship systems both in terms of the network (logical representation) and the physical representation of piping, cabling, or trunking routings incorporated in the ship. The SUB/RFLOW tool uses network theory and linear programming, with nodes and arcs modelled as a set of linear programming optimisation formulations. These formulations mainly consist of constraints that define the physics of the problem and the objective function to focus the solver to maximise or minimise the solution of the problem (e.g., the multiplication between “cost” and the commodity flow) (Trapp, 2015).

The tools to solve the optimisation can use the standalone CPLEX software (IBM, 2014) or CPLEX toolbox in MATLAB (2019). The use of CPLEX toolbox in MATLAB streamlines the network analysis to be done fully in MATLAB, which allows the use of matrices for defining network properties to be read sequentially and visualised instantaneously in MATLAB. Most importantly, the use of the CPLEX toolbox in MATLAB enables the naval architect to intervene in the network formulation code for CPLEX using a MATLAB programming language (i.e., use of matrix-based computation). This, in turn, can minimise any black-box tendencies in a linear programming formulation as it reveals the interaction between the objective function, constraints, and bounds in the form of several matrices which can be themselves a single matrix, depending on the size of the network problem. Such a matrix is referred to as the Operational Matrix framework in the UCL Network Block Approach (Mukti, 2022). That framework is the focus of this paper and has been proposed to assist the designer by formulating a linear programming description, able to reflect simplified steady state temporal relationship of ship systems and the operating conditions, which has been described as the operational architecture of the ship (Brefort et al., 2018). Also, the Operational Matrix framework could be seen as a subset of the logical architecture, which interacts with a specific operating condition (e.g., loads during sprint submerged and snorting) and a discrete system’s response (i.e., the simplified steady state response of specific distributed ship service systems during those particular operating conditions).

The next section of the paper provides an introduction to the proposed Operational Matrix Framework drawing on network theory. This is followed by design examples and applications of the framework to different Network Flow Optimisation setups. The Operational Matrix for the UCL Network Block Approach is then outlined. Lastly, the paper presents the advantages and limitation of the proposed framework approach and summaries what is novel in the approach through a high level comparison with previous research in the field of ship systems design.

## 2. THE BASIC FORM OF THE OPERATIONAL MATRIX FRAMEWORK

A network description is a set of points called nodes that are connected by lines called arcs or edges (Newman, 2010) while Network Flow Optimisation (NFO), in its basic form, is a method using linear programming that finds the lowest cost of the flow of a specific distributed commodity from a set of sources to a set of sinks (loads) through a network containing various flows (Trapp, 2015). In the case of the distributed ship service systems, the commodity can be anything that can be modelled in terms of flows, such as electrical power (energy) and data (Brown, 2020), or fluid (gas or liquid) (Trapp, 2015).

In the formulation of the linear programming of the NFO, a prescribed objective function (also called the “cost” function, which is not always the actual currency) is minimised (or maximised) by the solver, subject to constraints. The constraints define the physics of the distributed ship service systems problem in the form of equality and inequality constraints which mathematically define supply and demand limits considerations relevant to the appropriate distributed ship service systems. Thus, the units of the flow are determined and the equations describing the continuity at various supply, demand and distribution or hub nodes are derived to achieve a feasible NFO solution.

Consider a simplistic example of a NFO problem in Figure 1. This system consists of a source node, two distribution (or hub/intermediate) nodes, and a target (or sink/user) node. Described generally, an arc or edge which allows one-way flow from node  $i$  to node  $j$  is described by  $(i, j)$ . Let  $a$  be the set of all arcs. Each arc  $(i, j)$  is limited to  $u_{i,j}$  units of flow. There is a “cost”  $c_{i,j}$  (not always currency) associated with the rate of flow in each arc of the network. Let  $n$  be the set of all nodes. Each node provides a supply or a demand of  $b_i$  units of flow. For distribution nodes,  $b_i = 0$ . For a supply node,  $b_i > 0$  and for a demand node  $b_i < 0$ . The task of the solver is to find the minimum cost flow for the network such that (all) required demand is met. To do this, the solver must minimise total cost of transport over the arcs while accounting for the variation in cost for each arc (see the linear programming formulations in Table 1). To formulate as a linear programming problem, flow variables  $x_{i,j}$  are used, where the annotated flow is in arc  $(i, j)$ . Before there is no flow in the network, the arcs in Figure 1 are shown as thin lines. Lastly, the equation under each node represents the continuity of each node in the system as the set of constraints for the formulation.

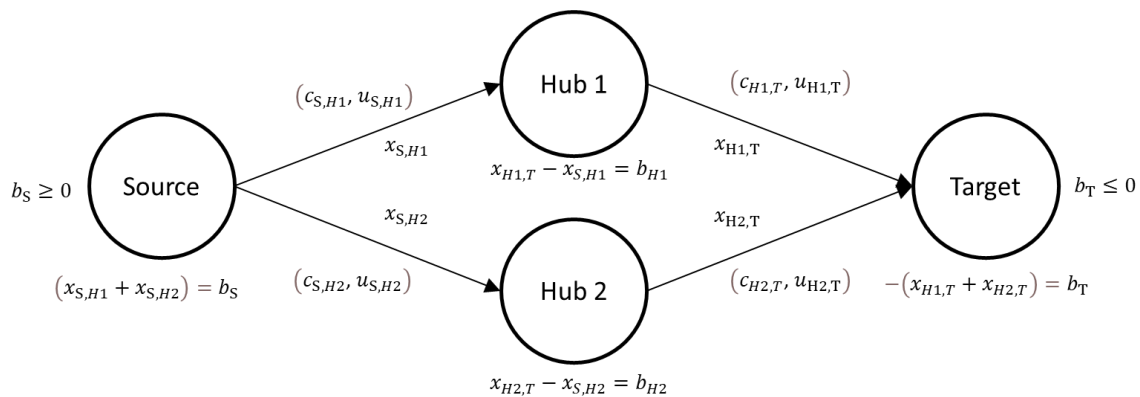

Figure 1: Simple network flow problem

**Table 1: Linear programming formulations of Figure 1**

Linear Programming Formulation	Mathematical Notation	Realisation
Objective Function	$\min. \sum_{(i,j) \in a} c_{i,j} x_{i,j}$	$c_{S,H1} x_{S,H1} + c_{H1,T} x_{H1,T} + c_{S,H2} x_{S,H2} + c_{H2,T} x_{H2,T}$
Subject To:		
Continuity	$\sum_{(i,j) \in a} x_{i,j} - \sum_{(i,j) \in a} x_{j,i} = b_i$	$x_{S,H1} + x_{S,H2} = b_S$ $x_{H1,T} - x_{S,H1} = b_{H1}$ $-x_{H1,T} - x_{H2,T} = b_T$ $x_{H2,T} - x_{S,H2} = b_{H2}$
Bounds	$0 < x_{i,j} \leq u_{i,j}$	$0 < x_{S,H1} \leq u_{S,H1}$ $0 < x_{H1,T} \leq u_{H1,T}$ $0 < x_{S,H2} \leq u_{S,H2}$ $0 < x_{H2,T} \leq u_{H2,T}$
Operating Scenario	$b_i$	$b_S \geq 0$ $b_{H1} = 0$ $b_{H2} = 0$ $b_T \leq 0$
Indices	$(i,j) \in a$	$(S,H1) \in a \dots (H2,T) \in a$
	$i \in n$	$S, \dots, T \in n$

Fundamentally, the operational matrix is used to compile all variables in the linear programming formulations into a set of rows and columns of a matrix. The matrix is called “operational” when it is specifically applied to distributed ship service systems subject to appropriate operating conditions, i.e., temporal relationships (as is demonstrated later in this paper). Thus, the operational matrix for the example in Figure 1 is shown in Table 2. The number of columns in Table 2 is given by the quantity of arcs and nodes in the network. Each row provides the “coefficients” in the linear programming formulation. In this example, it consists of the objective function or the cost function (to be minimised), the equality constraint for the continuity (i.e., all flow into and out of the node must equal the supply or demand  $b_i$  unit flow at each node), and the bounds limiting the flow to given arc capacities  $u_{i,j}$  and ensuring that the flow is unidirectional. The flowpaths or flow variables  $x_{i,j}$  are referred to as the set of decision variables. The solver then determines what value each of the variables in  $x_{i,j}$  should take in order to minimise (or maximise, whichever is specified) the cost function. The variables in brackets for the equality constraints are not in the actual Operational Matrix. They are there to aid the ship designer’s understanding of the framework.

**Table 2: A simplistic example of an Operational Matrix Framework**

Formulation	Arc 1	Arc 2	Arc 3	Arc 4	Source	Hub 1	Hub 2	Target
Objective function	$c_{S,H1}$	$c_{H1,T}$	$c_{S,H2}$	$c_{H2,T}$	0	0	0	0
Constraints (Equality)	$1(x_{S,H1})$	0	$1(x_{S,H2})$	0	$-1(b_S)$	0	0	0
	$-1(x_{S,H1})$	$1(x_{H1,T})$	0	0	0	$-1(b_{H1})$	0	0
	0	0	$-1(x_{S,H2})$	$1(x_{H2,T})$	0	0	$-1(b_{H2})$	0
	0	$-1(x_{H1,T})$	0	$-1(x_{H2,T})$	0	0	0	$-1(b_T)$
Lower bound	0	0	0	0	0	0	0	0
Upper bound	$u_{S,H1}$	$u_{H1,T}$	$u_{S,H2}$	$u_{H2,T}$	$\infty$	0	0	$-\infty$

As an example, let the node and arc properties are known as summarised in Table 3 and Table 4. The network demands a 10-unit flow at the target node, so each arc is limited to 10-unit flow. For a minimisation problem, flowing through Hub 2 would be more “costly” than Hub1.

**Table 3: Node properties of Figure 1**

Node	Unit Flow Supply/Hub/Demand $b_i$	$b_i$ value/bounds
Source	$b_S$	$\geq 0$
Hub 1	$b_{H1}$	0
Hub 2	$b_{H2}$	0
Target	$b_T$	-10

**Table 4: Arc properties of Figure 1**

Arc ( $i, j$ )	Cost $c_{i,j}$	Cost $c_{i,j}$ Value	Capacity $u_{i,j}$	Capacity $u_{i,j}$ Value
( $S, H1$ )	$c_{S,H1}$	1	$u_{S,H1}$	10
( $H1, T$ )	$c_{H1,T}$	1	$u_{H1,T}$	10
( $S, H2$ )	$c_{S,H2}$	2	$u_{S,H2}$	10
( $H2, T$ )	$c_{H2,T}$	2	$u_{H2,T}$	10

To solve the problem above, the following steps need to be undertaken:

- Generate a network matrix using an adjacency matrix or an adjacency list in MATLAB (see Table 5).
- Plug the numbers outlined in Table 3 and Table 4 into that network matrix (i.e., as network properties in MATLAB), following the format of the Operational Matrix Framework outlined in Table 2.
- The Operational Matrix can then be fed into a solver in MATLAB.
- Once the solver produces a set of flow solutions, this can be stored back in the Operational Matrix in MATLAB (see Table 6).
- Using that Operational Matrix, the system network with the network flow solution can be visualised using MATLAB.

**Table 5: The adjacency matrix (left) and the adjacency list (right) of Figure 1**

$\begin{bmatrix} \text{Node} & S & H1 & H2 & T \\ S & 0 & 1 & 1 & 0 \\ H1 & 0 & 0 & 0 & 1 \\ H2 & 0 & 0 & 0 & 1 \\ T & 0 & 0 & 0 & 0 \end{bmatrix}$	$\begin{pmatrix} i & j \\ \text{Source} & \text{Hub1} \\ \text{Source} & \text{Hub2} \\ \text{Hub1} & \text{Target} \\ \text{Hub2} & \text{Target} \end{pmatrix}$
---	---

The network flow solution for the problem above is shown in Figure 2.

**Figure 2: Simple network flow problem solution**

As expected, the solver chose Hub 1 since it gives the lowest objective function value. This is 20, rather than 40, which would be the case for flowing through Hub 2. At the Source node, 10 unit flow is produced and leaving the node via arc  $(S, H1)$ . The continuity can be seen at the Hub 1, where 10 unit flow is entering from  $(S, H1)$  and leaving the node to arc  $(H1, T)$ . Finally, the 10 unit flow commodity is received by the Target node from arc  $(H1, T)$ . The solutions satisfied the objective function (the lowest value), constraints, and the bounds. This is summarised in Table 6 using the Operational Matrix Framework (see Appendix A for the MATLAB code for this example).

**Table 6: Operational Matrix Framework solution of Figure 2**

Formulation	Arc 1	Arc 2	Arc 3	Arc 4	Source	Hub 1	Hub 2	Target	=
Objective function	1(10)	1(10)	2(0)	2(0)	0	0	0	0	20
Constraints (Equality)	1(10)	0	1(0)	0	-1(10)	0	0	0	0
	-1(10)	1(10)	0	0	0	-1(0)	0	0	0
	0	0	-1(0)	1(0)	0	0	-1(0)	0	0
	0	-1(10)	0	-1(0)	0	0	0	-1(-10)	0
Lower bound	0	0	0	0	0	0	0	-10	0
Upper bound	10	10	10	10	$\infty$	0	0	-10	0

From the simple example above, the general template of the Operational Matrix Framework is given in Table 7. By using the Operational Matrix Framework, the formulation of the Network Flow Optimisation can be manipulated easily by changing the coefficients in the matrix. Understanding the use of the Operational Matrix Framework is essential before modelling, formulating, and dealing with a much larger network that could represent a large number of distributed ship service systems equipment on a vessel (Mukti, 2022). Thus, the next section provides more comprehensive examples and applications of the Operational Matrix Framework.

**Table 7: The general template of the Operational Matrix framework**

Formulation	Number of Arcs	Number of Nodes
Objective function	Coefficients associated with the LP formulation	
Constraints, such as equality, inequality, and bounds		

### 3. APPLICATIONS OF THE OPERATIONAL MATRIX FRAMEWORK

To better understand the proposed Operational Matrix Framework, this section presents three examples: the application of the Operational Matrix Framework to a simple “transportation” Non-Simultaneous Multi Commodity Flow (NSMCF) problem (Trapp, 2015); the application of the Operational Matrix Framework to a simplified Power and Propulsion Systems (PPS) submarine (SSK) problem (Mukti et al., 2021); and lastly, the application of the Operational Matrix Framework for a high-level SSK problem (Mukti, 2022).

#### 3.1 Operational Matrix for a simple NSMCF problem

In this section, the use of an operational matrix framework for a simple NSMCF problem is presented. This is given in Figure 3 and the properties of the nodes and arcs in Table 8 and Table 9, respectively. In this example, there are two source nodes (A and E in green); two hub or intermediate nodes (C and D in black); and two user nodes (B and F in red). The top part of Figure 3 shows that the objective function result “OF” is equal to zero, as there is no flow yet in the network. Each arc has objective function “cost”  $c_{i,j}$  and flow capacity  $u_{i,j}$  in a form of  $c_{i,j} * u_{i,j} = OF_{i,j}$ . Thus, Figure 3 shows the value of  $u_{i,j}$  at each arc is zero before the solver is used.

**Figure 3: A simple NSCMF network problem(Trapp, 2015) coloured and revisited using the Operational Matrix framework before the NFO solver has been applied in this network**

**Table 8: Node properties of a simple NSCMF problem in Figure 3 so derived from Trapp (2015) node labelling, node type, and data type were added**

Node $n$	Type	Data	Notation	$b_i$ value/bounds
A or 1	Source	Output	$b_A$	$\geq 0$
B or 2	Target	Input	$b_B$	10
C or 3	Hub	Input	$b_C$	0
D or 4	Hub	Input	$b_D$	0
E or 5	Source	Output	$b_E$	$\geq 0$
F or 6	Target	Input	$b_F$	5

**Table 9: Arc properties of the NSCMF network problem in Figure 3 connecting node  $i$  to node  $j$  outlined in Table 8 so derived from Trapp (2015)**

Arc $(i, j)$	Cost $c_{i,j}$	Cost $c_{i,j}$ Value	Capacity $u_{i,j}$	Capacity $u_{i,j}$ Value
$(A, B)$	$c_{A,B}$	5	$u_{A,B}$	15
$(A, C)$	$c_{A,C}$	2	$u_{A,C}$	10
$(B, D)$	$c_{B,D}$	2	$u_{B,D}$	10
$(C, D)$	$c_{C,D}$	10	$u_{C,D}$	10
$(C, E)$	$c_{C,E}$	1	$u_{C,E}$	10
$(D, F)$	$c_{D,F}$	1	$u_{D,F}$	10
$(E, F)$	$c_{E,F}$	1	$u_{E,F}$	15

The objective function of this linear programming was to minimise the total value of the multiplication between the objective function coefficient  $c_{i,j}$  and arc flow capacity  $u_{i,j}$ . Compared to the simple Network Flow Optimisation in Figure 1, the flowpath in this problem can be bidirectional, i.e., it can change direction (but only one direction/ non-simultaneous) in an operating condition. This means the flow variable  $x_{i,j}$  can be positive or negative. Thus, inequality constraints, known as the ‘capacity roll-up’ (Trapp, 2015), were required to ensure the flow capacity  $u_{i,j}$  is always positive as does the multiplication between the objective function coefficient  $c_{i,j}$  and arc flow capacity  $u_{i,j}$  regardless the sign (direction) of the flow variable  $x_{i,j}$ . Such a formulation is summarised in Table 10.

Table 10: The linear programming formulation and the realisation of the simple “transportation” NSMCF problem (Trapp, 2015) are presented in a table form with colour added for the application of the proposed Operational Matrix framework (see Table 11)

Linear Programming Formulation	Mathematical Notation	Realisation		
Objective Function Subject To:	$\min. \sum_{(i,j) \in a} c_{i,j} u_{i,j}$	$c_{A,B} U_{A,B} + c_{A,C} U_{A,C} + c_{B,D} U_{B,D} + c_{C,D} U_{C,D} + c_{C,E} U_{C,E} + c_{D,F} U_{D,F} + c_{E,F} U_{E,F}$		
Continuity	$\sum_{(i,j) \in a} x_{i,j} - \sum_{(i,j) \in a} x_{j,i} = b_i$	$1x_{A,B} + 1x_{A,C} = 1b_A$ $-1x_{B,D} - 1x_{C,D} + 1x_{D,F} = 1b_D$	$-1x_{A,B} + 1x_{B,D} = 1b_B$ $-1x_{C,E} + 1x_{E,F} = 1b_E$	$-1x_{A,C} + 1x_{C,D} + 1x_{C,E} = 1b_C$ $-1x_{D,F} - 1x_{E,F} = 1b_F$
Capacity Rollup	$ x_{i,j}  \leq U_{i,j}$	$ x_{A,B}  \leq U_{A,B}$	$ x_{A,C}  \leq U_{A,C}$	$ x_{B,D}  \leq U_{B,D}$
		$ x_{C,D}  \leq U_{C,D}$	$ x_{C,E}  \leq U_{C,E}$	$ x_{D,F}  \leq U_{D,F}$
			$ x_{E,F}  \leq U_{E,F}$	
Bounds	$-\infty \leq x_{i,j} \leq \infty$	$-\infty \leq x_{A,B} \leq \infty$	$-\infty \leq x_{A,C} \leq \infty$	$-\infty \leq x_{B,D} \leq \infty$
		$-\infty \leq x_{C,D} \leq \infty$	$-\infty \leq x_{C,E} \leq \infty$	$-\infty \leq x_{D,F} \leq \infty$
			$-\infty \leq x_{E,F} \leq \infty$	
	$0 \leq U_{i,j} \leq u_{i,j}$	$0 \leq U_{A,B} \leq u_{A,B}$	$0 \leq U_{A,C} \leq u_{A,C}$	$0 \leq U_{B,D} \leq u_{B,D}$
		$0 \leq U_{C,D} \leq u_{C,D}$	$0 \leq U_{C,E} \leq u_{C,E}$	$0 \leq U_{D,F} \leq u_{D,F}$
			$0 \leq U_{E,F} \leq u_{E,F}$	
Operating Scenario	$b_i$	$b_A \geq 0$	$b_B = 10$	$b_C = 0$
		$b_D = 0$	$b_E \geq 0$	$b_F = 5$
Indices	$(i, j) \in a$	$(A, B) \in a \dots (E, F) \in a$		
	$i \in n$	$A, \dots, F \in n$		

Using the same procedure as outlined in Section 3.1, the linear programming formulation in Table 10 is then presented as a  $[23 \times 21]$  Operational Matrix and outlined in Table 11. The network solution is also included in brackets to understand the relationship between the objective function and the constraints of the linear programming formulation.

The network solution, which consists of values in brackets in the matrix, were divided into three groups based on the number of columns in Table 10. The first seven columns (black) give the flow capacity  $U_{i,j}$  values, whereas the second seven columns (blue) give the flow variable  $x_{i,j}$  values. The remainder values, which are in columns 15 to 20 (green or red), give the amount of supply or demand of the commodity  $b_i$ . The supply values (green) are part of the output while the demand values are part of the predefined input as shown in Table 8.

The first row of the matrix gives the objective function. The values, that are not in the bracket in the first seven columns in this row, provide coefficients  $\mu_{i,j}$  for the objective function, and the remaining columns (8 to 20) were set to zero because the flow capacity  $U_{i,j}$  (black) was the variable that was minimised, not the flow variable  $x_{i,j}$  (blue), nor the commodity  $b_i$  (green and red).

Values at rows 2 to 7 and the first seven columns are zero because these rows were given by continuity constraints. Continuity is given by the equality constraints matrix, which consists of rows 2 to 7 and columns 8 to 21 to model six continuity constraints in Table 10. Values +1 and -1 in purple represent coefficients of continuity constraints. The realisation of ‘capacity roll-up’ (Trapp, 2015) that connects the flow variable  $x_{i,j}$  (blue) and the flow capacity  $U_{i,j}$  was applied in the inequality constraints matrix located at rows 8 to 23 and columns 1 to 14 and 21. Values -1 (dark orange) in this region indicate coefficients for the capacity roll-up (Trapp, 2015). As this formulation was applied to arcs instead of nodes, the remaining values were seen for the inequality constraints matrix, situated at rows 8 to 21 and columns 15 to 21.

Rows 22 to 23 and columns 1 to 14 show the lower bounds and the upper bounds for the flow capacity  $U_{i,j}$  (black) and the flow variable  $x_{i,j}$  (blue), respectively. The flow capacity  $U_{i,j}$  could be used to limit the possible maximum flow capacity at each arc. However, such a formulation was not used and thus the flow capacity  $U_{i,j}$  could be any positive values. Lower bounds and upper bounds that define the supply or demand amount of commodity  $b_i$  are located in the same row but in different columns, which are 15 to 20.

Arrows were added to reveal the relationship between various values and coefficients of the linear programming formulation in the matrix. Although all elements (i.e., those without bracket) in the Operational Matrix provide the input of the linear programming formulation, bounds (situated at rows 22 to 23 and columns 15 to 20) are key inputs in this formulation. Therefore, the arrows are originated from this input, which directly constrains the commodity  $b_i$ , the flow variable  $x_{i,j}$ , and then the flow capacity  $U_{i,j}$  solutions. The flow capacity  $U_{i,j}$  and the flow variable  $x_{i,j}$  solutions are also constrained by bounds located at rows 22 to 23 and columns 1 to 14.

Table 11: The Operational Matrix of the basic NSCMF example, showing the simple “transportation” NSCMF example (Trapp, 2015) is presented using the proposed Operational Matrix framework with arrows showing relationships of constraints (see Table 10)

The Operational Matrix solution is visualised as a network. As shown in Figure 4, the multiplication between the “cost” coefficient  $c_{i,j}$  and the flow capacity  $U_{i,j}$  solution is shown as the label for each arc. Consistent with the Operational Matrix in Table 11, at the top part of Figure 4 the total objective function (OF) value is 45 (i.e., 15 from Arc (E, F) + 10 from Arc (D, F) + 20 from Arc (B, D) = 45).

**Figure 4: The network flow solution for a simple “transportation” NSMCF network problem from Trapp (2015), revisited using the proposed Operational Matrix framework**

The solution shown in Figure 4 would have been different if, for example, Arc (B, D) is unavailable or damaged. This has been referred to as the minus one (M-1) survivability, which guarantees the specified demands in the network can be met with a minimum “cost” flow although an arc is assumed to be lost (i.e., flow variable  $x_{i,j} = 0$ ) in a given loss scenario (Trapp, 2015). Thus, if there are seven arcs, as in this example, there are seven arc loss scenarios in the linear programming formulations. Once those formulations are solved, the ‘aggregate’ solution, which is a term introduced by Robinson (2018), then captures maximum capacity flows in those loss scenarios i.e., an arc from the aggregate solution is sized to accommodate all possible arc flow capacities ( $U_{i,j}$ ) in those loss scenarios. The application of such formulations in the Operational Matrix is now discussed.

To simulate arc loss scenarios for this simple “transportation” NSMCF example, the formulation becomes multicommodity or multiflow conditions (i.e., not just one flow condition as in Figure 4). Thus, more than one set of constraints could be considered where each set of constraints represents an arc loss scenario and would be incorporated in a ‘global’ objective function (Trapp, 2015). This means the implementation of multiflow conditions would result in a large number of constraints in the Operational Matrix, e.g., rows 7 to 23 and columns 8 to 21 of Table 11 will expand seven fold (i.e., necessary in this example for seven arc loss scenarios). Since this expansion depends on the number of arcs  $a$  and number of nodes  $n$  in a network problem, theoretically, it can be mathematically described as a  $[a^2 \times (a + n)^2]$  matrix. Hence, the scalability of the Operational Matrix for a network with (say) 100 arcs and 50 nodes would be about 10,000 rows and 22,000 columns, which would increase both the designer’s workload and the solver computational resources.

Rather than expanding the Operational Matrix from that shown in Table 11, the optimisation was solved individually in each flow situation, using a loop in MATLAB. Thus, the Operational Matrix was repeated seven times (as many as the number of arcs in the network) with a flow variable  $x_{i,j} = 0$  for each arc loss scenario. This can be referred to as a “single” flow formulation rather than “multi-commodity” flow formulation. The results are presented in Table 12 for each pair of networks such that the aim (left) are compared with the results of multicommodity formulation from Trapp (2015), which is given in Table 12 (right). In this comparison, some differences were found, more specifically, the flow path of scenarios (a), (c), (e), and (f), which are marked with an asterisk (\*) in Table 12. These flow path discrepancies reveal that in those arc loss scenarios, the single flow formulation always gives a local minimum, i.e., the multicommodity formulation in some cases results in a higher objective function (OF) value than the single flow formulation.

Table 12: Results comparison of a simple “transportation” NSCMF network problem between single flow formulation and multicommodity formulation, the results due to single flow formulation in the proposed Operational Matrix framework are given in the left part of each cell, while the multicommodity solution from Trapp (2015) is presented in the right part of each cell with the OF value added by the candidate at the top part of each cell (nodes A, B, C, D, E, F are equivalent to nodes 1, 2, 3, 4, 5, 6)

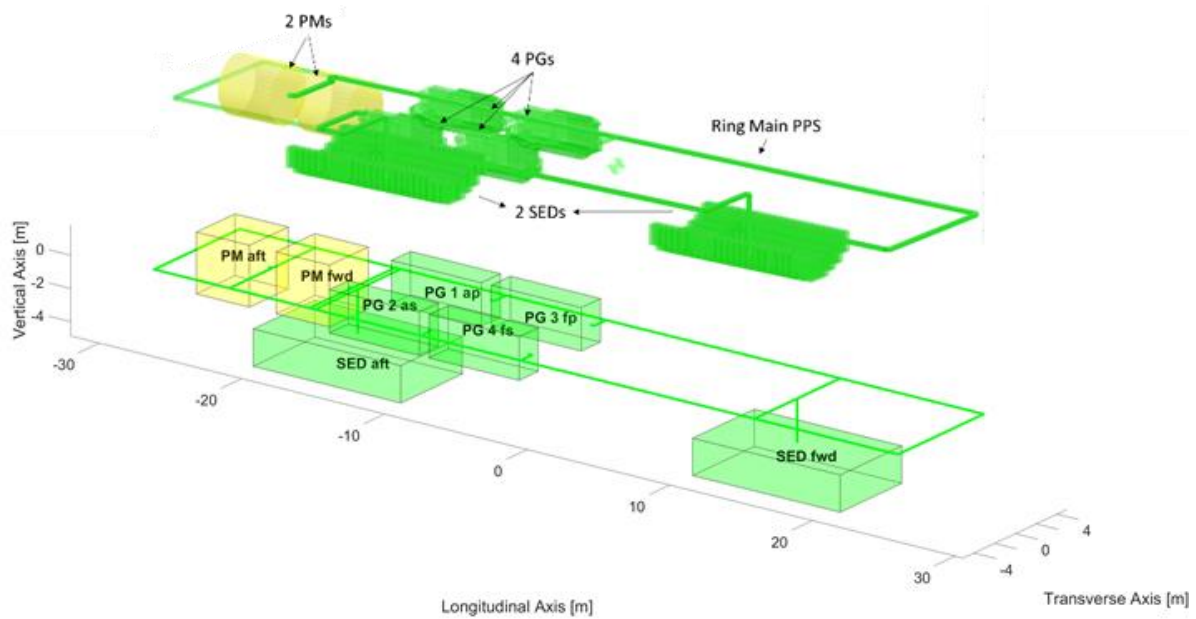

<p>(a) No loss*</p> <p>OF=45</p>	<p>(b) Loss of arc A,B</p> <p>OF=90</p> <p>(Trapp, 2015)</p>	<p>(c) Loss of arc A,C*</p> <p>OF=45</p>	<p>(d) Loss of arc B,D</p> <p>OF=55</p> <p>(Trapp, 2015)</p>
<p>(e) Loss of arc C,D*</p> <p>OF=45</p>	<p>(f) Loss of arc C,E*</p> <p>OF=90</p> <p>(Trapp, 2015)</p>	<p>(g) Loss of arc D,F</p> <p>OF=55</p>	<p>(h) Loss of arc E,F</p> <p>OF=90</p> <p>(Trapp, 2015)</p>
<p>Aggregate solution</p>			
<p>OF=120</p>		<p>OF=120</p> <p>(Trapp, 2015)</p>	

Despite the difference in terms of the local minima, the single flow formulation gives the same aggregate result as the multicommodity formulation (see the aggregate solution at the bottom part of Table 12). This confirms that the same aggregate solution in this specific NSMCF example can be obtained more efficiently with fewer constraints without the need to include all arc loss scenarios in the global objective function. Therefore, this example suggests that by using the proposed Operational Matrix Framework, the input required for the NFO could potentially be easily manipulated and reduced. This would be more efficient for quick distributed ship service systems sizing focused investigations and thus more appropriate for early-stage ship design applications.

The next section provides the application of the Operational Matrix Framework to simplified power and propulsion systems in a diesel-powered submarine.

### 3.2 The Operational Matrix applied to simplified submarine power and propulsion systems

This section describes the Operational Matrix Framework used to solve a simplified power and propulsion systems (PPS) SUBFLOW problem outlined in (Mukti et al., 2021). In the SUBFLOW formulation, there are only two broad types of nodes: terminal nodes and hub nodes (Mukti, 2022). Terminal nodes were used to model sources or sinks at the extremities of the flow. The extremities in the network were identified by the number of in-degree and out-degree flows. If a terminal node has only one or multiple out-degree flows (diverging), that node was taken to be a source. Conversely, if the flow(s) were converging and there were no out-degree flow(s), that node would have been considered as a sink/ target. Figure 5 shows the PPS configuration of a diesel-powered submarine (SSK) study, which was taken from a 3D Paramarine-SURFCON synthesis process (Mukti et al., 2021).

**Figure 5: A simplified PPS architecture displayed in Paramarine-SURFCON (top) translated into MATLAB model for the SUBFLOW analysis (bottom) on the SSK Case Study**

The simplified PPS 3D model above was then taken as a basis for the logical network as shown in Figure 6 with the network properties in Table 13. Figure 6 shows the PPS ring-main configuration network consists of 32 nodes and 36 arcs. There are two Propulsion Motors (PMs) as target (user) nodes, four Power Generations (PGs) as source nodes, and two electrical Stored Energy Devices (SEDs). The SED nodes can be the demand nodes during a snorting operating condition and can be supply nodes during a submerged operating condition. The rest of the nodes in the PPS network are hub or junction nodes. The nodes properties in Table 13 had to be defined from design requirements, i.e., the demanded power was based on the baseline SSK design (Mukti et al., 2021).

Figure 6: Nodes labelling to the PPS architecture MATLAB (not to scale)

Table 13: The summary of the power commodity in snorting and transit

System Component	Supply $Y_s$ (kW)	Demand $Y_t$ (kW)	Node ID (Figure 6)
PM aft	-	346	9
PM fwd	-		11
PG 1 ap	1600 (max)	-	15
PG 2 as	1600 (max)	-	21
PG 3 fp	1600 (max)	-	17
PG 4 fs	1600 (max)	-	23
SED aft	-	2930	13
SED fwd	-	2930	19

As an early development of SUBFLOW formulation as outlined in Table 14, this PPS example was kept simple (i.e., it does not represent myriad components in the actual submarine PPS). The equations are now briefly described in turn, the reasonings for the formulation are addressed in detail in (Mukti et al., 2021).

Table 14: Linear programming formulation and realisation of a simplified PPS SUBFLOW problem

Linear Programming Formulation	Mathematical Notation	Realisation
Objective Function:	$\sum_{(i,j) \in a} (\alpha \delta_{i,j} + \beta \delta_{i,j} + \lambda_{i,j} P_{i,j})$	$(\alpha \delta_{1,2} + \beta \delta_{1,2} + \lambda_{1,2} P_{1,2}) + \dots$ $(\alpha \delta_{31,32} + \beta \delta_{31,32} + \lambda_{31,32} P_{31,32})$
Subject To		
Continuity	$\sum_{(i,j) \in a} x_{i,j}^k - \sum_{(i,j) \in a} x_{j,i}^k = \gamma_i^k$	$x_{1,2}^k - x_{25,1}^k = \gamma_1^k \dots$ $x_{32,8}^k - x_{31,32}^k = \gamma_{32}^k$
Capacity Rollup	$ x_{i,j}^k  \leq P_{i,j}^k$	$ x_{1,2}^k  \leq P_{1,2}^k \dots$ $ x_{31,32}^k  \leq P_{31,32}^k$
Inequality constraints	$\gamma_s^k \leq Y_s^k$	$\gamma_{15}^k \leq Y_{15}^k \dots \gamma_{23}^k \leq Y_{23}^k$
Bounds	$\gamma_h^k = 0$	$\gamma_h^k = 0$
	$\sum_{(t) \in n} \gamma_t^k = Y_t^k$	$\gamma_9^k + \gamma_{11}^k = Y_{PM}^k$ $\gamma_{13}^k = Y_{13}^k$ $\gamma_{19}^k = Y_{19}^k$
	$\gamma_t^k = Y_t^k$	
	$P_{i,j}^k \geq 0$	$P_{1,2}^k \geq 0 \dots P_{31,32}^k \geq 0$
Operating Scenario	$P_{i,j}^{k,m} = 0$	$P_{1,2}^{k,m} = 0 \dots P_{31,32}^{k,m} = 0$
Indices	$\delta(i,j) \in \{0,1\}$	$\delta(i,j) \in \{0,1\}$
Capturing aggregate solution	$P_{i,j} = \max_{(k,m) \in K,M} (P_{i,j}^{k,m})$	$P_{1,2} = \max_{(k,m) \in K,M} (P_{1,2}^{k,m}) \dots$ $P_{31,32} = \max_{(k,m) \in K,M} (P_{31,32}^{k,m})$

In this example, the SUBFLOW formulation adopts the M-1 survivability (Trapp, 2015) by looping a  $144 \times 176$  Operational Matrix (see Table 16) as many as the quantity of arcs in the PPS network, i.e., 32 arcs. The objective function for the PPS study, which is given in Table 14, is in the first row and columns 1 to 108 in the Operational Matrix (see Table 16). To define variables  $\alpha$  and  $\beta$  in (located in the first row and the first 72 columns) there were two assumed ‘standard’ edge components.

In this formulation, the network solution can be used into two different ways. The first one was termed as the ‘binary variables’ method that minimised the space taken by PPS connections using coefficients  $\alpha$  and  $\beta$ . These coefficients categorised arcs in the PPS network to a certain standard edge component via binary decisions  $\delta_{i,j}$ . The second one was the ‘integer variables’ method, which also minimised the value of multiplication between the power to volume ratio  $\lambda_{i,j}$  and the power  $P_{i,j}$ . The power to volume ratio  $\lambda_{i,j}$  quantifies the power  $P_{i,j}$  for each set of arcs connecting a node  $i$  and a node  $j$  into a discrete volume. By assuming some variables related to the PPS cabling specifications, the power to volume ratio  $\lambda_{i,j}$  was obtained. Since there were unique x, y, z locations for each node from the DBB synthesis, the distance between nodes  $L(i,j)$  could be calculated (see Table 15).

**Table 15: Assumed variables in the PPS study**

Variable	Description	Value
$\alpha$	Binary coefficient of first category for cable sizing via the binary variables in the objective function	1.4 MW
$\beta$	Binary coefficient of second category for cable sizing via the binary variables in the objective function	4.8 MW
$\lambda_{i,j}$	Power to volume ratio for sizing via the integer variables in the objective function	$\frac{1.043 \times 10^{-5} m^2}{kW} L_{ij}$

In this case study, SUBFLOW did not just seek the minimum space for PPS cabling but also satisfied several constraints. These constraints were developed to show the distinctive SSK PPS operating conditions. In these constraints,  $k$  is an indexed scenario within a set of operating conditions  $K$  to represent various operating conditions, such as snorting and submerged conditions. In this PPS study, only the snorting (and transit) condition was considered, where the SEDs become the highest load in the PPS network, letting operating condition  $k = 1$ . The continuity formulation ensures the flow variable or flow path  $x$  entering and leaving a node  $n$  from a node  $i$  or  $j$  within a set of nodes  $n$  is equal to the amount of commodity  $\gamma$  at that node  $n$  and is preserved throughout the arcs  $A$ , except at relevant sources and targets. This equation is indicated in rows 2 to 33 and columns 109 to 176 in the Operational Matrix (Table 16).

For bidirectionality, the flow variable  $x_{i,j}$  was ‘rolled up’ (Trapp, 2015) and converted to power capacity flow  $P_{i,j}$  as the decision variables in SUBFLOW. Thus, the required power  $P_{i,j}$ , as the decision variables in the SUBFLOW formulation, is always positive. This formulation is located in two parts in the Operational Matrix (see Table 16): rows 35 to 106 and columns 72 to 144; rows 143 to 144 and columns 109 to 144. The bounds in the formulation define the amount of power source and demand  $Y$  in the PPS network. The source nodes in the PPS study were the PGs, i.e., nodes 15, 17, 21, and 23 (see Table 16). This equation is assigned at rows 143 to 144 and columns 145 to 176 in the Operational Matrix framework. The bounds for hub nodes were set to zero. The examples of hub nodes in the PPS study were nodes 1, 2, 3, etc (see Figure 6). This equation is assigned at rows 143 to 144 and columns 145 to 176 in the Operational Matrix.

For applying the M-1 survivability by Trapp (2015) in this PPS network problem, each operating condition  $k$  is associated with an edge loss scenario  $m$  (the flow was set to zero) within a set of damaged scenarios  $M$ . This equation was applied by setting the upper bound of a power capacity flow  $P_{i,j}$  to zero in the Operational Matrix, which is located at row 144 and columns 72 to 108. This setup forced the solver to be unable to use that arc and then search for an alternative set of flowpaths in the network.

Table 16: The Operational Matrix of the simplified PPS study, which is developed based on the formulation in Table 14

		$\delta(i,j) \in \{0,1\}$		$P_{i,j}^k \geq 0$	$ x_{ij}^k  \leq P_{ij}^k$			

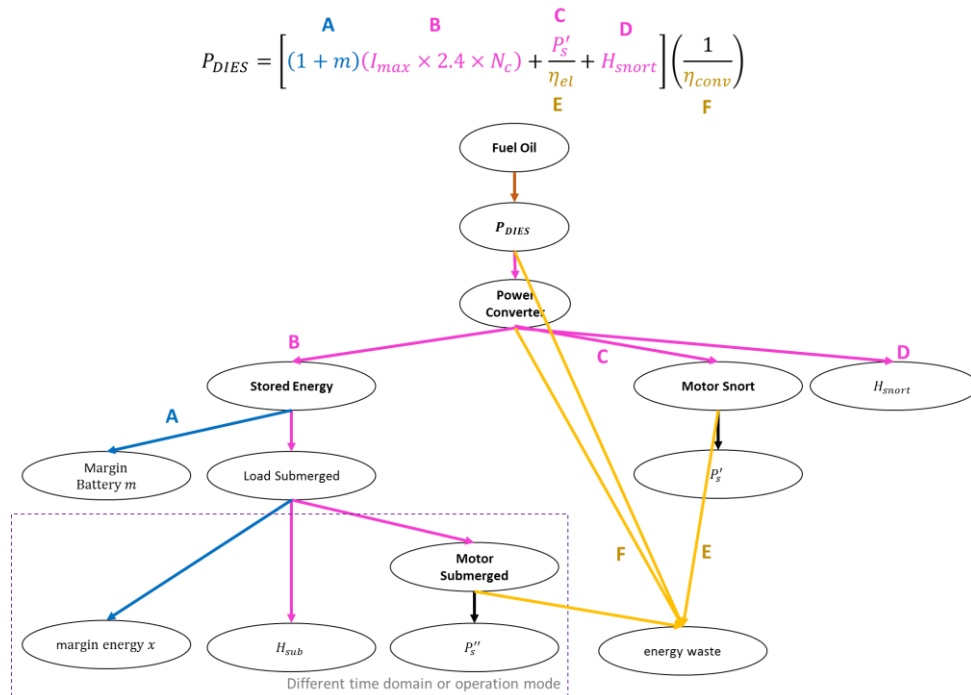

The  $\delta$  in Equation in Table 16 serves as the binary decision to classify a capacity of an edge  $i$  to  $j$  to achieve certain standards for an edge component (type  $\alpha$  and  $\beta$ ). This equation is assigned at rows 143 to 144 and columns 1 to 72 in the Operational Matrix (see Table 16).

The redundant Propulsion Motors (PM)s were set as user nodes, but the solver could only select one PM to be online in an operating condition  $k$ . Other user nodes in the same operating condition (snorting) were set as the hard constraints. These are the batteries (SED) charging demands. Therefore, in the PPS study, the user nodes  $t$  were PMs and SEDs (nodes 9, 11, 13 and 19 in Table 14). These equations are shown in rows 34 and 143 to 144 and columns 145 to 176 in the Operational Matrix (see Table 16). Finally, the network solutions from the solver, which consisted of numerical data in a matrix, were presented in Table 17. This used the last equation in Table 14.

Using the Operational Matrix framework, the solver was able to find the solutions. Table 17 shows three different set of network solutions. The first solution is referred to as a “conservative” solution as it was obtained by selecting the maximum possible power flow in the PPS problem, i.e., maximum power available from the four PGs. The second and third solutions were based on the Objective Function of the SUBFLOW PPS explained above. The three solutions can be used as a basis for sizing the PPS cabling although it was recognised that the aft part of the PPS network would have required further operating scenarios  $k$  to be considered beyond snorting and transit (e.g., sprint condition). In this simple PPS example, there were found to be three possible options, the designer was able to choose between a smaller space solution (3 m<sup>3</sup> and 5 m<sup>3</sup>) or the conservative solution (10 m<sup>3</sup>) for the PPS cable sizing. Another example is provided and thus the next section outlines another version of SUBFLOW formulation for an SSK power load network at a high level.

### 3.3 Applying the Operational Matrix using high-level submarine power sizing variables

Network can also be used to represent the constants, coefficients, and variables within the concept design model as opposed to the items of the distributed ship service systems. This means the nodes are not directly representing the actual distributed ship service systems equipment unlike the previous examples. Therefore, a mathematical relationship for diesel power ( $P_{DIES}$ ) sizing was used, which is given in Figure 7 (top) (Burcher and Rydill, 1994). This algorithm expresses that the power output that a diesel engine fit must be able to satisfy the electric service demand for charging batteries, propulsion load, and hotel load, as well as the likely inefficiencies and margins required to accomplish snorting operations.

**Figure 7: A high level SSK power system problem based on the power sizing algorithm due to Burcher & Rydill (1994)**

**Table 17: Sizing results of the Power and Propulsion Systems (PPS) study**

The network in Figure 7 shows the hierarchical sources and sinks of a SSK power system with several nodes starting from the fuel (oil) tankage node as the source of energy followed by the diesel generator node (quantified by  $P_{DIES}$ ), which converts the fuel is chemical energy (brown) to electric energy. The electrical energy is then converted and distributed by a power converter node to the three main electric loads which are coloured in magenta: the energy storage or battery charging for fully submerged operation (B); the hotel load in the snorting operation (D); and the propulsion load in snorting operations (C). Further nodes have been modelled to represent margins (coloured in blue) for battery charging (A) and submerged energy (B), as well as efficiencies (F and E) coloured in yellow, which contribute to energy waste or power loss. The detailed heat due to battery charging and hotel load in the snorting operation was not considered in this modelling.

The properties of the nodes shown in Figure 7 are given in Table 18. The source node in this study was the Fuel Oil (FO) node, while the rest of the terminal nodes were sinks and between the terminal nodes, there were hub nodes. Unlike terminal nodes, hub nodes have to have at least one in-degree and one out-degree flow. The hub nodes shown in Table 18 are the Diesel Generator (DG), the Power Converter (PC), the Stored Energy (SE), the Margin Battery (MM), the Load Submerged (LS), Motor Submerged (MS), and Motor Snort (MT). Compared to the AFO approach (Brown, 2020), each arc in the SUBFLOW network also focuses on one commodity, which is energy (chemical, electrical, mechanical, or heat loss). However, in the AFO approach, there could be a non-energy flow, such as data flow (carrying binary 0 and 1 numerical data), as the ‘parallel’ commodity in the AFO formulation (Robinson, 2018). Reducing the number of commodities within the SUBFLOW then reduced the number of inputs and the complication in the network formulation, making the SUBFLOW more appropriate to be applied early in the design process, as in the implementation shown in Table 18. The energy storage was also explicitly modelled as the Load Submerged (LS) node in this network.

**Table 18: Nodes properties for an SSK power system network in Figure 7**

Node Name	Relevant Variable	Node Identification	SUBFLOW Setup	Node Type	Data
Fuel Oil	$P_{Fuel}$	FO	$P_{FO} \geq 0$	Terminal	(Output)
Diesel Generator	$P_{Dies}$	DG	$P_{DG} \geq 0$	Hub	(Output)
Power Converter	$P_{Conv}$	PC	$P_{PC} \geq 0$	Hub	(Output)
Stored Energy	$P_{Batt}$	SE	$P_{SE} \geq 0$	Hub	(Output)
Margin Battery	$m$	MM	$P_{MM} \geq 0$	Hub	(Output)
Load Submerged	-	LS	$P_{LS} \geq 0$	Hub	(Output)
Margin Energy	$x$	MX	$P_{MX} \geq 0$	Terminal	(Output)
Hotel Submerged	$H_{sub}$	HS	$P_{HS} = H_{sub}$	Terminal	280 kW
Motor Submerged	$P''_{Motor}$	MS	$P_{MS} \geq 0$	Hub	(Output)
Velocity Submerged	$P'_s$	VS	$P_{VS} = P'_s$	Terminal	68 kW
Motor Snort	$P'_{Motor}$	MT	$P_{MT} \geq 0$	Hub	(Output)
Velocity Snort	$P'_s$	VT	$P_{VT} = P'_s$	Terminal	(Output)
Hotel Snort	$H_{snort}$	HT	$P_{HT} = H_{snort}$	Terminal	224 kW
Heat Loss	-	HE	$P_{HE} \geq 0$	Terminal	(Output)

In this example, a formulation used in the AFO approach (Robinson, 2018) was applied to continuity constraints and to define how much energy could come in and out of a hub node, denoted as an energy coefficient  $e_i$  in this SUBFLOW simulation (see Table 19 and the continuity in Table 21). For example, at the Diesel Generator (DG) node, 100% of the incoming energy flow from the Fuel Oil (FO) node would be converted to the Power Converter (PC) node as the electric energy (48%) and Heat Loss (HE) node (52%). This split could be said to be similar to the Sankey diagram that can be used to breaking down energy inputs and outputs (Kennedy and Sankey, 1898). Thus, all hub nodes’ energy coefficients  $e_i$  in this SUBFLOW network (Figure 7) are provided in Table 19.

**Table 19: Arcs properties for an SSK power system network in Figure 7**

Arc ( $i, j$ )	Energy	Colour Code	SUBFLOW Setup $\sum_{(i,j) \in E} P_{i,j} - e_i P_i = 0$
(FO,DG)	Chemical	Brown	$P_{FO,DG} = P_{FO}$
(DG,PC)	Electrical	Magenta	$P_{DG,PC} = 48\% P_{DG}$
(DG,HE)	Heat	Yellow	$P_{DG,HE} = 52\% P_{DG}$
(PC,SE)	Electrical	Magenta	$P_{PC,SE} = 98\% P_{PC} - P_{PC,MT} - P_{PC,HT}$
(PC,MT)	Electrical	Magenta	$P_{PC,MT} = 98\% P_{PC} - P_{PC,SE} - P_{PC,HT}$
(PC,HT)	Electrical	Magenta	$P_{PC,HT} = 98\% P_{PC} - P_{PC,SE} - P_{PC,MT}$
(PC,HE)	Heat	Yellow	$P_{PC,HE} = 2\% P_{DG}$
(SE,MM)	Electrical	Blue	$P_{SE,MM} = 4.8\% P_{SE}$
(SE,LS)	Electrical	Magenta	$P_{SE,LS} = 95.2\% P_{SE}$
(MT,HE)	Heat	Yellow	$P_{MT,HE} = 3\% P_{MT}$
(MT,VT)	Mechanical	Black	$P_{MT,VT} = 97\% P_{MT}$
(LS,MS)	Electrical	Magenta	$P_{LS,MS} = 64\% P_{LS} - P_{LS,HS}$
(LS,HS)	Electrical	Magenta	$P_{LS,HS} = 64\% P_{LS} - P_{LS,MS}$
(LS,MX)	Electrical	Blue	$P_{LS,MX} = 36\% P_{LS}$
(MS,HE)	Heat	Yellow	$P_{MS,HE} = 3\% P_{MS}$
(MS,VS)	Mechanical	Black	$P_{MS,VS} = 97\% P_{MS}$

All arcs in the network were not capped and thus it can be any positive values  $0 \leq P_{i,j} \leq \infty$  (or Inf). This will also be the case for the supply node, the Fuel Oil (FO)  $\gamma_s$ , all hub nodes  $\gamma_h$ , and some target nodes  $\gamma_t$ , such as the Margin Energy (MX), the Motor Submerged (MS), the Motor Snort (MT), and the Heat Loss (HE) (see the bounds in Table 14). The capacities of the user nodes  $\gamma_t$  in the network then need to be calculated, which are dependent on the operating scenarios (see Table 14). They are the Hotel Submerged (HS), the Velocity Submerged (VS), the Velocity Snort (VT), and the Hotel Snort (HT). Finally, the coefficients of the objective function coefficient  $c_{i,j}$  in this SUBFLOW example were set to zero (see Objective Function equation in Table 14), because the aim of this optimisation example was not to cost the distributed ship service systems configuration, as in the case of Trapp's (2015) NSMCF investigation or Robinson's (2018) AFO study (including its variants (Parsons et al., 2020)). In this study, SUBFLOW was used to solve the energy balance, through a linear programming, set of equations. This ensured that the total energy demand on the submarine would be equal to the total energy available, indicating an initial systems design balance. Thus, in this SUBFLOW example, the network styles were proposed on the basis of prior expert knowledge and were deliberately not validated by analysis in early stage of ship design. Nonetheless, the SUBFLOW network created could have provided a suitable basis for further analyses in subsequent design phases, if required.

The Operational Matrix for this particular SUBFLOW example is outlined in Table 21. Since undirected network or bidirectional network contains more information than an undirected network (Mukti, 2022), the size of the Operational Matrix would have become quite large if bidirectionality had had to be considered (i.e., a  $[61 \times 47]$  matrix). Nonetheless, in this case, bidirectionality was not necessary as there had to be no backward flow from the target to the source nodes and thus the Operational Matrix has only 29 rows and 31 columns. Compared to the Operational Matrix for Sections 3.1 and 3.2, the Operational Matrix in this example shows how to arrange the energy coefficient from the AFO approach (Parsons et al., 2020) in the matrix, which is reflected as the coefficient  $e_i$  for the continuity constraints (rows 2 to 27 and columns 17 to 30).

By using the Operational Matrix in Table 21, the solver can provide the network solution as shown in Figure 8. Figure 8 shows 5.7 MW of power is transferred from the Fuel Oil node to the Diesel Generator node. The Diesel Generator node then converted the 5.7 MW of the fuel flow to 2.7 MW to Power Converter node (as electrical flow shown in magenta) and 2.9 MW to Heat Loss node (as waste heat shown in yellow). At the Power Converter node, the 2.7 MW of electrical flow was divided into 2.3 MW electrical flow for Stored Energy node, 166 kW for Motor Snort node, 224 kW to Hotel Snort node, and 55 kW to Heat Loss node. For the Stored Energy various flows simulate how much energy is needed during the submerged operating condition, i.e., a different time domain from the snorting operating condition. All of the flows shown in Figure 8 satisfied the SUBFLOW constraints given in Table 21.

## 4. THE OPERATIONAL MATRIX FRAMEWORK APPLIED TO THE UCL NETWORK BLOCK APPROACH

Section 3 addresses how the Operational Matrix Framework can be used to assess different types of network flow formulations. This section presents the setup of the Operational Matrix Framework that has been adopted in the UCL Network Block Approach (Mukti, 2022). Unlike the previous examples, the SUBFLOW formulation in the UCL Network Block Approach was devised to be ship design efficient, yet without losing the advantages of capturing the complexity of distributed ship service systems using a range of applicable network tools. In the UCL Network Block Approach, spreadsheet-based tools are used to define the ship design and its distributed ship service systems (Mukti et al., 2022). The tools specific for defining the network configuration and SUBFLOW inputs for the distributed ship service systems are the Component Granularity Program (CGP) and System Connection Program (SCP) (see (Mukti et al., 2022)).

Table 22 shows the example of the CGP inputs: the type of components (nodes), which were either terminal or hub nodes; the equipment load demand or maximum capacity was used to define the lower and upper bounds for the SUBFLOW in various operating conditions, for example, snort or sprint submerged; the objective function coefficient, which was set to zero; the energy coefficients  $e$  of each component up to 15 different types of distributed ship service systems commodities; and the logical layout (x, y, z coordinates) to create a “logical” multiplex network.

The energy coefficients  $e$  of each component node in Table 22 are defined as follows:

- The energy that enters a node is expelled 100% outside the node (IN=-1). This option was used for terminal source nodes, such as fuel, or terminal sink nodes, such as propulsion load.
- The energy that enters a node is dispersed to different types of energy in a form of some fraction (IN=fractional OUT). This reflects the Sankey Diagram practice and could have been used for electrical consumer nodes, including energy storage.
- The energy that enters a node is determined by the proportion of the energy from at least two different nodes in different systems. This option could have been used for modelling the fuel-air (energy) ratio of the diesel generator.
- The energy that might have entered a node could have been specified as a fraction of the total heat received at the node and that fraction of energy that has not been forwarded beyond that node (fractional IN=OUT). This choice could be used to describe the ‘coefficient of performance’ of cooling systems components.
- A ‘child’ node could receive 100% energy from two parent nodes from different systems and then store 100% energy output to that child node. This could have been used to model sink nodes on the vessel, for example, a seawater node.

Like the CGP, the System Connection Program (SCP) also provides necessary inputs for the SUBFLOW formulation, particularly for the connections/arcs. As shown in Table 23, the input consists of the identification of distributed ship service systems commodity/ technology (e.g., DT for data, EL for electric), the minimum and maximum capacity of the connection based on a given scenario (e.g., snort or sprint submerged for submarine case), and the objective function coefficient, which was also set to zero.

**Table 23: Example of the SCP inputs for performing SUB/RFLOW**

Once these inputs had been defined, the inputs above (captured in CGP and SCP) needed to be converted into an Operational Matrix format so that the solver in MATLAB could produce the SUBFLOW network solution. The generation of the Operational Matrix format can be demanding in the early stage of ship design if it was not automated as there can be thousands of rows and columns for defining a network of distributed ship service systems SUBFLOW problem. Thus, to make SUBFLOW as efficient as possible, the generation of the Operational Matrix need to be automated (see Figure 9).

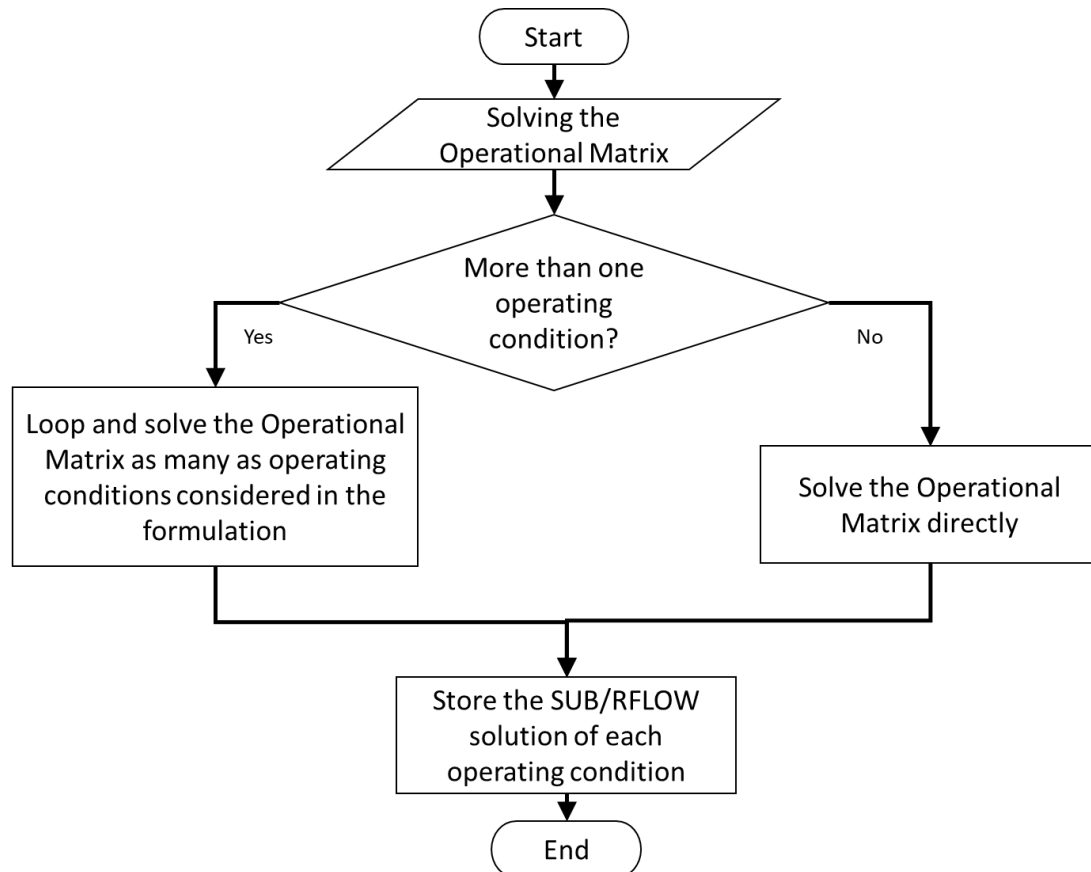

**Figure 9: Automatic generation of the Operational Matrix from CGP and SCP inputs**

To make an automated generation of the Operational Matrix possible, a MATLAB script was developed. Figure 10 shows the process including reading the CGP and SCP inputs and storing them into the network matrix in MATLAB. The SUBFLOW formulation is next converted into the Operational Matrix format and the Operational Matrix is fed into a solver in MATLAB to find the SUBFLOW solution. If the solver fails to find a set of feasible solutions, the CGP and SCP inputs need to be evaluated and altered. Once the SUBFLOW solution is found, the data is stored back in the network matrix in MATLAB.

**Figure 10: The procedure for automatic Operational Matrix generation**

The pattern of the Operational Matrix for the UCL Network Block Approach is given in Table 24. The number of columns of the Operational Matrix depends on the number of arcs in the SUBFLOW network. This matrix is divided into several groups of boxes in rows. The first box of the matrix in Table 24 gives the objective function coefficients, which is set to zero to obtain the energy balance. The second box is allocated to continuity as well as the energy coefficient  $e$  for each node, which can be positive or negative. The third box contains the inequality constraints and the last two boxes consists of the lower bounds and the upper bounds. The lower and upper bounds are where the ‘operational’ aspect is defined, i.e., the supply or demand of a commodity of a node in each operating condition. Therefore, a different operating condition (e.g., snort and sprint submerged) requires a different Operational Matrix, which can be treated as a loop in MATLAB (see Figure 11).

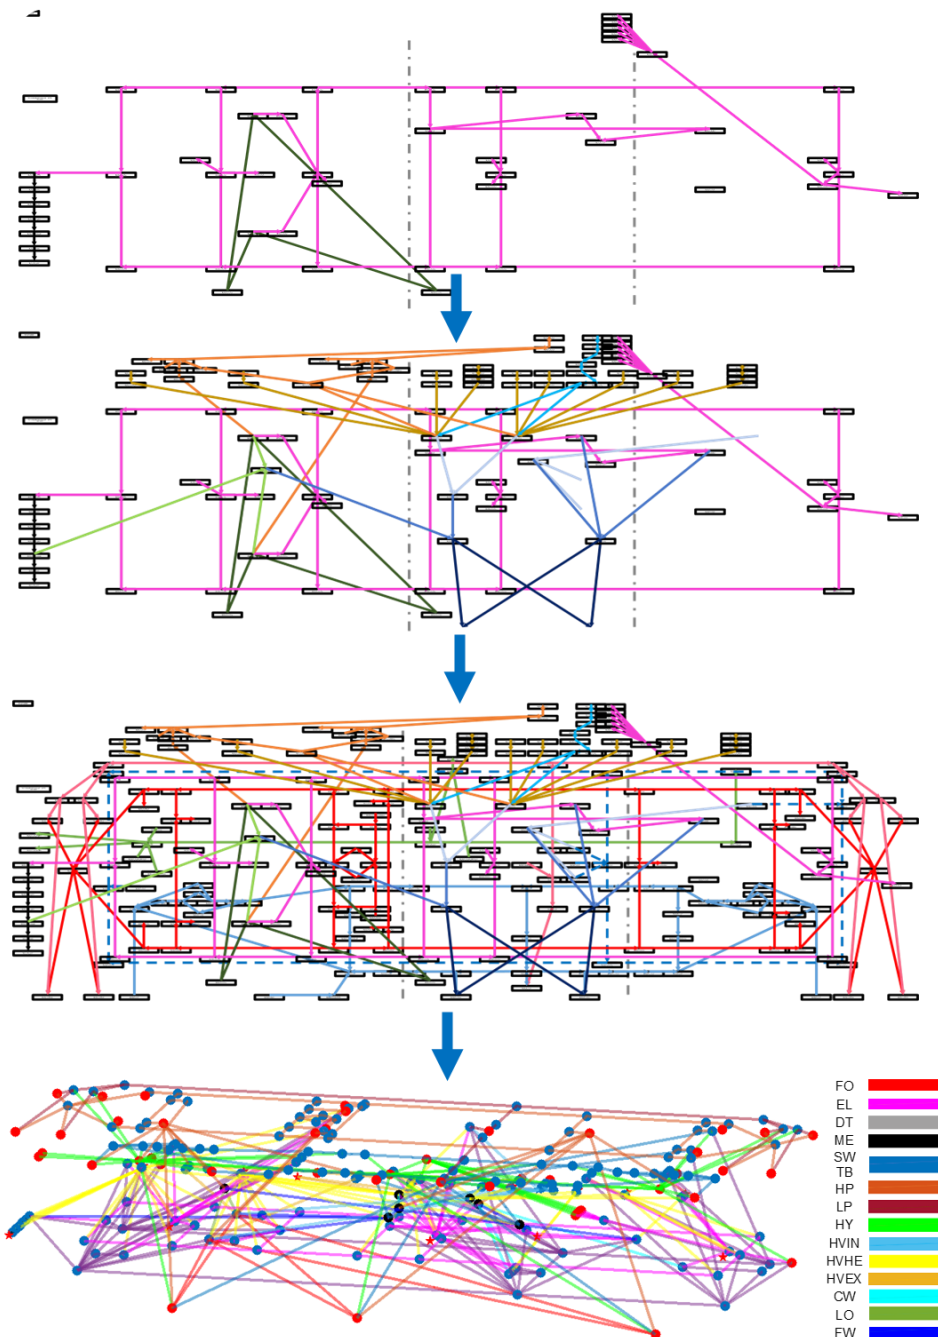

**Figure 11: Solving the Operational Matrix based on operating condition(s)**

Compared to example Operational Matrices in the previous section, the matrix in Table 24, is scalable and simpler. This was to reduce the extent of the SUBFLOW analysis to be commensurate with early stage ship design. SUBFLOW was used to perform a steady state simulation of power flow in a distributed ship service systems network. SUBFLOW was employed to provide early estimates of the distributed ship service systems space and weight input as well as to explore distributed ship service systems options as part of the Requirement Elucidation process (Andrews, 2018).

The continuity constraints in the SUBFLOW network for the UCL Network Block Approach were hardcoded, i.e., automatically generated. However, the rest of the mathematical model for SUBFLOW formulation could be adjusted/ defined in the Component Granularity Program (CGP) and the System Connection Program (SCP). The formulation process was iterative and substantial to achieve a feasible network solution, i.e., if the formulation is incorrect, the solver will not be able to find the linear programming network solution (see Figure 10). Still, the SUBFLOW required more engineering and inputs than parametric approach, such as the configuration of the distributed ship service systems, also specifying its properties, and creating mathematical models for the energy balance analysis.

The SUBFLOW in the UCL Network Block Approach allows the style (Andrews, 2018) of distributed ship systems to be captured and can aid the designer to understand how a given system functions. Most importantly, when combined with the whole ship UCL Design Building Block approach (Andrews and Pawling, 2003), it enabled a more realistic distributed ship service systems synthesis to be undertaken. This was thus not just numeric but also addressed spatial/architectural aspects which a parametric approach lacking. However, it is not as detailed as collaborative analysis tools which are more appropriate to detailed design of such distributed ship service systems. Figure 12 shows an example of modelling a range of submarine systems: fuel (FO); electrical (EL); data (DT); mechanical (ME); hydraulics (HY); trim and ballast (TB); saltwater (SW); high-pressure air (HP); low-pressure air (LP); ventilation (HVIN/HE/EX); chilled water (CW); lubricating oil (LO); fresh water (FW) cooling systems (see (Mukti, 2022) for details).

**Figure 12: An example of SUBFLOW network development and solution in the UCL Network Block Approach (Mukti, 2022), showing energy flows in various distributed ship service systems**

## 5. CONCLUSION AND FUTURE WORK

There are several possible applications of the Operational Matrix Framework, such that it could be employed to suit several specific network flow formulations. Table 25 shows the high-level comparison between various Network Flow Optimisation setups. Generally, the SUB/RFLOW excludes the survivability analysis to allow enhancement in several aspects, such as the incorporation of a colour-coded 3D multiplex network with the labels showing how much energy flowing from system to system (Figure 12). The Operational Matrix Framework approach has enabled the solvers to be very efficient compared to millions of lines of CPLEX scripts (Brown, 2020). Most importantly, SUB/RFLOW enabled the incorporation of the 3D rich architecturally centred approach, the UCL DBB approach, which shows the potential benefits in assessing wholship impact of a new (style) of distributed ship service systems design (Mukti, 2022). However, as aforementioned, the design data in the UCL Network Block Approach could have provided a suitable basis for further (survivability) analyses in subsequent design phases, if required.

**Table 25: General comparison between different types of Network Flow Optimisation setup for naval ships applications**

Formulation	Network Flow Optimisation for Ship Systems Application		
	NSMCF (Trapp, 2015)	AFO (Brown, 2020)	SUBFLOW (Mukti, 2022)
Objective Function	Procurement and installation cost	Procurement and installation cost	None (“constraints only” approach to find energy balance)
Solver	CPLEX	CPLEX	CPLEX toolbox (or <i>linprog</i> ) in MATLAB
Software interface/ Programming language	MATLAB script to CPLEX script	MATLAB script to CPLEX script	Fully in MATLAB using Operational Matrix Framework
Survivability analysis	Yes	Yes	No
Can be used for sizing distributed systems	No	Yes	Yes
Application	Integrated Engineering Propulsion (IEP) plant	Surface ship systems	Submarine/ Surface ship systems (Mukti et al., 2024)
Using energy coefficient	No	Yes	Yes
Using flow capacity	Yes	Yes	No
Hot and cool model	Yes	Yes	No/Simplified
Multilayer network/ all arcs visible to inspect the energy flow between systems	No	No	Yes, using SUB/RFLOW Multiplex Framework
Support 3D rich ship architecture definition (e.g., equipment arrangement and routings)	No	No	Yes, via Paramarine-SURFCON

In this paper, studies range from the simplest application of Operational Matrix Framework to an example of one of the more complex Operational Matrix applications to the 3D multiplex submarine systems problem in the last section. The use of the proposed Operational Matrix Framework can reveal the relationship between objective functions, constraints, bounds, and solutions of that linear programming formulation. This is demonstrated particularly by the arrows in Table 11, which shows that the network formulation is driven by the constraints at the user nodes, i.e., the lower and upper bounds for the user nodes. These values first influence the equality constraints and subsequently the inequality constraints (these are defined earlier in the paper). The set of solutions in the inequality constraints is directly influenced by the lower and upper bounds for the inequality

constraints. Ultimately, the solver ensures that the objective function produces the possible minimum value for the network solution (see the values in the bracket in the first seven columns in the first row of Table 11).

By mapping the coefficients of the linear programming formulation and the network solution in a manner of the Operational Matrix Framework, coefficients that drive the network solution could be identified before incorporating more extensive cost/survivability coefficients as part of meeting an objective function and responding to further constraints. This gave the ship designer awareness, clarity, and confidence in understanding the logical reasoning behind why the solver produces such a network solution. Without the Operational Matrix Framework, the linear programming in the UCL Network Block Approach would not have been sufficiently simplified for early-stage ship systems sizing applications. An overcomplicated network formulation could distract the designer from the main focus of requirement elucidation: to understand the impact of distributed ship service systems (DS3) choices on the overall submarine design, which could have consequences for the vessel's overall architecture. Thus, the Operational Matrix Framework can be seen to reduce the “black box” nature when using the linear programming tool to explore DS3 choices in early stage of ship design.

One of the main areas of future work is to consider whether the existing execution time of the MATLAB script could be further improved by incorporating a new solver other than CPLEX toolbox (e.g., MATLAB *linprog*) to ensure a designer could perform the many iterations required to formulate SUB/RFLOW. Another area would be to expand the application of the Operational Framework to other complex vessels, including but not limited to various surface warships or oil and gas service vessels (Floating Production Storage and Offloading (FPSO) ship, OSVs, drilling ship, etc). This includes expanding the consideration of aspects of maintenance, and supportability for evaluating various submarine systems style choices. The Operational Matrix Framework could also be developed further for investigating the analysis of energy balances for new systems to achieve net zero energy demands for future naval vessels.

## CONTRIBUTION STATEMENT

**Author 1:** conceptualisation, data curation, formal analysis, methodology, writing – original draft. **Author 2:** funding acquisition, supervision. **Author 3:** funding acquisition, writing – review and editing.

## ACKNOWLEDGEMENT

This research stems out of a multinational university collaboration involving: University of Michigan, Delft University of Technology, University College London, and Virginia Tech. These partners gratefully acknowledge the funding of this Naval International Cooperative Opportunities in Science and Technology Program (NICOP) contract number N00014-15-1-2752, sponsored by Ms. Kelly Cooper of the US Navy Office of Naval Research, which is a follow-on of a previously successful collaboration. That was undertaken by the first three universities exploring ship layout in early stage of ship design (Andrews et al., 2012). The original work was focused on studying methods for generating and analysing general arrangements in early-stage ship design (Andrews et al., 2012). The second NICOP extended that layout work to study the relationship between distributed system design and general arrangements, in the context of ship survivability (Brefort et al., 2018). The current study could be seen to build on both NICOP projects activities in early stage of ship design research and the current outcome acknowledges the insights from both collaborative endeavours.

## DISCLAIMER

The work presented in this paper is part of the thesis of the first author (Mukti, 2022), which in part has been presented in several other papers also referenced in this paper. However, the Operational Matrix focus of this paper has not been presented directly beyond the thesis.

## ABSTRACT

*Well-designed hydrofoils improve ship resistance and seakeeping by lifting the hull above the water. With greater speeds come greater loads, and the two-way interaction of structural deflections of lifting surfaces on the hydrodynamics must be considered. Tailored structural anisotropy can improve hydrodynamic and structural efficiency of lifting surfaces compared to rigid counterparts by exploiting the layup of composite materials. Structural efficiency here means reduced risk of structural failure for a given amount of material, and hydrodynamic efficiency means lower drag. A T-foil is a prototypical multi-component appendage, consisting of the foil wing and the strut, which we investigate in this work. We use simple composite beam and lifting line theory to explore the static fluid-structure interaction of a composite T-foil for a variety of fiber angles ( $\theta_f = 0^\circ, \pm 15^\circ$ ). We apply a simple approximation on lift coefficient at infinite Froude number ( $Fn$ ) to model the free-surface effects, which is valid at high depth-based Froude numbers ( $Fn_h > 10\sqrt{h/c}$ ) when  $C_L$  is independent of  $Fn_h$  and the inertial effects dominate. Results for the moth rudder T-foil geometry studied here indicate that aligning composite fibers towards the leading edge results in a more hydrostructurally efficient foil and that free-surface effects are minor because of the large submergence for this flow condition.*

Hydrodynamics; Composite structures; Hydrofoil; Hydroelasticity; Fluid-structure interaction

## INTRODUCTION

T-foils are prototypical lifting surface configurations commonly used to lift a vessel above the free surface. Flying above the water improves seakeeping performance because of the reduced waterplane area. Foiling also removes any resistance associated with hullborne operation: hull wetted skin friction drag, hull form drag, hull wave making drag, wave added resistance, etcetera. For a fixed amount of total resistance, a foiling vessel can sail much faster than a hullborne one since drag force scales with speed squared. In other words, foilborne vessels have better energy efficiency than hullborne vessels in higher speed regimes, which was investigated by Godø and Steen (2023a). However, faster vessels come with concerns for cavitation and ventilation phenomena on the foils. Additionally, loads on the structure approach yield limits, and the two-way coupled effect of the deformed state of the foils on the hydrodynamic loads must also be considered. Hydroelastic analysis is thus critical for the accurate assessment of higher speed vessels.

More recently, composite materials have gained the interest of foil designers because of hydroelastic tailoring, which improves the hydrodynamic and structural performance of these devices in off-design conditions. Directional stiffness, or *material anisotropy* opens up the potential for passive, load-dependent, shape-adaptative marine structures. A more structurally efficient foil can be realized because deflections under fluid load can be designed to avoid critical stresses and deflections, and hence material failure. Flow-induced vibrations and noise can also be designed away through tuning of plies and structural sizing variables (Ng et al., 2022; Mulcahy et al., 2014; Groo et al., 2019). These structurally efficient foils require less material to achieve a given objective. Composites also improve hydrodynamic efficiency through lower drag designs because the load-dependent deflections favorably reduce subcavitating drag as demonstrated by Liao et al. (2021).

The composite structure can be modeled with varying fidelity to capture quantities of interest. For example, Faye et al. (2024) used low-fidelity composite beam elements to model material bend-twist coupling for a deflecting hydrofoil. Beam theory is cheap, but it can miss some material failure mechanisms. In contrast, Liao et al. (2023) modeled grouped layers of composite laminates with brick finite element models of a hydrofoil to more accurately capture through-thickness stresses and deformations that can then be used in more rigorous material failure criteria. Maung et al. (2023) went further with their composite hydrofoil optimization using a detailed finite element model of a hydrofoil with curved fibers that also captured ply drops.

For lifting surfaces operating near the free surface, one must additionally consider the effects of free-surface proximity on the loads and local pressures on the appendage to accurately optimize a design. The first-order effects of the free surface boundary on hydrodynamic loads can mostly be captured with potential flow methods and a linearized free-surface boundary condition. A numerical lifting line method is the lowest order potential flow model appropriate for loads on a hydrofoil wing. Godø and Steen (2023b) present one example of a lifting line method for determining the hydrodynamic loads on a hydrofoil with linearized free-surface effects computed through a Green's function, which avoids the need to mesh the free surface boundary. Nicolas et al. (2023) used the linearized free-surface boundary condition as well but modeled the hydrofoil with panels on the body, which captures thickness and lifting effects more accurately than a lifting line method. Beck and Reed (2001, Fig. 1) presents an overview of numerical methods for handling free surface effects from inviscid potential flow to viscous direct numerical simulation. The latter is too costly for preliminary design and analysis, which is the area of focus for this work.

At low speeds, the free surface behaves like a rigid wall boundary, whereas at high speeds, it acts as pressure relief because the perturbations forces of the moving body overcome the gravity of the water that maintains the rigid wall behavior at low speeds (Faltinsen, 2006, Ch. 6). The non-dimensional number that best characterizes these regimes of free-surface effects is the *Froude number*, which is the ratio of inertial to gravitational forces. The chord-based ( $c$ ) and depth-based ( $h$ ) Froude numbers are given by

$$Fn_c = \frac{U_\infty}{\sqrt{gc}}, \quad Fn_h = \frac{U_\infty}{\sqrt{gh}}. \quad (1)$$

Faltinsen (2006, Ch. 6) presents approximations to the hydrodynamics loads in the Froude number limits used in this work.

The choice of hydrodynamic and structural model fidelity depends on the balance between computational speed and required accuracy of the physics to assess a candidate design. This work deals with preliminary hydroelastic design of foils so we deem lifting line and composite beam theories as adequate. First, we discuss the theoretical background and the case setup of our hydro-structural model in the Dynamic Composite Foil (DCFoil.jl) program. Then, we present and discuss the static hydroelastic behavior of a moth T-foil rudder for various material configurations with the free-surface effect turned on and off. We conclude with overall insights based on our results and suggestions for future work.

## METHODOLOGY

The following sections describe the basic background of the static analysis mode of the Dynamic Composite Foil (DCFoil.jl) program. DCFoil.jl was originally developed considering second-order dynamical system analysis in the mass-

spring-dashpot sense of  $\mathbf{M}_s \ddot{\mathbf{u}} + \mathbf{C}_s \dot{\mathbf{u}} + \mathbf{K}_s \mathbf{u} = \mathbf{f}_{\text{hydro}}$  (Ng et al., 2023), but we remove time derivative terms for static analysis. The governing discrete equation for static analysis is

$$\mathbf{K}_s \mathbf{u} = \underbrace{\mathbf{f}_{\text{hydro}}(\mathbf{u})}_{= -(\mathbf{K}_f) \mathbf{u}} \quad (2)$$

where  $\mathbf{u}$  are the structural states,  $\mathbf{K}_s$  is the structural stiffness matrix, and  $\mathbf{K}_f$  is the hydrodynamic stiffness matrix. We solve this equation for  $\mathbf{u}$  using a Newton-Raphson scheme. The next section describes the computation of  $\mathbf{K}_s$ ; the following,  $\mathbf{K}_f$ . The global coordinate system, shown in Figure 1, is  $x$  streamwise,  $y$  to starboard, and  $z$  up.

**Figure 1:** Global coordinate system for the composite T-foil with positive fiber angle convention.

## Composite beam finite element model

The composite beam model has been previously developed and validated against a composite plate model in ABAQUS (Ng et al., 2023). The beam finite element has two nodes with nine degrees of freedom at each node to account for structural warping. The only noteworthy new extension to the implementation is the mesh generation routine for a T-foil. Previously, we only studied cantilevered beams (half-wing). We updated the routine for generating meshing and element connectivity to handle three “half-wings”: two port-starboard (P/S) symmetric wings and one strut. Figure 2 shows the stick model.

As for structural properties, we specify only two sets of parameters for the half-wing and strut, since the wings are P/S symmetric. For example, a fiber angle of  $\theta_f = 15^\circ$  on the starboard wing (aligned towards the leading edge) is mirrored on the port wing. We assume the elastic axis (locus of shear centers) is along the midchord.

## Hydrodynamic lifting line model

The basic lifting line model builds on our previous work (Ng et al., 2022, 2023) that follows Glauert’s method (Glauert, 1983, Ch. 11) for the static lifting line of a hydrofoil of arbitrary planform. We assume a Fourier sine series expansion for the spanwise vorticity  $\gamma(y)$  and solve a linear system for the Fourier coefficients using relations for the spanwise downwash and vorticity. Because the strut interrupts the wing at the centerline, the spanwise vorticity is zeroed out at the junction collocation node. Then we compute the spanwise lift slope  $c_{\ell_\alpha}(y)$  to populate the  $\mathbf{K}_f$  matrix. The center of lift is at  $c/4$  for each section, which is an inviscid thin-airfoil assumption. Note, the quarter-chord center of pressure assumption does lose validity at higher angles of attack because of flow separation that causes the center of pressure to migrate towards the mid-chord.

In steady-state potential flow, the *negative image method* is appropriate for representing the free surface in the high Froude number limit. Conversely, the *positive image method* is for low Froude number flows. The *linearized*<sup>1</sup> *free-surface bound-*

<sup>1</sup>Assuming small wave slopes and removing higher order velocity terms

**Figure 2:** Stick model of a T-foil with overall dimensions labeled. Airfoil slices are drawn at node locations to aid with visualization.

ary condition, which can be derived from combining a dynamic and kinematic boundary condition (Newman, 2018, Sec. 6.1), is

$$U_{\infty}^2 \frac{\partial^2 \varphi}{\partial x^2} + g \frac{\partial \varphi}{\partial z} = 0 \quad \text{for } z = 0, \quad (3)$$

where  $z = 0$  is the mean free surface and  $\varphi$  is the perturbation potential of the lifting body. The total potential is  $\Phi = U_{\infty}x + \varphi$ . Equation 3 tells us the first term vanishes for low  $Fn$ , and the second term vanishes for high  $Fn$ . For high Froude numbers,  $\varphi = 0$  on  $z = 0$  is a solution to the boundary condition equation 3. Putting negative images of source and vortex singularities equal distances from the free surface as the actual body satisfies this. Approximations to the asymptotical behavior of lift and drag at high Froude numbers exist that facilitate rapid analysis for submerged lifting surfaces. Faltinsen (2006) gives this 2D lift relation accounting for free-surface effect

$$c_{\ell} \left( \frac{h}{c} \right) = c_{\ell} \left( \frac{h}{c} = \infty \right) \cdot \left[ \frac{1 + 16(h/c(y))^2}{2 + 16(h/c(y))^2} \right] \quad \text{for } Fn_h > 10/\sqrt{h/c}, \quad (4)$$

where the bracketed term is a “corrective” factor accounting for the negative image vortex. The extension to a 3D foil follows as a correction on the spanwise vorticity. The spanwise vorticity, is a decomposition of circulation in 2D and downwash-induced circulation from neighboring vortex elements

$$\gamma(y) = \underbrace{\gamma_{2D}}_{\text{airfoil}} - \underbrace{\pi c(y) w_i(y)}_{\text{downwash effect}}. \quad (5)$$

The correction applies to the airfoil vorticity

$$\gamma_{2D} \left( y, \frac{h}{c} \right) = \underbrace{-U_\infty c(y) \pi \alpha}_{\gamma_{2D}(y, \frac{h}{c} = \infty)} \left[ \frac{1 + 16(h/c)^2}{2 + 16(h/c)^2} \right]. \quad (6)$$

We compute the total spanwise vortex strength  $\gamma(y)$  from Glauert's method so we simply subtract the  $\gamma_{2D}$  with no free-surface effect and add back the circulation with free-surface effect (Equation 6).

## CASE SETUP

The T-foil model is based on the moth rudder T-foil studied by Liao et al. (2022); Ashworth Briggs (2018); Binns et al. (2008). The foil has a 0.4 m strut with a NACA0015 section. The wings are NACA0012 sections with a  $b = 0.333$  m semispan, a root chord of 0.14 m, and a tip chord of 0.095 m. The stick model showing the dimensions is given in Figure 2. We use 19 elements for each half wing and nine for the strut. The planform area of a half-wing is  $0.039\text{m}^2$ , and the area we use in nondimensionalization of forces in the next section is twice that value ( $A = 0.078\text{m}^2$ ).

The material properties are for uni-directional (UD) carbon fiber-reinforced plastic (CFRP) given in Table 1. In reality, the foil would be made of a laminate with several plies of different angles embedded in a resin matrix to avoid crack propagation, but for the purposes of exploring anisotropy effects, these mechanical properties are adequate.

**Table 1:** Subscript 1 is along the fiber, 2 is in-plane, and 3 is out-of-plane.

Variable	Symbol	CFRP	Units
Solid density	$\rho_s$	1,590	$\text{kg/m}^3$
Elastic moduli	$E_1$	117.8	GPa
—	$E_2 = E_3$	13.4	GPa
Shear moduli	$G_{12} = G_{23}$	3.9	GPa
Poisson's ratio	$\nu_{12} = \nu_{13}$	0.25	—

For the flow setup, we consider one speed of  $U_\infty = 18\text{ m/s}$  ( $\approx 35\text{ kts}$ ), which corresponds to the top speed analyzed by Liao et al. (2022) and is consistent with typical hull speeds sailors can achieve during races. The depth Froude number is then  $Fn_h = 9.09$ , which is greater than the highest limiting value of  $10/\sqrt{h/c} = 5.92$  at the root chord, so the negative image method applies. Fluid density is  $\rho_f = 1025\text{ kg/m}^3$  for seawater. We assume no yaw angle or leeway effects, so flow comes head on and the strut produces no load. The wing has a base rake angle of  $\alpha_r = 2^\circ$ .

We look at three hydrofoils with varying fiber angles on the wing. The first is  $\theta_f = 0^\circ$  and the next two are  $\pm 15^\circ$ . The strut fiber angle stays at  $\theta_f = 0^\circ$  because there will be no side loads in these cases. We also divide the results further into the ones with a deeply submerged assumption (no correction to  $\gamma(y)$ ) and ones with the free surface model as explained prior. The foils will not all produce the same lift, so at the end, we run a polar varying  $\alpha_r$ .

## RESULTS

The following section first discusses the case setup and then presents the results.

## Static hydroelasticity of the T-foils

### Lifting forces and deflections

In Table 2, we see the lift generated by the various foils. As one would expect, as fiber angle goes from negative to positive (trailing edge to leading edge), the total lift decreases because of an increased de-pitching effect to which the material anisotropy contributes. Furthermore, the lift between no free surface model and the free surface model decreases marginally because of the reduction in circulation caused by proximity to the free surface at high  $Fn_h$ . The reduction is minor because depth-to-chord ratio ( $h/c$ ) is high. The depth-to-chord ratio is squared in Equation (6) and thus brings the correction factor close to unity. The reduction in forces is also less pronounced when less lift is produced.

**Table 2:** Lift of the various foils with percent difference from no free surface model.

	$\theta_f = -15^\circ$		$\theta_f = 0^\circ$		$\theta_f = 15^\circ$	
	$L$ [N]	$C_L$	$L$ [N]	$C_L$	$L$ [N]	$C_L$
No free surface model	5738.7	0.442	2469	0.190	1787	0.138
Free surface model	5527.9 (-3.7%)	0.425	2444 (-1.0%)	0.188	1776 (-0.6%)	0.137

Table 3 presents the moments about the midchord where positive is nose-up. Consistent with the lift trend, the moments also decrease as the fiber angle goes from negative to positive angle alignment. The percentage difference between free sur-

**Table 3:** Moment about midchord line of the various foils.

	$\theta_f = -15^\circ$		$\theta_f = 0^\circ$		$\theta_f = 15^\circ$	
	$M_y$ [N-m]	$C_{My}$	$M_y$ [N-m]	$C_{My}$	$M_y$ [N-m]	$C_{My}$
No free surface model	165.1	0.108	73.2	0.048	54.0	0.035
Free surface model	159.2 (-3.6%)	0.104	72.5 (-1.0%)	0.047	53.7 (-0.6%)	0.035

face and no free surface model are also consistent with lift trends, since the differences are smaller for more lightly loaded foils. The overall moments remain positive because the center of lift (assumed  $1/4$  chord) are all upstream of the midchord location. Moments decrease because there is less lift applied.

The total lift loads and coefficients are consistent with Reynolds-averaged Navier-Stokes (RANS) simulations by Liao et al. (2022) as these foils are also around  $C_L = 0.2$  except for the  $\theta_f = -15^\circ$  foil, which produces much more lift. We would not expect identical loads since the foils are not identical to Liao et al. (2022), and we have structural compliance in the current study. Furthermore, Liao et al. (2022) used a symmetry boundary condition, which is analogous to the positive image method, so we would expect their results to have slightly more lift than the present study if everything else were the same.

The deflected states of the hydrofoils with no free-surface effect are visualized in Figure 3. The deflections are scaled by two to better visualize the differences between the different fiber angle foils. The  $\theta_f = -15^\circ$  T-foil experiences significantly more deflection.

Figure 4 shows the half-wing spanwise loading and deflections for the three fiber angles with no free-surface effect in solid lines and with free-surface effect in dashed lines. There are minor differences, which makes sense because this is a relatively high  $h/c$ . At lower submersion depths (smaller  $h/c$ ), we expect there to be a greater reduction in lift and moments because of free-surface proximity, and thus, the wings would deflect less. The spanwise loads and deflections here illustrate the minor impact the free surface proximity has on the foils.

An implication of these lift and deflection studies is on susceptibility to cavitation and ventilation. Cavitation depends on local pressure dropping below the saturated vapor pressure of water (Brennen, 2014). Ventilation depends on proximity to the free surface, the existence of flow separation, and going above a critical lift threshold (Damley-Strnad et al., 2019;

**Figure 3:** 3D views of the deflected hydrofoil. Deflections scaled by two for visualization purposes.

**Figure 4:** Spanwise vertical bending, twisting, lift, and moment distributions for the different fiber angle T-foils using the deeply submerged assumption (solid) and infinite Froude number free surface effect (dashed).

Young et al., 2017). Based on this intuition, one could deduce that the  $\theta_f = -15^\circ$  composite T-foil would have many issues. It produces more lift at the tip than the other foils at this rake angle. The tip twist is around  $\theta_{\text{tip}} + \alpha_r = 9^\circ + 2^\circ = 11^\circ$ , which when coupled with any variations in angle of attack due to waves or vessel motions could create a strong tip vortex and stall the tip. A strong tip vortex has a low-pressure core, which can result in undesired tip vortex cavitation. Cavitation can be particularly damaging to composite structures (Yamatogi et al., 2009), and it also creates noise and vibrations that

are harmful to the vessel operation. In addition to the cavitation problems, the stalled tip could create a low-energy flow area that is a pathway for air to be sucked down onto the foil. It is also possible for tip vortex cavitation to promote tip ventilation. Collapse of vaporous bubbles induces local velocities towards the body, which break the surface seal earlier than without cavitation. Another effect is that the buoyancy of a cavitating tip vortex is greater than that of a subcavitating tip vortex (Young et al., 2017, Sec. 4.1.4). Sudden ventilation would be detrimental to overall vessel performance and controllability since lift would suddenly drop by about half.

Furthermore, the overall deflections of the  $\theta_f = -15^\circ$  hydrofoil are quite high (about 8% of semispan) and structural failure may also be a concern. In contrast, the  $0^\circ$  and  $15^\circ$  are more well-behaved and safer candidate designs for further exploration because they do not have as high a risk of static structural failure or ventilation. There appears to be little merit to aligning fibers towards the trailing edge unless there were some aileron-like surface outboard, in which case, the controllability of the foiling vessel would be improved. Any dynamic hydroelastic failure mechanisms, such as flutter, remain to be explored.

### Drag build-up

A steady-state drag build-up model must consider parasitic drag ( $D_p$ ) and drag due to lift. Drag due to lift is not the same as lift-induced drag (Kroo, 2001). In equation form, total drag (not considering multiphase flow) is

$$D = D_p + \underbrace{\frac{L^2}{q\pi b^2 e}}_{\text{drag due to lift}} \quad \text{where } D_p = D_{\text{fric}} + D_{\text{form}} + D_w + D_{\text{int}} + D_{\text{spray}}, \quad (7)$$

and  $e$  is the Oswald efficiency factor. For this hydrofoil assuming single-phase flow, the parasitic drag (everything that is not drag due to lift) consists of interference ( $D_{\text{int}}$ ), spray ( $D_{\text{spray}}$ ), wave-pattern ( $D_w$  assumed zero), skin friction ( $D_{\text{fric}}$ ), and form drag ( $D_{\text{form}}$ ). To supplement the equation form of total drag, Figure 5 hierarchically categorizes the drag components and typical nomenclature used to describe calm-water drag.

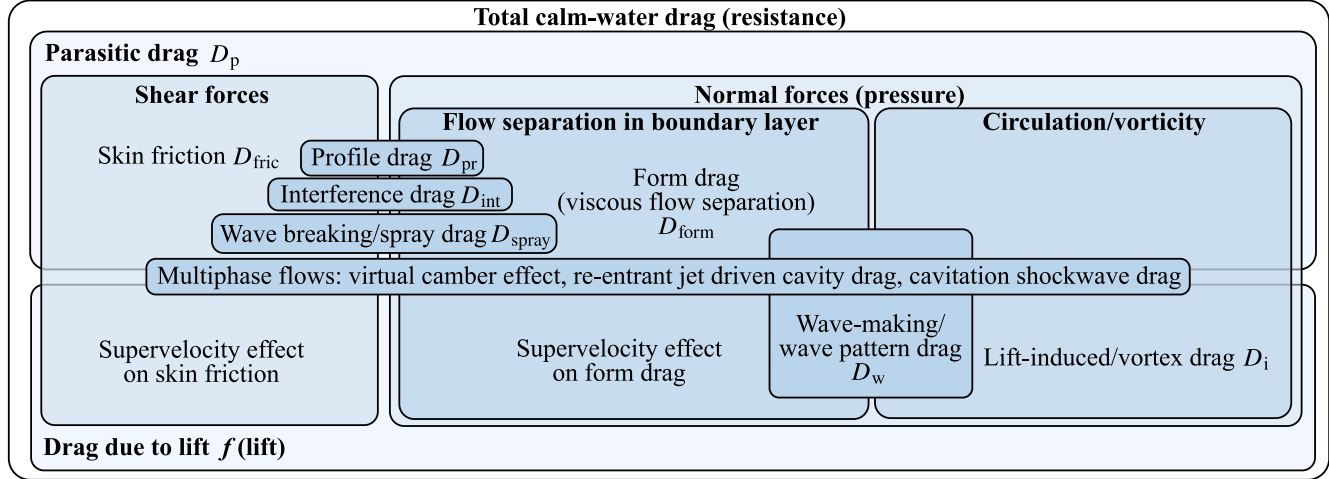

Figure 5: Sources of hydrodynamic drag

A model for the lift-induced drag is based on the spanwise vorticity and downwash. The total induced drag is computed via

$$F_x = -\rho \int_{-b}^b \gamma(y) w_i(y) dy \approx -\rho \sum_{n=1}^{n_{\text{strips}}} \gamma_n(y) w_{i,n}(y) dy_n. \quad (8)$$

The empirical relation for interference drag for a strut junction with no fairing from Hoerner (1965, Ch. 8) is

$$C_{D,j} = \frac{D_{\text{int}}}{qt^2} = 17 \left( \frac{\bar{t}}{c} \right)^2 - 0.05, \quad (9)$$

where  $\bar{t}$  is the mean thickness of the strut and wing near the junction and  $q = \frac{1}{2}\rho_f U_\infty^2$  is the dynamic pressure. In reality, junction drag depends on much more than the thickness-chord ratio, such as the bluntness of the nose that affects the strength of the necklace vortex (Simpson, 2001).

Due to lifting and thickness effects, the foil generates surface waves, which adds a component called wave drag. The lifting effect on the generated waves tends to be more important. In 2D, wave drag goes to zero at very high  $Fn_h$  (Faltinsen, 2006, Ch. 6) and hence we assume it to be zero. In the case of 3D flow, the aforementioned behavior is that of the transverse waves. The divergent waves still contribute to wave drag regardless of how high  $Fn_h$  is. It behaves asymptotically at high enough  $Fn_h$ , so it would be a constant offset in our results. Nevertheless, we neglect this component due to time constraints, but Faltinsen (2006, Eq. 6.167) gives the relation.

Hoerner (1965, Ch. 10) gave an empirical relation for the spray drag caused by water piling up on the forebody and shooting into the air as  $C_{D,s} = D_{\text{spray}}/(qt_{\text{strut}}^2) = 0.24$ , which applies to  $Fn_c > 3$ . However, this does not consider some details of the strut form, so we use the spray drag relation from Chapman (1971)

$$C_{D,s} = \frac{D_{\text{spray}}}{qc_{\text{strut}}t_{\text{strut}}} = 0.009 + 0.013 \left( \frac{t}{c} \right)_{\text{strut}}, \quad (10)$$

where the location of maximum thickness  $(x/c)_{\text{max}}$  is around 35%.

The profile drag (skin friction plus form) at hydrofoil sections assumes a flat-plate estimate with form factor corrections. The friction drag is estimated via the ITTC 1957 line

$$C_f = \frac{D_{\text{fric}}}{q\text{WSA}} = \frac{0.075}{(\log_{10}(Re) - 2.0)^2}, \quad (11)$$

where WSA is wetted surface area. The equation is an empirical formula for skin friction of naked ship hulls assuming turbulent flow (Carlton, 2018). The empirical form factor  $(1 + k)$  is determined from Torenbeek (1990) for a subsonic wing

$$1 + k = 1 + 2.7 \left( \frac{t}{c} \right) + 100 \left( \frac{t}{c} \right)^4, \quad (12)$$

where the first term with thickness captures the increased skin friction from thickness effects and the quartic term accounts for flow separation drag. This equation misses the angle of attack effects on the profile drag, sometimes referred to as a superelevation effect (Raymer, 2012, Sec. 12.5.5), which increases the skin friction and form drag. Full profile drag is then just  $D_{\text{pr}} = (1 + k)D_{\text{fric}}$ .

The total drag of the foils at  $\alpha_r = 2^\circ$  are in Table 4. Since the foils are not all at the same lift condition, the lift-induced

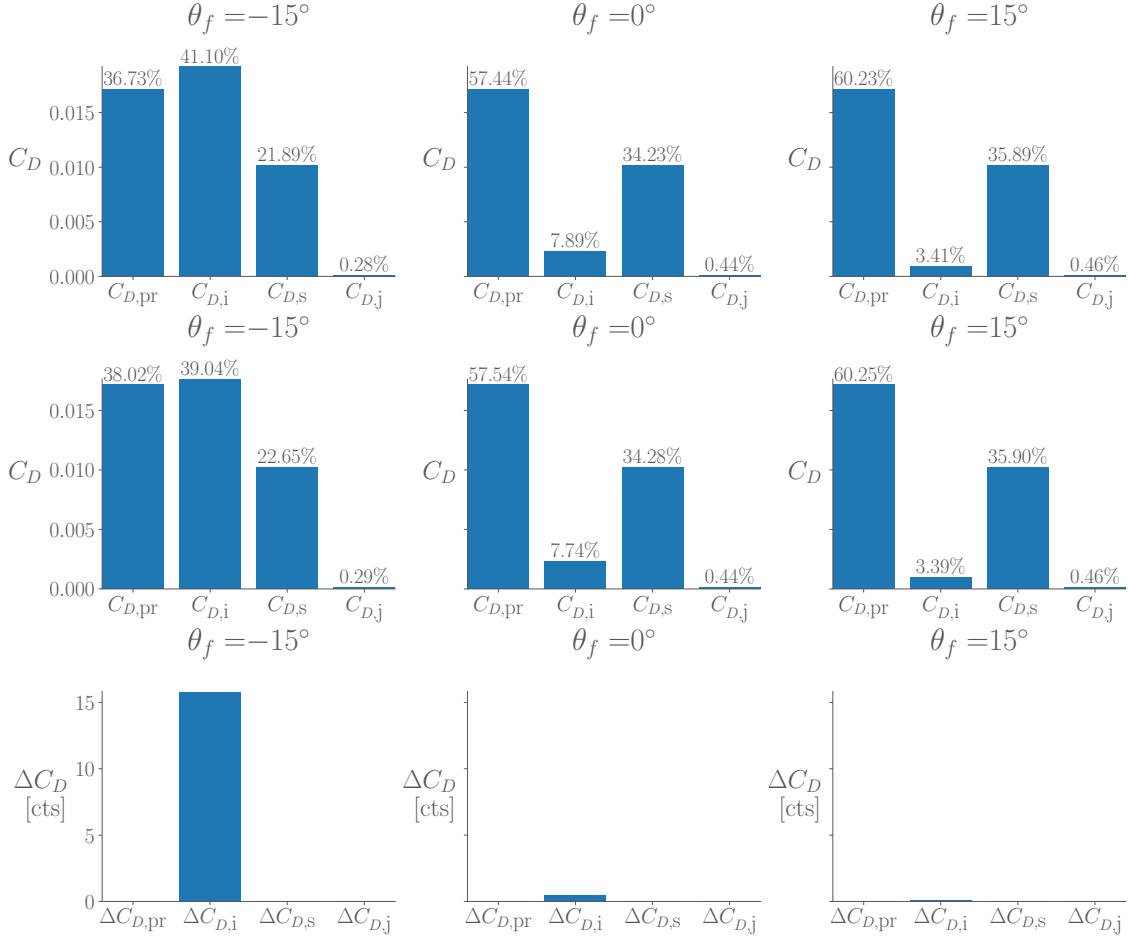

**Table 4:** Total drag of the various foils.

	$\theta_f = -15^\circ$		$\theta_f = 0^\circ$		$\theta_f = 15^\circ$	
	$D$ [N]	$C_D$	$D$ [N]	$C_D$	$D$ [N]	$C_D$
No free surface model	605.7	0.0468	387.3	0.0299	369.4	0.0285
Free surface model	585.2 (-3.4%)	0.0452	386.7 (-0.2%)	0.0299	369.3 (-0.03%)	0.0285

drag plays the biggest role in the differences. The spray and junction drag relations do not depend on lift, so they are identical between the foils. The drag is highest for  $\theta_f = -15^\circ$  and decreases for more positive fiber angle since the foils produce less lift. The drag is also reduced when adding free-surface effects because of the reduction in lift. Figure 6 shows the drag build-up for the runs. The results tell the same message that lift-induced drag is the largest contributor to drag differences

between the various foil configurations. Figure 6 also shows that the free surface influences the lift-induced drag calculation for all foils, but the effect is greatest for the foil that produces the most lift ( $\theta_f = -15^\circ$ ). The drag build-up also tells us that profile drag and spray drag are significant portions of total drag that dominate the drag at low  $C_L$  conditions; however, this finding is not novel, at least for rigid hydrofoils research. Godø and Steen (2023b) found that strut-related drag, comprised of profile and spray, were large components in total drag (around a quarter of total drag, similar to here).

**Figure 6:** Drag build-up for different fiber angles with no free-surface effect (top row) and with free-surface effect (middle) at  $U_\infty = 18$  m/s. Drag deltas between no free-surface and free-surface given in drag counts (bottom).

As a final exploration into the performance, we run polars by varying the wing mounting rake  $\alpha_r$  from  $-5^\circ$  to  $15^\circ$  in  $0.5^\circ$  steps. This could correspond to a rake control mechanism or a designer choice. The polars are in Figure 7 where dashed lines are with the free surface model. We add a rigid hydrofoil case as well to see if tailored flexibility offers performance gains. There are some experimental results from Ashworth Briggs (2018, Sec. 6.4.1) for a pitching polar (not wing mounting rake) at  $Re = 0.48 \times 10^6$  and  $U_\infty = 4$  m/s, which is a very different flow condition; however, we plot them as a comparison to have a general idea of the polar trends. The overall bucket shape comparisons will not be entirely fair because (1) the simulations are at a high enough speed where structural deflections occur and influence drag, whereas the experiment can be assumed to have mostly rigid T-foil hydrodynamics, (2) the angle of attack here is base rake whereas the experiment varied overall pitch, and (3) laminar flow existed in the experiment but our empirical model assumes fully turbulent flow. Nevertheless, we can look at the  $\alpha = 0^\circ$  cases between experiment and simulation and draw some parallels.

As expected, the simulated polars are symmetric about  $C_L = 0$  and  $\alpha_r = 0^\circ$  because of the uncambered hydrofoil section. All T-foils have the same  $C_{D,min} = 275$  drag counts at the  $C_L = 0$  condition corresponding to the same parasitic drag. The

**Figure 7:** Performance polars of T-foils for  $U_\infty = 18$  m/s varying base rake. Solid lines are no free surface and dashed are with the free surface model. The experimental results varied strut rake.

$C_L = 0$  drag value is slightly higher than the experimental  $C_{D,\min}$ , but this could be a combined effect of inaccurate spray drag, junction intersection drag, and skin friction drag because of the mismatched Reynolds and Froude numbers between experiment and simulation. The experiment had laminar flow at low angles of attack (Binns et al., 2008) while we assumed turbulent flow in the ITTC 1957 line. Future work may warrant an improved parasitic drag model accounting for these effects to accurately assess drag trades.

The more positive fiber angle foils have wider drag buckets, indicating that the max  $L/D$  would be best for the  $\theta_f = 15^\circ$  T-foil. This would suggest that the  $\theta_f = 15^\circ$  T-foil is able to maintain a spanwise lift distribution closer to elliptical across angles of attack and thus reduce the lift-induced drag. This hydrofoil even outperforms the rigid hydrofoil, though not noticeably until much higher  $C_L$  and  $\alpha_r$ . The polar makes sense because the  $\theta_f = 0^\circ$  has positive tip twist (see Figure 4) with increasing lift, but the  $\theta_f = 15^\circ$  has washout at the tips from the nose-down bend-twist coupling. The  $\theta_f = 0^\circ$  T-foil would therefore have too much load outboard. Lastly, since the lifting line model is potential flow, we do not capture the stalling effect at higher  $\alpha_r$ , so we should actually see a precipitous drop-off in  $C_L$  in the polars at higher angles. Based on these results, the  $\theta_f = 15^\circ$  seems to be the best-performing T-foil of the studied configurations, indicating that a designer should look in the direction of more positive fiber angle composite T-foils that promote washout at higher lift.

## CONCLUSIONS

Through simple structural and hydrodynamic models, we explored the influence of free-surface effects and material anisotropy on the static hydroelastic response of a composite T-foil. We explored the hydrostructural performance of three composite T-foils, each with different fiber angles.

Negative fiber angles produce more outboard lift and moment, resulting in more outboard deflections with nose-up tip twist. This behavior is bad for both hydrodynamics and structures because of increased cavitation, ventilation, and tip stall susceptibility as well as material failure risk. Zero or positive fiber angles are better for load alleviation because there is more tendency towards washout via nose-down bend-twist coupling. The more positive fiber angle T-foils had better drag polars because of the lower lift-induced drag. We deduce that these types of composite T-foils tend to be hydrodynamically and structurally better, at least for the given initial geometry.

The free surface model used here assumes infinite Froude number and reduced all lift and moments (and hence deflections) on the T-foils. In the cases studied, lift-induced drag dominated, so the free surface also reduced drag because of the reduced lift. The effect was minor because of low depth-to-chord ratio, though further studies into heel or cant angle would be interesting to see the asymmetric loading effect on the flexible composite structure.

In a more sophisticated hydrodynamics lifting line model, finite Froude number effects would more accurately model the bound vorticity ( $\gamma$ ) on the foil than the infinite Froude number assumption. This would then enable more accurate lift-induced drag and wave drag estimates that depend on vorticity. The accuracy across finite Froude numbers will be important for higher fidelity design optimizations that may tune submergence depth and chord of hydrofoils if they were design variables, which both affect Froude number. A possible future avenue for considering free-surface effects that balances accuracy and cost is the desingularized Rankine-source panel method with a body-exact, linearized free-surface condition (Cao et al., 1991).

Overall, material anisotropy offers potential for customized spanwise loading of T-foils, which is important for control surface effectiveness, hydrodynamic efficiency through lower drag, and structural efficiency through less/more effective material usage. The models presented here are a computationally cheap way to evaluate preliminary composite foil designs whilst capturing the necessary fluid-structure interactions present in high-speed surface craft design. Our results also show expected and consistent trends with previous numerical and experimental work that verifies the current toolset for rapid, conceptual, design space exploration of more complicated marine appendage geometries. Future work could consider a Froude number-dependent free surface model, coupling of T-foil deflections to vessel dynamics, or unsteady analyses to capture the vessel response in waves.

# Improve Ship Design Success by Utilising Proactive Elicitation to Enhance Communication Among Diverse Stakeholders

Chengfeng Ou <sup>1</sup>, David Trodden <sup>2</sup>, and Serkan Turkmen <sup>3</sup>

## ABSTRACT

*Ships serve as crucial tools for maritime transportation and account for over 80% of global trade. However, the boundary between naval architecture and the maritime industry has existed for 150 years since the first Industrial Revolution. Despite the current ship design processes ensuring compliance with standards, a significant gap exists in effectively communicating and incorporating diverse stakeholders' expectations and desires during the ship design process. This communication gap may lead to a potential risk for incidents and compromise safety. To tackle this issue, this paper proposes to use proactive elicitation as a means to enhance the communication between various stakeholders and naval architects. To verify the impact of proactive elicitation on ship design success, discrete event models were developed in the study to simulate the ship design process. The simulation results demonstrated that the earlier the proactive elicitation is applied to ship design, the higher the level of design success can be achieved. In the short term, this approach can assist shipyards in the timely delivery of ships, while in the long term, it fosters improved compatibility between stakeholders and ships, enabling effective adaptation to future complex design conditions.*

## KEY WORDS

Ship design; Conceptual design; Tender phase; Elicitation; and Whole ship design

## INTRODUCTION

In the current ship design practice, Ships are often tailor-made and designed to meet the specific expectations of the stakeholders. So, the design brief is provided by stakeholders at the beginning of the ship design process. Then naval architects utilise their knowledge and engineering expertise to plan, formulate and design the ship according to the stakeholders' design brief. According to the statistics of the ship design flaws observed from 1545 to 2006 (Andrews, 2020), misunderstanding, poor communication, and overconfidence are the primary causes of ship design flaws in the commercial shipping sector. To minimise these flaws, international organisations established standards and regulations for design criteria that stakeholders and naval architects should adhere to. However, eliminating ship design flaws has not been entirely achieved today, which poses a potential risk of operational accidents.

Long-term marine accident investigation data reveals that approximately 80% of accidents are attributed to human error, with 30% specifically resulting from human failure to take evasive action (Baker & Seah, 2004). The remaining 70% of accidents happened when no one was aware that something was happening (Bafang & Chen, 2021). Nevertheless, the majority of reports persistently attribute human error as the primary cause of accidents, thereby placing a disproportionate burden on seafarers.

However, among the maritime incidents widely cited as being caused by human error, it is worth noting that 80% of them lack substantial supporting evidence (Wróbel, 2021). One potential contributing factor to these accidents is flaws resulting from a ‘communication gap’ between various stakeholders during the ship design process.

In the current era of highly advanced information and communication technology, the ‘communication gap’ between diverse stakeholders arises mainly from the assumption on each side that the other will actively familiarise themselves with their respective knowledge rather than a lack of willingness to communicate. For example, sailing, navigation, and naval architecture are all interconnected with ships. However, they represent distinct fields. Seafarers may assume that naval architects will naturally incorporate user-friendly features into ship designs, while naval architects may assume that seafarers will provide explicit guidance on the need for such features. If seafarers did not provide clear requirements for these features, naval architects may assume that these features are not necessary. On the other hand, management personnel focus more on integrating the entire ship design plan, providing comprehensive solutions, and demonstrating and communicating the overall ship design concept and capabilities to customers during the early ship system design (ESSD) (Andrews, 2018). Consequently, these differing understandings among the parties naturally lead to discrepancies.

In the past, some efforts have been made to address the barriers within the maritime and shipbuilding industry. For instance, the Nautical Institute (1998) conducted a study examining the relationship between ship design and operation, especially focusing on incorporating the input of seafarers. In the study, the institute distributed a survey questionnaire to seafarers, generating 185 comments. The study concluded that enhancing naval architects' understanding of nautical knowledge is crucial for improving communication with stakeholders and ensuring that the design meets stakeholders' needs. Hughes (1989) categorised operational problems into ten topics, with dedicated sections on equipment and management. The study advocated for the use of precise standards as guidelines for naval architects to facilitate communication with stakeholders during ship design. Those studies highlight the importance of communication between naval architects and stakeholders in ship design. Additionally, several studies have highlighted the significance of incorporating stakeholders' requirements across various aspects of ship design, particularly during the conceptual stage. For instance, Heather (1993) and Graham (1996) emphasised the aspect of 'Requirement' Andrews (1985) and Tibbitts et al. (1993) focused on 'Functional Requirement' Andrews (1985) and Burcher & Rydill (1995) considered 'Operational requirements' Rawson (1986) explored 'Reliability, Maintainability, availability, and logistics' Andrews (1985) delved into 'Systems operating and upkeep philosophies' Andrew (1985) considered the aspect of 'Performing need analysis' and Andrew & Dicks (1997) considered the aspect of 'Functional hierarchical decomposition', and so on. However, how to implement such a recognition in the actual ship design process remains an issue today. Moreover, as the issue evolves and the range of stakeholders may expand under increasingly complex design conditions, incorporating diverse stakeholders' requirements and desires into ship design becomes more challenging. This motivates the research of this paper, which aims to improve ship design success by utilising proactive elicitation as a means to bridge the ‘communication gap’ among diverse stakeholders.

## **STUDY FOR GAINING INSIGHTS INTO THE ‘COMMUNICATION GAP’**

To facilitate the study, a preliminary survey was conducted, and the stakeholders' backgrounds covered ship owners, ship managers, equipment suppliers, shipyard naval architects, ship design firm naval architects, seafarers, and academics. A total of 20 people participated in this survey. The first part of this survey was conducted to gain insights into the ‘communication gap’ between stakeholders and naval architects. A questionnaire was thoughtfully designed based on 12 keywords. The survey results are illustrated in Fig.1. During the survey, the 12 keywords were classified into two distinct groups: i.e. ‘concrete’ and ‘cogitation’. The former, indicated by the colour orange, signifies data and standards. Meanwhile, the latter, indicated by the colour blue, highlights the need for exploration and research. In each group, subcategories are distinguished using different shades of the colours. Lighter shades represent aspects that have already been integrated into existing ship design practices, while darker shades indicate areas that require improvement in the future. The degree of concern indicates the areas within ship design to which three distinct stakeholder groups attach importance.

**Figure 1 Results of the preliminary survey**

Based on the insights depicted in Figure 1, the elements along the horizontal axis are arranged chronologically from the comprehensive planning to the quality control of the shipbuilding production process. It is evident that information providers exhibit greater concerns before the “construction” stage. They prioritise the integration and enhancement of their ideas with lofty expectations. By contrast, information recipients, primarily naval architects, express concerns at every stage and tend to emphasise practical considerations over abstract thinking. This disparity between stakeholders and naval architects highlights the need for additional sources to complement the information provided, as stakeholders' expectations might not be explicitly outlined in the design brief.

Subsequently, a further survey was conducted to investigate the additional sources the naval architects tend to favour. These information sources are categorised into primary (first-hand) and secondary (second-hand), and the findings of the survey are presented in Figure 2. In the figure, the primary sources are depicted on the left side, while the secondary sources are shown on the right. The vertical axis of the chart displays the degree of preference. The results in Figure 2 highlight that naval architects predominantly rely on secondary sources to supplement the design information, with a higher proportion leaning towards indirect means. This observation suggests that naval architects demonstrate a preference for sources that acquire information through intermediaries or administrative procedures, thereby aiding in the reduction of design risks.

Figure 2: Survey results of information sources.

## IMPACT OF COMMUNICATION ON SHIPBUILDING PROJECTS

From 2017 to 2020, a shipyard implemented an experimental policy aimed at successfully delivering 11 shipbuilding projects, as outlined in Table 1. It was discovered that proactive engagement with stakeholders and the broadening of design information sources by naval architects, coupled with an active approach to integrating diverse requirements during the concept design stage, led to a notable enhancement in design success. To assess the implications of this policy, an on-site investigation was conducted at the shipyard, employing a readily understandable market indicator known as the ‘on-time delivery rate’ of ships. This indicator signifies the ratio between the scheduled and actual building time, offering insights into the efficiency of project management within the organisation. The on-time delivery rate contributes to the effective utilisation of resources, including manpower, materials, and time, while also aiding in waste reduction. Moreover, the ‘on-time delivery rate’ serves as a measure of the cognitive gap between stakeholders and naval architects throughout the entire project execution process. This cognitive gap represents the additional time required to explore solutions. By successfully completing a project on time, it can be inferred that the surplus time spent on the project is relatively minimised. Thus, the on-time delivery rate serves as a tangible representation of the effectiveness of the experimental policy.

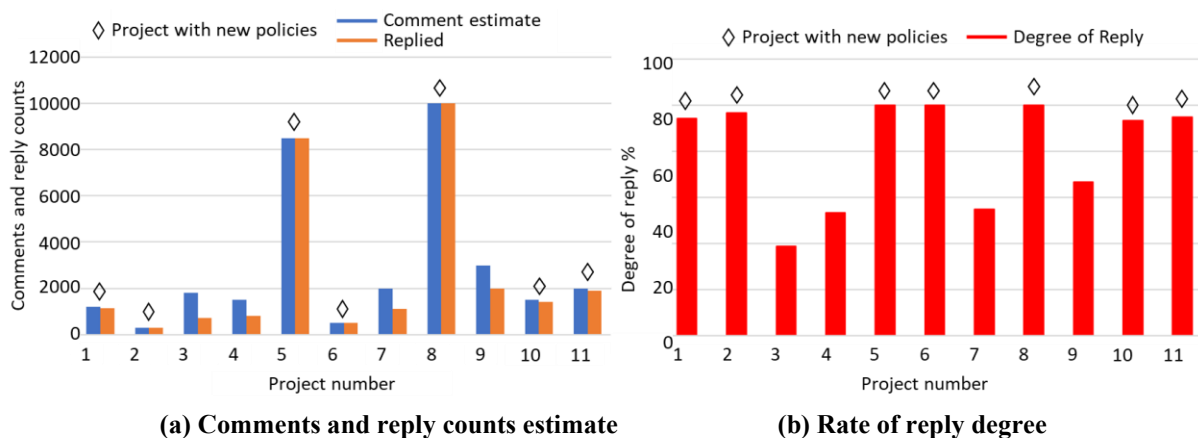

Table 1. Ship projects are being observed.

Project No.	Size and function	Hull type
1	16m Patrol Boat	Monohull
2	17m Attack boat	Monohull
3	18.5m Rapid Response boat	Monohull
4	19m Patrol Boat	Monohull
5	41m Utility craft	Monohull
6	28m Missile boat	Catamaran
7	35m Firefighting boat	Catamaran
8	65m Patrol craft	Catamaran
9	25m Crew Transfer Vessel	SWATH
10	25m Hydrographic vessel	SWATH
11	25m Crew Transfer Vessel	SWATH

In 2018, the shipyard faced two significant challenges that had notable impacts on its operations. Firstly, during the bi-annual audit inspection for ISO 9001 compliance, the International Standard Organization (ISO) identified deficiencies in the shipyard's handling of comment replies, particularly regarding the ISO 9001 8.2.1 Customer Satisfaction standard. Secondly, clients raised complaints asserting that comments on drawings or inspections were not adequately addressed, leading to delays in delivery. These incidents directly affected the shipyard's production quality and design management. To address these issues, the shipyard issued the following directives to all naval architects:

- (1) All naval architects and marine engineers must comprehensively understand the requirements and criteria before initiating any schematic drawings.
- (2) Issues, comments, and conflicts should be resolved through consensus and approved by both parties prior to considering them as completed.
- (3) When explicit instructions are unavailable from the client, it is advisable to seek guidance from individuals possessing relevant expertise. If required, contractual adjustments should be considered.
- (4) Should a proposed solution deviate from established rules, regulations, practical engineering handbooks, previous references, or contractual documents, it is imperative to initiate immediate discussions. Design work should not commence without a viable solution.
- (5) All outstanding issues must be resolved prior to the commencement of production.

The objective of this observation is to assess the number and percentage of comments that have been formally addressed and accepted, as well as to compare the on-time delivery rates across various ship projects. Figure 3a provides an overview of the approximate number of comments received (indicated by the blue bar) and replied comments (indicated by the orange bar) for 11 projects. Figure 3b illustrates the degree of reply. In both charts, the diamond shape stands for the project that is applied to the new policies.

(a) Comments and reply counts estimate (b) Rate of reply degree  
**Figure 3. Comments and replies count corresponding to the Rate of reply degree.**

The bar chart in Figure 3b shows a significant increase in the number of comment replies within projects that have been applied with the new policies. This observation highlights a noticeable shift in the behaviour of naval architects, who previously prioritised substantive design tasks (Andrews, 2015) over administrative paperwork. Prior to the enforcement of the new policy, naval architects may have viewed the process of addressing comments as burdensome, potentially hindering the progress of design work and causing distractions and disruptions. Imposing a mere requirement of a 100% response rate to comments may result in counterproductive outcomes resembling a checkbox approach. Such an approach fails to address the fundamental issue of precision in ship design. Consequently, three different approaches have been revealed between conventional design philosophy and new policies. These disparities serve to underline critical areas for improvement, and these two aspects are related to the idea of elicitation:

- (1) Under the new policies, the project places a strong emphasis on completing the design phase to ensure alignment among stakeholders and the shipyard, even if it results in a delay to the construction schedule.
- (2) In situations where the contract, specifications, and design brief are not adequately defined, the shipyard engages in collaborative efforts with stakeholders to enhance and augment these elements, identifying potential solutions that effectively align with the established criteria.

Figure 4 illustrates the on-time delivery of each project, represented by the blue diamonds or circle, along with their respective reply rates, indicated by the red diamonds or circles. Notably, projects 1 and 2 remain on schedule despite a lower reply rate. Nevertheless, the overall trend demonstrates that the implementation of new policies has played a significant role in ensuring adherence to the established project schedule. In the figure, two additional bars are also presented, i.e. 'Eliciting from client'

represented by the grey bar and ‘Eliciting beyond client’ represented by the yellow bar. These bars reflect the efforts of naval architects in expanding their search for additional sources of information, which has contributed to the timely delivery of ships.

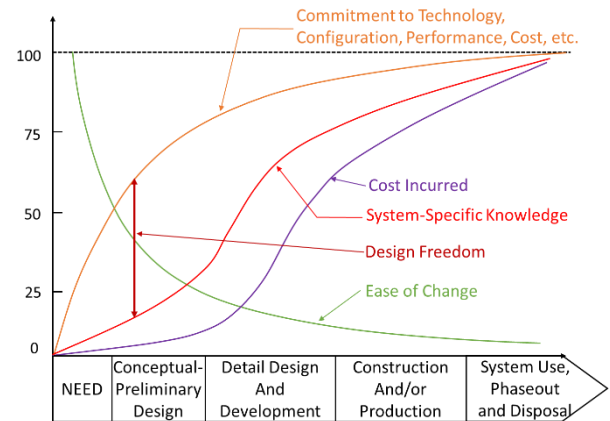

**Figure 4. Comments replied corresponding to on-time delivered rate and elicitation source.**

In Figure 4, projects 1 and 2 stand out as exceptions to the general trend due to their status as repeat projects. Many of the challenges faced in these projects have already been addressed based on feedback from previous batches, resulting in a consensus between the shipyard and clients. Consequently, most potential conflicts have already been anticipated, and corresponding solutions are readily available.

### THE CONCEPT OF PROACTIVE ELICITATION

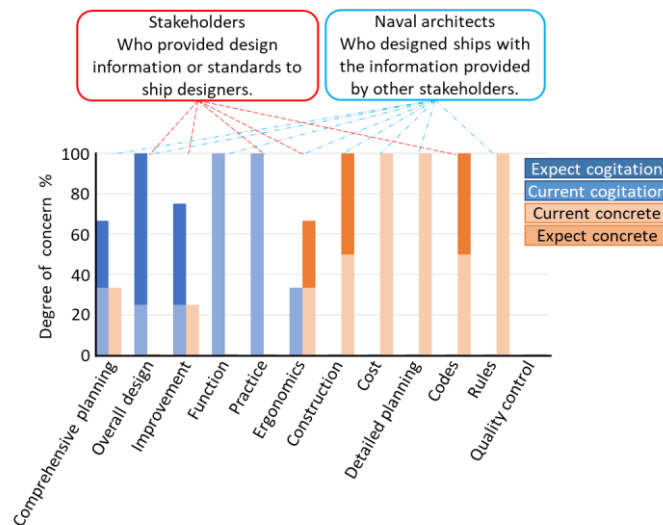

The aforementioned study unearths a notion of ‘elicitation’, which emphasises proactive information-seeking and problem-solving approaches (Delicado, 2019). ‘Elicitation’ extends its focus beyond the customer and includes a wide range of stakeholders, placing a strong emphasis on establishing comprehensive requirements through a rigorous and independent process. It is worth noting that elicitation is not limited by design briefs. Since elicitation focuses on capturing the essence of diverse stakeholders' desires, it can be used as a means to gather information for decision-making and bridge the gap between stakeholders and the ‘real design’ (Andrews, 2021).

In this study, proactive elicitation endeavours to gather comprehensive information during the initial or concept stage of ship design. Conflicts between stakeholders' expectations and the design brief can be resolved by proactively seeking additional information beyond design briefs. The timing of applying proactive elicitation can significantly impact its effectiveness in improving ship design accuracy. To facilitate understanding, Figure 5 illustrates an area between the curves of Commitment Technology (represented by the orange curve) and System-Specific Knowledge (represented by the red curve). This area between the two curves is referred to as ‘design freedom’.

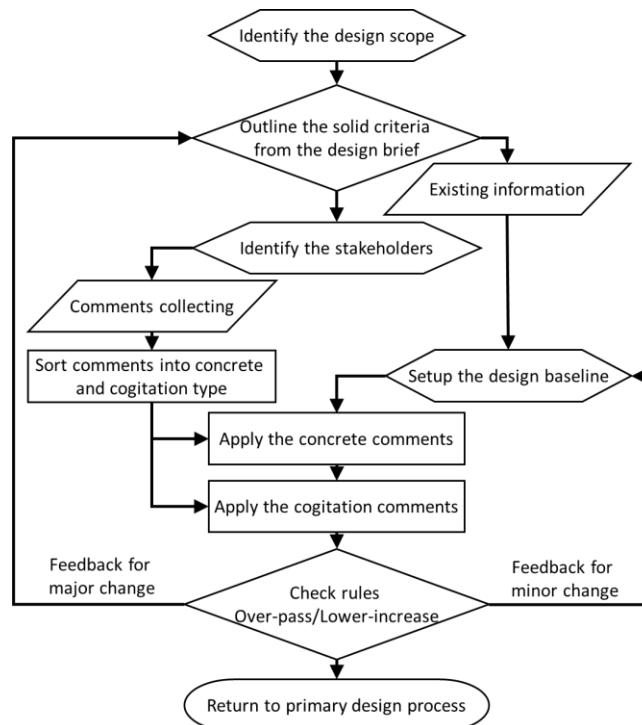

**Figure 5. Illustration of project phases and design freedom (Malmgren & Ulfvarson, 2006).**

During the conceptual design phase, naval architects will explore various design options in a variety of ways, with the goal of minimising 'design freedom' while meeting the stakeholder's requirements. To fully harness the advantages of proactive elicitation, it is imperative to establish it as a systematic workflow. Therefore, an extensive survey, called the full survey in this paper, was conducted, encompassing stakeholders at various management levels in the shipbuilding industry. The aim was to investigate the essential tasks involved in this workflow. In the survey, the stakeholders were divided into two groups. The first group are stakeholders who contribute design information or standards to naval architects. They responded favourably when questioned about their capacity to integrate their requirements and actively identify potential needs. This signifies that they recognise and appreciate the willingness of naval architects to enhance the design of their products. Another group of stakeholders consists of naval architects responsible for driving the ship design process and overseeing it at a supervisory level. They also expressed a positive inclination towards proactively considering potential requirements beyond the initial design brief. This underscores the naval architects' awareness of their pivotal role in shaping ship design and the significance of adopting a proactive approach to overcome constraints. The keywords adopted in the open-end questionnaires are categorised into 12 stages throughout the design process, concrete and cogitation aspects and current/expectation concepts. The survey results are shown in Figure 6. The degree of concern indicates the areas within ship design to which two distinct stakeholder groups attach importance.

**Figure 6. Results of the full survey.**

Figure 6 indicates a significant emphasis by both groups of stakeholders on the cogitative and expectation aspects of the design process, particularly in the pre-construction phase. The survey results suggest that all stakeholders hold high expectations and demonstrate a strong desire to explore the design's potential. However, as the design progresses towards the detailed and construction plan stage, both groups of stakeholders tend to prioritise preserving a particular style while solidifying their ideas, aiming to minimise potential risks. This approach is justifiable as it ensures that the design plan is well-defined and carries minimal risk upon completion. Additionally, the survey results also suggest that stakeholders require additional information to meet their design expectations during the ESSD stage. It is evident that stakeholders' concerns encompass two distinct aspects: concrete and cogitation. To establish proactive elicitation as a self-contained process and seamlessly integrate it into the current ship design process, a potential implementation approach is depicted in Figure 7.

**Figure 7. Implementation approach of proactive elicitation.**

The proactive elicitation implementation approach depicted in Figure 7 originates from numerous shipbuilding projects. Through extensive trial and error, it has been observed that design issues can generally be classified into two principal categories: concrete issues, which can be resolved through specific information such as rules, regulations, or quantitative analysis, and cogitation aspects, which necessitate thoughtful deliberation or brainstorming for resolution. This approach can be incorporated at any stage of ship design to acquire additional information. To be specific, at the initial stage of ship design, there is a lot of room for design freedom, which needs to be decreased in subsequent stages. The process commences by utilising existing information to establish a design baseline, serving as a reference point. Subsequently, stakeholders are identified, and their concrete and cognitive comments are extracted for application. The final stage involves evaluating the design against concrete criteria, such as industry rules and regulations. If the design meets the specified criteria, it can proceed. Otherwise, adjustments are made to ensure compliance, or it may be sent back to the appropriate stage for reevaluation.

## Development of discrete event models

To assess the efficacy of proactive elicitation in improving the success of ship design, two discrete event models were constructed in Simulink in the following. The agent-based discrete event model is appropriate for tracing the agent that travels through the model to study the interactions between agents and events. The agent-based model is built with a series of events as a loop according to individual agents (stands for accuracy and elicitation accuracy in this paper) assigned certain attributes and could be processed by each event. These models were designed to simulate real bureaucratic systems, aiming to provide a realistic representation of the workflow of ship design. The first model serves as a generic bureaucratic system model, simulating design-related tasks, while the second model is specifically tailored to implement and incorporate proactive elicitation in the ship design process.

The general bureaucratic system model for design work was derived from an on-site investigation and transformed into a series of discrete events. These events are scheduled over time, with sequential processing events representing the progress of the design tasks. This event-driven simulated model effectively captures the characteristics commonly found in bureaucratic systems. However, it should be noted that each design team have its own unique bureaucratic culture. This discrete event model cannot fully represent a specific design team or serve as a standard process for the overall design system. Nonetheless, the model serves as a valuable testing platform, allowing the simulation of specific work nodes within the design process. Simulation enables the examination of the impact and effectiveness of these nodes. The proactive elicitation model is built upon the proactive elicitation process depicted in Figure 7. It comprises a series of events aligned with the specific tasks outlined in the flowchart. This model serves as a modular component that can be seamlessly integrated at any stage within the generic bureaucratic system model. When simulating real-world systems using these two discrete event models, certain assumptions

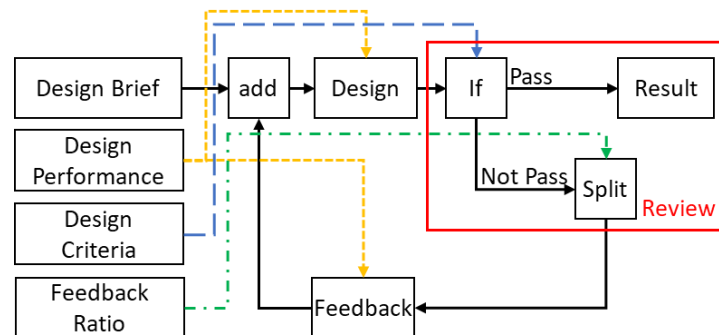

must be made, and relevant variables need to be accounted for. The assumptions considered in this study are outlined below, and the variables are listed in Table 2.

- The 'agent' is named as the accuracy for the general bureaucratic system model and elicitation accuracy for the proactive elicitation model. Both stand for the level of the design that could reflect the stakeholders' expectations and desires. Both units are in %.
- The agent going through the design/feedback node will decrease by multiplying the design performance when going through the split node, which results in the split rate. This stands for the agent portion going to feedback or sharing. The agent from feedback or sharing will add to the agent in the mainstream.
- In the model, the term 'Time' represents a specific phase in the design process. It does not refer to the duration or length of time.
- The 'model' represents the entire design process, which means the process is complete once the agent reaches the last node.

**Table 2. Variables.**

Types	Variables
Explanatory Variables	1. Design parameters.
	2. Split parameters.
	3. Sharing parameters.
	4. Criteria for the design check.
Controlled Variable	1. Total design time.
	2. Feedback time.
	3. Information exchange time.
	4. 'Dream' represents 100% accuracy.
Dependent Variable	Accuracy (%)

Figure 8 depicts the generic bureaucratic system model, which serves to simulate the activities carried out by a single team at each event node. In the figure, the nodes are represented by black font, while the activities are indicated using red font.

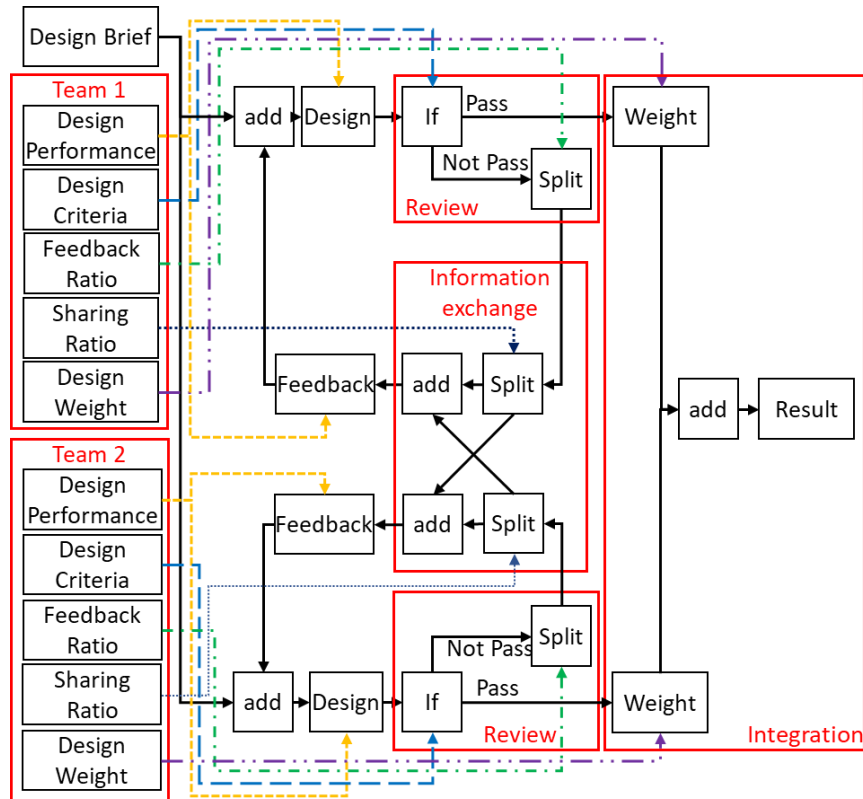

**Figure 8. Generic bureaucratic system model for simulating the activities of a single team.**

In Figure 8, the term "Design Performance" refers to how well the design team interprets the Design Brief throughout the design process. A higher value indicates a stronger alignment between the design outcomes and the expectations outlined in the Design Brief. On the other hand, "Design Criteria" represents the set of standards utilised to assess the design outcomes during the review process. If the outcomes meet these criteria, they are considered satisfactory; otherwise, feedback is provided to the design team for improvement. The "Feedback Ratio" illustrates the proportion of outcomes that require feedback and subsequent redesign. All these values are expressed in percentages (%), and their specific values depend on the particular design environments being considered. Regarding the "Design Brief," it is also expressed as a percentage (%), with its value indicating the accuracy of the Design Brief in conveying stakeholders' requirements and expectations. A value of 100% signifies a Design Brief that perfectly and completely reflects the needs of the stakeholders. It is important to note that the accuracy of this parameter depends on the initial stage of the design process. If the design process starts with direct stakeholder engagement, the accuracy of the Design Brief may be close to 100%. However, during the Concept Design phase, the Design Brief might be derived from contractual documents, resulting in a lower accuracy level (e.g., 80%). As listed in Table 3, all the aforementioned parameters will be assigned fixed values in subsequent simulations to ensure consistent simulation conditions.

**Table 3. Values of model parameters.**

Parameters	Value	Remark
Design Brief	80%	Design Brief at the ESSD represents stakeholders' expectations and requirements with 80%.
Design Performance	70%	The design team has comprehension of up to 70%.
Design Criteria	70%	The approval criteria of the Review is 70%.
Feedback Ratio	20%	Assuming that 20% of the design needs to be rechecked when the design is not approved.

The model depicted in Figure 8 can be easily extended to incorporate the activities of multiple design teams, thus enhancing its flexibility and applicability. In order to provide a clearer representation, Figure 9 presents an illustration of the model specifically tailored to simulate the activities of two design teams.

**Figure 9. Generic bureaucratic system model for simulating the activities of two teams.**

From Figure 9, it is seen that the model has been expanded to include additional event nodes, facilitating the exchange of information between different design teams and enabling the integration of design outcomes. The 'Sharing Ratio' parameter has been introduced to account for the cross-team collaboration within a specific team. Furthermore, individual design teams are assigned different design weights, which capture their specific characteristics and account for the variations arising from their respective design responsibilities within the overall design process.

In the simulations conducted for this study, the focus was on a scenario involving two design teams. While maintaining the unified simulation conditions with Design Brief and Design Criteria set respectively at 80% and 70%, the remaining parameter

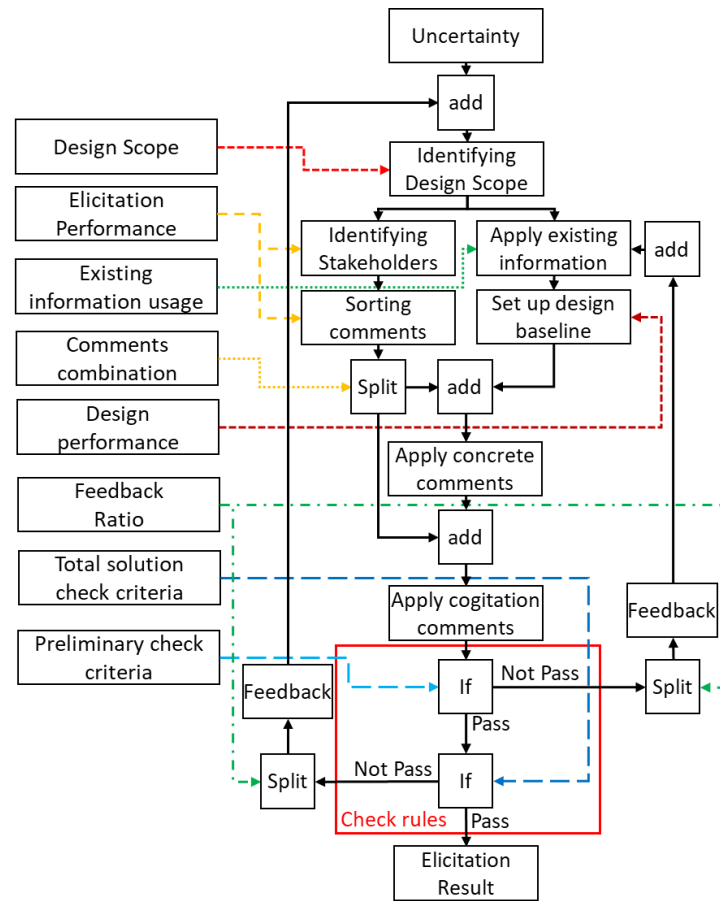

values are provided in Table 4. It is necessary to note that these parameter designs were based on the relationship between a Structure Design Team (Team 1) and a Propulsion Design Team (Team 2) in a real ship design office. However, different ship design offices may have their own unique cultures and systems in place. Therefore, this particular case serves as only a reference for parameter configuration and should not be considered an absolute standard.

**Table 4. Model parameter values for a two-team model.**

Team 1 (Structure)		Team 2 (Propulsion)		Remark
Parameters	Value	Parameters	Value	
Design Performance	70%	Design Performance	40%	Team 1 has more personnel than Team 2, with higher performance.
Feedback Ratio	10%	Feedback Ratio	50%	The structure is concrete knowledge, so the propulsion is more flexible with a higher value.
Sharing Ratio	10%	Sharing Ratio	50%	Team 1's sharing range is the engineering section, but Team 2 needs to share all information to help Team 1.
Design Weight	70%	Design Weight	30%	The range of Team 1 in the design is more than that of Team 2.

Overall, these two models serve as testing platforms to validate the effectiveness of the proactive elicitation model. The single-team model is suitable for representing a comprehensive organisation, such as a shipyard, design firm, or similar entity, where the precise breakdown of work information may not be available. In such cases, the single-team model can be utilised, with each node in the model representing the overall performance of similar teams. On the other hand, the multi-team model allows for the incorporation of efficiency parameters specific to individual teams within the organisation. This enables a more in-depth analysis of team efficiency and provides a more detailed understanding of organisational performance. The functionality of this model accurately reflects the operational performance of a particular organisational structure, offering insights into how different teams interact and contribute to the overall success of the organisation. The proactive elicitation model is depicted in Figure 10, which is developed based on the flowchart illustrated in Figure 7. The agent of this model is referred to as 'elicitation accuracy'. It is independent of the accuracy of the design process.

**Figure 10. Proactive elicitation model.**

In this proactive elicitation model, a total of eight parameters are configured based on the simulation conditions. They are explained in Table 5. In Figure 10, the term ‘Uncertainty’ represents the flexibility of proactive elicitation in addressing issues during the design process. Generally, as the design progresses and achieves higher completion, the value of Uncertainty tends to decrease. The term ‘Design Scope’ indicates the design freedom in the design process. A higher value indicates greater design freedom, and it is typically higher at the initial stages of the design process, gradually decreasing as the design progresses.

**Table 5. Parameter values in the proactive elicitation model.**

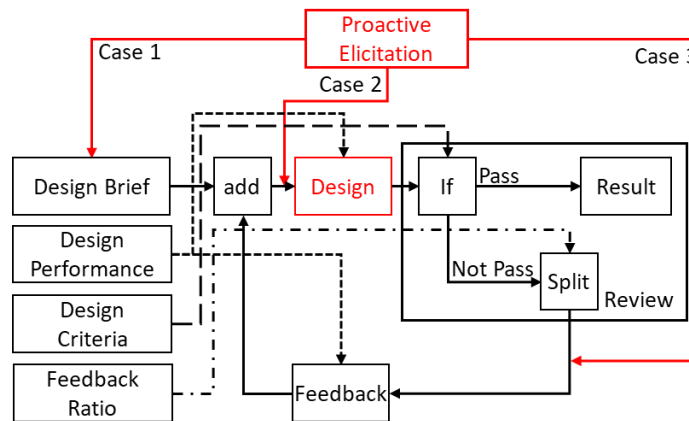

Parameters	Value	Remark
Elicitation performance	80%	This team has 80% performance in identifying the stakeholders and understanding their comments.
Existing information usage	40%	The design brief could provide information with 40% accuracy.
Design performance	80%	This design team has comprehension of up to 80%.
Comments combination	80%	This design team has 80% accuracy in sorting the comments into correct categories.
Feedback ratio	50%	50% of the information must be reviewed if it does not meet the criteria.
Preliminary check criteria	20%	The criteria of the preliminary check are 20% accuracy.
Total solution check criteria	50%	The criteria of the Total solution check is 20% accuracy.

## CASE STUDY

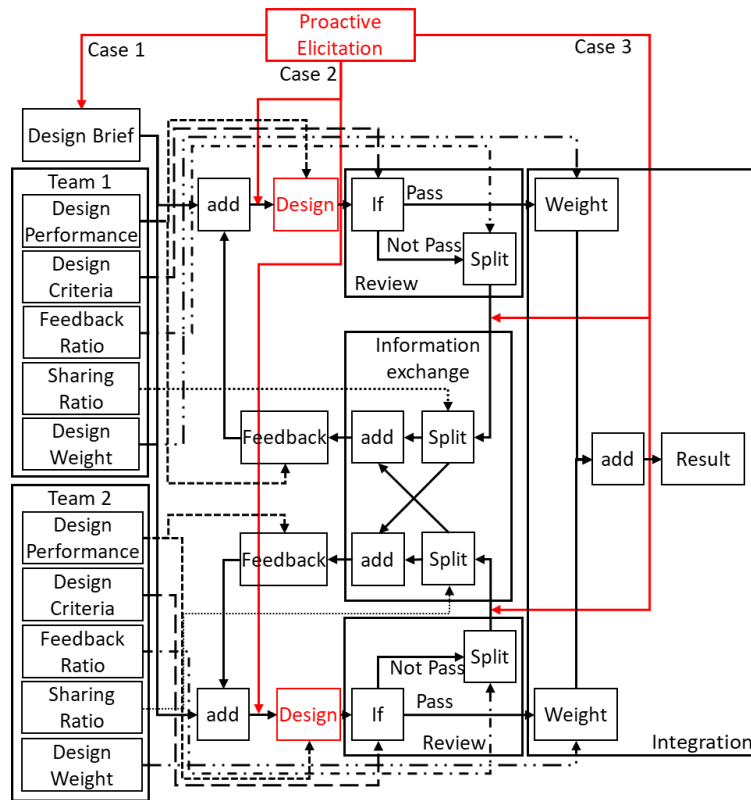

The case study in this section comprises simulations involving both single-team and multiple-team scenarios, focusing on investigating the influence of the intervention stage of proactive elicitation. The objective is to find which stage at which the implementation of proactive elicitation can yield the highest effectiveness. Figures 11 and 12 show the nodes that represent the three different intervention points of proactive elicitation in the simulations of each model. Table 6 presents the values of Uncertainty and Design Scope when proactive elicitation is incorporated in different stages of ship design. In the table, Case 0 is designated as the control group, where no proactive elicitation intervention is applied. This case serves as a baseline for comparison with the other three cases that incorporate proactive elicitation.

**Table 6. Uncertainty and Design scope in different cases.**

	Case 0	Case 1	Case 2	Case 3
Parameters	control group	Before the design stage	During the design stage	After the design stage
Uncertainty	0	100%	75%	50%
Design scope	0	80%	60%	40%

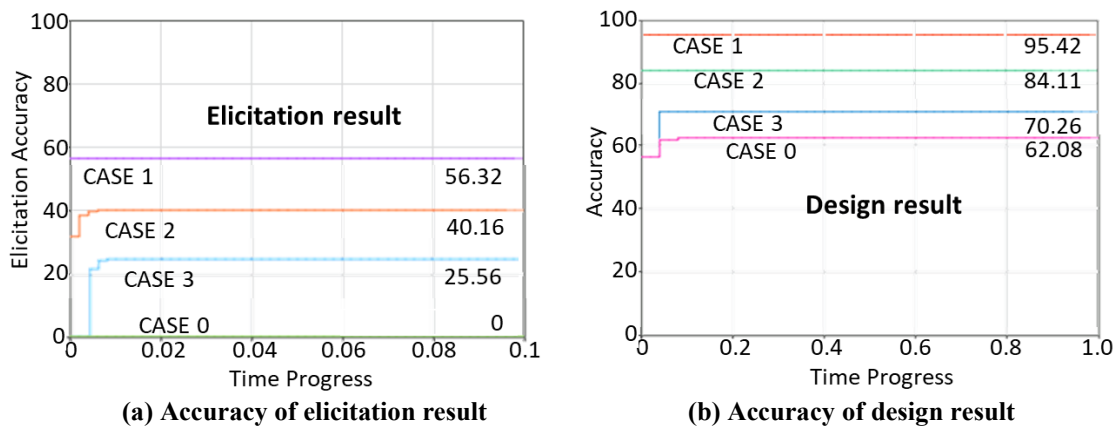

**Figure 11. Intervention on the single-team generic bureaucratic system model.**

**Figure 12. Intervention on two-team generic bureaucratic system model.**

The simulation results for the single-team generic bureaucratic system are presented in Figure 13. Figure 13a depicts the proactive elicitation to assess the level of understanding through elicitation accuracy. In the four different cases, CASE 0 serves as the control group, where the elicitation accuracy is 0. On the other hand, CASE 1-3 presents the elicitation accuracy levels of proactive elicitation under varying conditions of different stages. Similarly, Figure 13b illustrates the accuracy of the design result, which serves as an indicator of the level of understanding in the design brief through the design process of a single-team generic bureaucratic system. CASE 0 represents the control group without proactive elicitation intervention, thus reflecting the design result accuracy achievable under the design brief. CASE 1-3 demonstrate the design result accuracy achieved by incorporating proactive elicitation at different intervention points and considering the associated elicitation accuracy. The simulation results for the two-team generic bureaucratic system are presented in Figure 14. As shown in Table 4, different parameters are assigned to each team in the simulation to highlight the differences between the two teams. In Figure 14, the curve indicated by 'total' represents the overall design outcome.

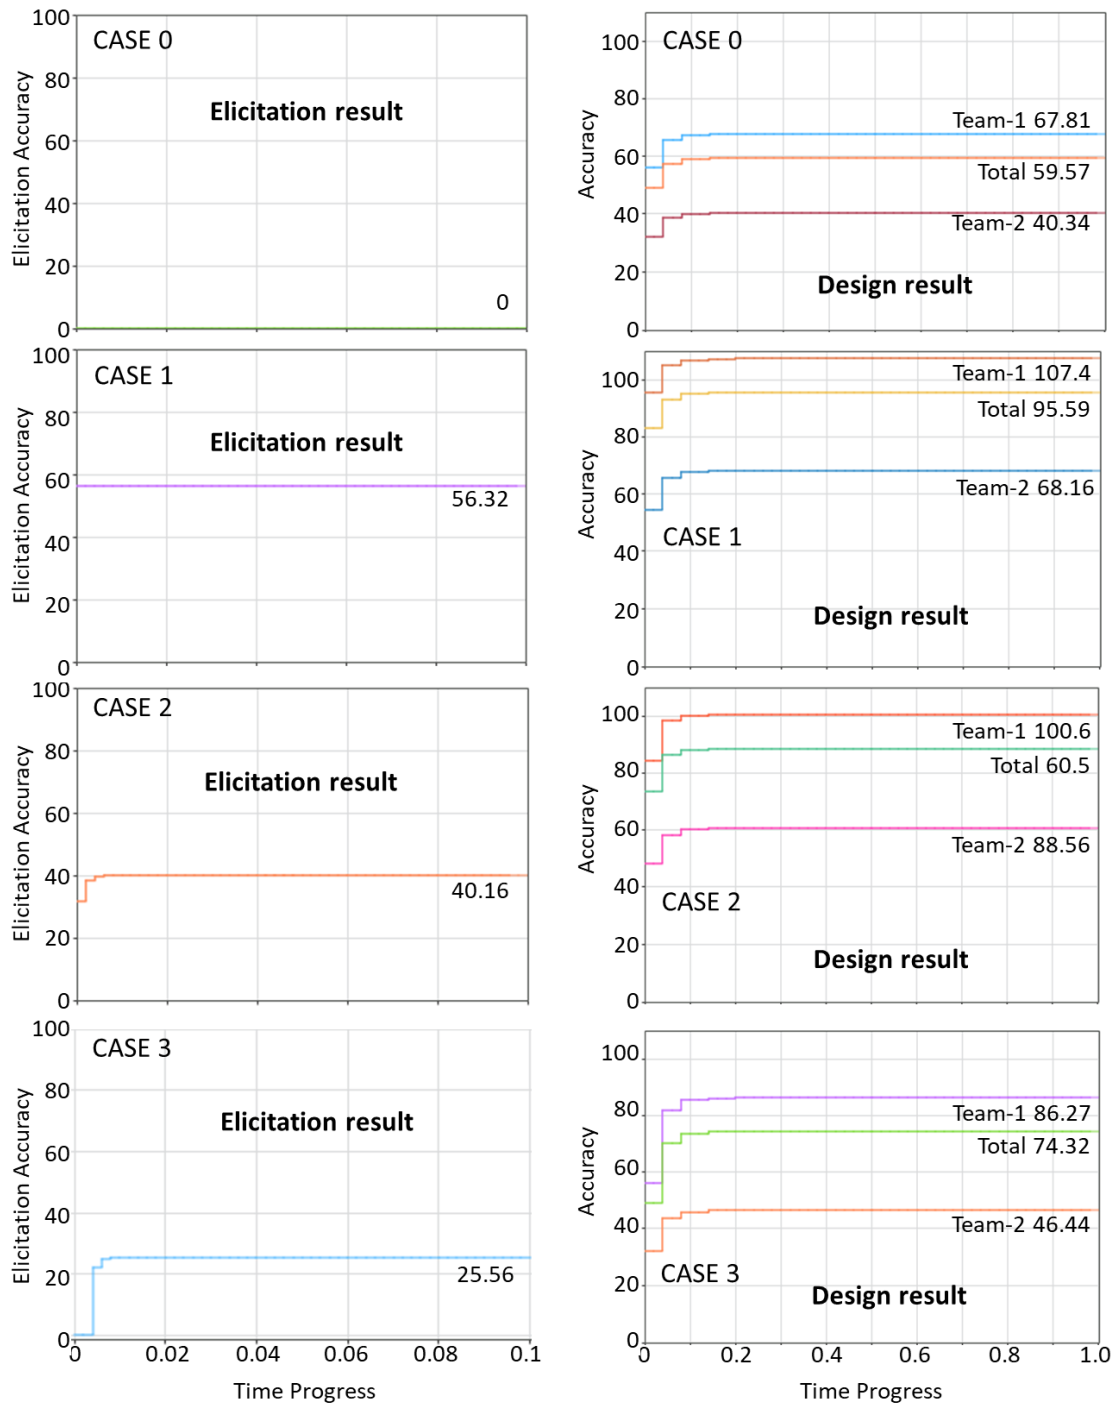

**Figure 13. Impact of proactive elicitation on a single-team generic bureaucratic system.**

From Figure 13b, it is seen that in Case 0, the design information enters the design process through the design brief. However, due to imperfect understanding, the comprehension of the design brief is not flawless, leading to a result that the efficiency of understanding is not as high as 100%. For this reason, the efficiency of understanding will decline gradually over time in the

simulation. However, by employing the 'review process', any components of the agent that fail to meet the design criteria will be fed back to the design stage. They are then redesigned and incorporated into the original design, resulting in an iterative process. Consequently, the overall trajectory of the process remains upward. Nevertheless, as the design accuracy improves, the instances where design outcomes fail to meet the criteria and are returned to the design stage will progressively diminish. As a result, the rate at which the process is increasing will continuously decelerate until it eventually approaches zero and stabilises at a certain level.

In contrast to the outcomes observed in Case 0, which does not incorporate proactive elicitation, the results obtained in Cases 1, 2, and 3 show the impact of employing proactive elicitation at different stages of ship design. These results reveal that proactive elicitation indeed enhances design effectiveness, regardless of when it is implemented. The underlying rationale behind this phenomenon can be attributed to the design process itself. When supplementary information is provided, the agent's 'accuracy' achieved through proactive elicitation is integrated with the existing accuracy. This process mirrors real-world scenarios, where the inclusion of new information enriches the comprehensiveness of design outcomes. In other words, by considering additional information through proactive elicitation, the design process becomes more comprehensive, thereby leading to improved design effectiveness. However, the effectiveness of proactive elicitation varies across the three intervention points, with Case 1 demonstrating the highest impact, followed by Case 2 and Case 3. This implies that the earlier the proactive elicitation is introduced, the greater benefits will be yielded.

In Figure 14, in addition to the intervention of proactive elicitation prior to the design stage, which resembles the operations in the single-team model, the two teams also engage in proactive elicitation during and after the design stage. As a result, the information presented in Figure 14 is more abundant compared to the results shown in Figure 13. From Figure 14, it is noticed that the outcomes of Case 1 and Case 2 show an 'accuracy' exceeding 100%. In real-world terms, this situation can be interpreted as heightened stakeholder involvement and the incorporation of a broader range of information, which can lead to designs that surpass the expectations outlined in the design brief. This phenomenon can also be understood as the generation of superior alternative solutions based on the design brief.

**Figure 14. Impact of proactive elicitation on a two-team generic bureaucratic system.**

By summarising the simulation results depicted in Figures 13 and 14, it can be inferred that:

- Proactive elicitation functions as a self-contained module unaffected by the quality of the design brief. The information generated through this independent process is directly incorporated into the "accuracy" of specific stages within the design process, leading to an additive effect. Consequently, irrespective of the accuracy of the design process or proactive elicitation, any enhancement in accuracy contributes to an overall improvement in the success of the design results.
- It is evident that proactive elicitation yields the greatest benefits when applied 'before the design stage'. This particular stage presents a direct opportunity to enhance the quality of the design brief. Moreover, during this stage, proactive elicitation exhibits the widest ranges in terms of 'uncertainty' and 'design scope'. These aspects indicate that the initial design stage offers the most significant potential for exploring improved design solutions. However, as the design progresses towards

completion, the scope for modifications diminishes. That will limit the effectiveness of proactive elicitation within the constraints of the existing design.

## CONCLUDING REMARK

This paper focuses on studying proactive elicitation and its effectiveness in enhancing ship design success. It is important to reiterate that proactive elicitation transforms naval architects from passive information receivers into active information seekers. It is not a management tool or organisational standard. Instead, it represents an attitude and philosophy towards design embraced by naval architects. Therefore, implementing proactive elicitation involves training personnel in this mindset or utilising policies to encourage naval architects to strengthen their collaboration and communication with stakeholders. The simulation results demonstrate that the timing of applying proactive elicitation has an impact on the attainment of design success (higher design accuracy in the model). This suggests that individual factors can also contribute to enhancing the design process. Therefore, enhancing the design process or proactive elicitation is meaningful.

Future research on proactive elicitation will emphasise interdisciplinary integration and its influence on education and training for naval architects. This study advocates for naval architects to proactively explore design information. However, it raises the question of whether naval architects possess the ability to understand and effectively apply such information. Observations suggest naval architects rely on accumulated experience but lack comprehensive understanding and application of design information. Therefore, adjustments to education and training are needed to cultivate naval architects who can effectively apply proactive elicitation during the initial design phase.

## CONTRIBUTION STATEMENT

Cheng Feng Ou Conceptualised the study and chose the Methodology. Cheng Feng Ou performed Data curation, Investigation, Formal analysis, and original draft and manuscript Writing. David Trodden and Serkan Turkmen contributed to Supervision, Resource provision, Reviewing the draft, and Editing the manuscript.

# New Conventions: Intentional Implementation of Set-Based Design Leveraging Point-Based Approaches

Jonathan E Page<sup>1,\*</sup>, Warren P Seering<sup>2</sup>, Christopher J Higgins<sup>3</sup>, and Drake M Platenberg<sup>3</sup>

## ABSTRACT

*This article communicates a practical application of Set-Based Design (SBD) during its adoption within the U.S. Navy's latest surface ship design processes. It highlights how the team harnessed SBD to explore the vast design space and make critical decisions. Intriguingly, the article explores the design team's use of point-based designs (PBD), a counterintuitive approach within the context of SBD. It delves into the rationale behind their implementation and the diverse purposes they serve in bridging knowledge gaps such as prototyping, integration, and evaluation of set interfaces. Furthermore, the article presents a preliminary ontology outlining various use cases for these PBDs. A key focus of this article is understanding how these PBDs coexist within the larger set-based construct while recognizing their inherent differences. The article examines the utility and boundaries of this approach, shedding light on the pragmatic interplay.*

## KEY WORDS

Set-based design; point design; risk management; ship design

## INTRODUCTION

This article shares some observations made through action research while designing the U.S. Navy's next class of destroyers, currently designated DDG(X). The article first reviews some principles of point- and set-based design methods. These reviews intend to ground the reader in the methods and lead to a comparison of the two. Next, the article introduces the design effort for DDG(X), including excerpts of the fundamental philosophical, organizational, and methodological principles. Finally, the article reveals the authors' use of point-based designs and methods within their set-based design construct. It instigates an important observation that the two methods are not necessarily mutually exclusive and can be complimentary or necessary.

## POINT-BASED DESIGN AND THE TRADITIONAL DESIGN SPIRAL

Gale (2003) documented the known point-based design (PBD) methods for ships that had been developed and refined over decades. Figure 1 presents a typical formulation of that process. Despite the appearance of a spiral, the process is linear. Each discipline performs its tasks in succession and passes its products to the subsequent discipline. Each loop through the spiral includes changes invoked by previous stages and adds fidelity to the design in their domain. This process iterates through these steps and spirals until the design converges to the final solution.

Ship design methods evolved to this over time because of the complexity of the undertaking; there is no simple or finite set of equations that define a ship. Instead, each discipline involved in ship design has unique equations and relationships dependent on the other disciplines. This method may suffice with a competent and practiced workforce because their initial educated guesses for the ship's parameters are well-informed. That situation dictates minimal rework and refinement as the design converges. Therefore, as the name suggests, this method creates and analyses one point in a basically infinite plane of possible ship designs. If any parameter changes substantially (an ill-defined modifier), a new point in that design space must be explored because it drives a different balance through the various parameters of the various disciplines.

**Figure 1: The Design Spiral in Point-Based Design (Gale, 2003)**

A point-based method may be appropriate when the requirements present a well-understood design problem with known technologies. In this case, the characteristics and values within the disciplines can be easily determined or derived from a parent design with similar requirements. Even if one or two parameters change, for instance, a new propulsion engine to meet emissions standards and a new mission system topside, the boundaries of the new design space may only require minimal expansion from existing knowledge. Once again, point-based methods can be used effectively in these conditions. Similarly, suppose the requirements call for optimization within the design along one or two parameters, such as speed and survivability. In that case, point-based methods may be appropriate since other disciplines will acquiesce to optimizing those parameters.

Outside those example conditions, point-based design methods can present risk. The highest risk of PBD is forfeiting the globally optimal design. Because the method is generally a refinement of initial rough parameters, many more designs and design parameters are *-not-* considered compared to the single point that *-is-* considered, refined, and analyzed. Another risk is that of rework. Suppose the initial estimates of parameters are not accurate enough. In that case, subsequent efforts through the spirals rework those parameters instead of refining them because there may be initial divergence instead of convergence of the parameters into a balanced design. The risk of significant rework is exceptionally high if the requirements change, as is often the case for naval vessels.

## SET-BASED DESIGN AND ITS TENETS

On the contrary, set-based design (SBD) is a method that considers sets of variables in the design space instead of a single point. The method considers more than one viable option for variables of interest and, depending on the design requirements, potentially for most variables. Ideally, the options evaluated are also diverse (Doerry, 2015), allowing the opportunity for refinement and avoiding analysis that is similar across variables and potentially duplicative and inefficient. Ward and Seering (1993) introduced the engineering design community to SBD and started formalizing this teachable doctrine and methodology in addressing design needs (Simon, 2019). Since that time, several publications have extended its tenets from those origins of detailed design to concept development, preliminary design, and contract design activities across a variety of platforms and industries, most notably with its alignment to Toyota's design processes (Burrow et al., 2014; Garner et al., 2015; Raudberget, 2010; Sobek II et al., 1999). During those studies, SBD was also called set-based concurrent engineering (Sobek, 1996). The recent publication by Toche et al. (2020) provides an extensive review of research on SBD. It concludes that few complete examples of SBD exist regarding large complex systems like naval vessels. Dullen et al. (2021) also provide a review of relevant research, especially relevant to quantitative methods within an SBD construct. Shallcross et al. (2020) assess the state-of-the-

practice of SBD. Each article presents that the SBD method incorporates distinguishable tenets, principles, and practices (D. Singer et al., 2017; D. J. Singer et al., 2009).

First, SBD has philosophical tenets worth understanding. The name derives from the primary tenet: consider a range or group of alternatives – a set. A set for a variable or solution should consist of all viable and diverse options. Further, none of these options should be eliminated from further consideration unless there is a logical reason for doing so. That logic ought to be robust such that no new information will likely reverse the elimination of the option(s). That tenet discloses a tangential philosophical point; the method operates by removing infeasible and dominated solutions from the set instead of selecting one that seems dominant or preferred. Therefore, one arrives at decisions by systematically removing the “worst” answer(s) instead of trying to select the “best” or “right” one. The sets exist at every perceivable level of abstraction in the design space, from fully synthesized and converged artifacts to subcomponents several levels down in the design structure. This abstraction range means a design team can create non-traditional sets for trade-space exploration and decisions, such as sets encompassing entire power and propulsion architectures. Such approaches allow comparison and analysis at those abstraction levels instead of component or sub-component levels, a necessary condition for enabling decisions from the limited data and knowledge that is available in the earlier stages of a complex design process. An important implication of this method is that the design manager decides to keep or remove portions of the design space based on data instead of intuition. Therefore, this technique forces important and recurring conversations regarding what type and amount of data is sufficient to support any given decision. Design team leadership, in conjunction with the team, continues to refine the measures of effectiveness and measures of performance that constitute “adequacy.” Another tenet of the method is that these decisions are made at the last responsible moment, often leading to delayed decisions and a process in which a design manager keeps more of the trade space open longer. This is difficult for engineers, leadership, and program managers alike since, under the historically used measures of team performance, it may appear the team is not making progress on the design. One last tenet is improved communication because concurrent engineering approaches necessitate this.

**Figure 2: Conceptual Structure of SBD Method** (Page & Seering, 2023)

Figure 2 shares a new conceptual structure of SBD that utilizes and moves away from the usual cited construct from Bernstein (1998). The figure first relates that several sets are in consideration at once, labeled Set<sub>1</sub> through Set<sub>n</sub>. The “points” within each set represent the different options within that Set space, thus the Figure labels the middle portion in each Set with “Articulate All Conceivable Solutions.” The other portions of a Set space represent analyses that remove portions of the fully articulated Set due to either infeasibility or dominance. The different approaches to removing portions of the fully articulated trade space are neither linear nor sequential. The removals result from analyses that close knowledge gaps in the space.

Additionally, each Set represented may have intersections to the other Sets along shared dimensions. For instance, each point in  $Set_1$  could have a connection with one or several points in  $Set_2$  and one or several points in  $Set_n$ . This creates an intricate tapestry of connections between solutions in each space with each other, invoking concepts related to Hilbert spaces to bring multi-dimensional relationships into lower-dimension arithmetic.

Second, Sobek et al. (1999) suggest several fundamental principles of SBD, which have withstood significant modification (Ghosh & Seering, 2014). First, they discuss mapping the design space, which includes defining feasible regions for the parameters under evaluation, exploring trade-offs within that region using multiple alternatives, and communicating those sets of possibilities. Their next principle suggests that the design combines and integrates the feasible and non-dominated regions of the various parameters by intersection – a difficult principle with the tightly coupled and complex design of a ship where thousands of parameters exist to intersect with each other in numerous primary and secondary ways. This principle expects imposing minimum constraints for these intersections to avoid unnecessarily deciding on parameters before the time is right and potentially invoking rework. This principle also seeks conceptual robustness, meaning designs will work regardless of the various parameters' outcomes. Invoking conceptual robustness in design decisions requires a process that supports the knowledge structures of the decisions in a way that enables this. The last principle is establishing feasibility before commitment. This principle starts with gradually narrowing sets while increasing detail. Doing so saves the computationally expensive analyses for the smallest number of solutions. It eliminates more significant swaths of the design space using first-principle and computationally inexpensive analyses at the beginning of the process. This principle also means that once the design manager decides to remove a portion of the design space, the team must stay within the boundaries of the new design space once committed. The team addresses uncertainty around these commitments at gate reviews with appropriate criteria, data, and experience communicated.

Third, following these tenets and principles reveals practices common to SBD (Ghosh & Seering, 2014). One practice is that SBD emphasizes frequent, low-fidelity prototyping to gain new knowledge on the design space and its integration. While Toyota executed this practice physically with clay models and complete prototypes, the practice does not preclude virtual prototyping and invites an intersection between SBD and model-based systems engineering. Another practice with SBD is under-defined system specifications; the method is tolerant to this condition. If the design manager deems one characteristic infeasible, then every design that uses that characteristic is also infeasible. The SBD method instills better communication practices among subsystem teams when executed properly. Another critical SBD practice emphasizes documenting lessons learned and new knowledge. This documentation allows the design teams to reapply the knowledge in other projects and understand decisions for the life cycle of the artifact. SBD enables decentralized leadership and distributed teams through concurrent engineering and improved communication practices. SBD also allows suppliers and subsystems to explore their versions of optimality within the communicated boundaries instead of attempting optimality at the system-of-systems level for a complex product like a naval vessel. Lastly, the SBD method promotes flow-up knowledge creation from the various disciplines' engineers and creators involved instead of flow-down decisions from design management.

Altogether, the tenets, principles, and practices provide a view of SBD and how the method manages complexity, uncertainty, communication, decision-making, and design space exploration. SBD presents a natural step forward in managing these aspects of a complex system design, but it may only sometimes be appropriate. Therefore, the two methods deserve a comparison and contrast.

## COMPARISON

The preceding sections revealed aspects of PBD and SBD that allow one to compare and contrast the methods. Both are methods developed to manage the complexity of a tightly coupled design, in this case, that of a naval vessel. Both start with relatively little information and low-fidelity analyses for the first decisions. The similarities quickly end, however. Singer et al. (2009) provide a good accounting of the differences between the two methods, including the points made here and derived from Bernstein (1998).

In the face of little information and low fidelity, a PBD method selects one point in the design space to iterate around and refine with increasing levels of fidelity. In contrast, SBD uses the information to decide what areas of the design space to stop exploring but keeps many options open for longer. This difference generates a key divergence in the performance of the methods. PBD commits to cost with selection decisions early in the process, with less available information and fewer completed analyses, thus making rework more likely and expensive. Put another way, SBD encourages management to make the right decision the first time by delaying until the appropriate information is available and shifting their influence and cost obligations later in the process.

Another point of comparison between the two methods considers the number of variables involved. With PBD, only a few design space parameters should be independent variables. The method still analyzes, refines, and adjusts all necessary

parameters. However, most are dependent variables adjusted due to decisions made and optimizations elsewhere in the design space. This condition applies at both system and subsystem levels. The dependent parameters are known, specific technologies that are well understood and only require refinement instead of exploration. Alternatively, SBD encourages variations and independent variables to explore a broader solution set across more parameters. Both methods recognize tightly coupled parameters, but PBD controls variation through early decisions, while SBD encourages variation and global optima exploration across several parameters. Therefore, SBD is better suited to design challenges where requirements conflict or the technology or design challenge still needs to be better understood.

Additionally, the two methods differ based on idea generation. PBD methods generate ideas from the tacit knowledge of the individuals involved, typically derived from previous work experience. To reach a solution, the design team iterates around this point solution. Suppose the solution does not and cannot converge. In that case, the team may invoke brainstorming techniques to determine the rework necessary in the design, whether a new technology solution or changing a previously dependent variable to an independent one. Alternatively, SBD defines a feasible space with boundary conditions and systematically reduces it by removing infeasible or dominated regions. Thus, the SBD method promotes ideation up front so that the team considers more solutions and possibilities from the outset.

The two methods also take alternate approaches to optimization. PBD uses known optimization techniques with fitness functions and preferences and applies them when suitable. They are applied against a single point to refine and optimize given parameters, which will likely sacrifice the performance of the other parameters. On the other hand, SBD creates alternatives and tests multiple parameters in parallel, eliminating infeasible and dominated solutions from further consideration. This approach considers a more global consideration to optimization, striking a different balance in the design space with the interaction of the coupled parameters. To enable this, SBD uses minimum control specifications and constraints to allow the intersections of parameters to create this global optimum and mutual adjustment. PBD, alternatively, imposes maximum constraint early in the process, attempting to ensure functionality and interface compatibility. The constraints in PBD also lead to the behavior that invokes margins and allowances around specific parameters and constraints to account for uncertainty and give design teams "budgets" to stay within. These margins developed empirically over time and are potentially fraught with the same risks as other parameters regarding the educated estimates that create these values early in the process. Alternately, SBD allows the knowledge to develop with time, reducing the uncertainty as much as possible before committing to a design decision.

Within those constraints and uncertainty, a team using PBD methods integrates by using synthesis methods, typically conducted using software codes. If a particular discipline cannot stay within its budgets and constraints, leadership must reallocate or reapportion the risk and budget to another domain. At the end, a prototype may be built for testing and validation purposes, including virtually. However, SBD integrates by intersection. Suppose two elements of two sets do not intersect along a common parameter. In that case, there is clear data to remove those portions of the design space from further consideration, validating the minimal-constraint approach: the design space naturally culls itself as more information becomes available without transferring risk throughout the team. SBD encourages prototyping along the way to generate knowledge that can flow up to higher levels of abstractions and sets in the system of systems. These prototypes tend to invoke lower-cost tests that prove the infeasibility or dominance of a select portion of the design space versus the converged artifact as a whole.

Lastly, the two methods differ regarding risk management. SBD engenders a decentralized risk management approach. Each discipline establishes feasibility before commitment. All disciplines pursue their options in parallel. They have a charter to find solutions robust to physical, logical, market, and design variations. Once the design manager commits to a choice, the team stays within the sets and manages uncertainty at least as often as process gates. PBD requires centrally managed feedback channels with high frequency. The disciplines must respond quickly to changes due to analysis in other disciplines or decisions by management. Table 1 provides a summary of these comparison points. Singer et al. (2009) first developed a similar table.

**Table 1: Summary Comparison of PBD and SBD**

Characteristic	Point-Based Design	Set-Based Design
Variables	Very few independent variables, many dependent variables	Many with tight coupling. Most are treated as independent
Requirements Stability	Known, stable, thoroughly documented	Uncertain; flexibility and trades are required or desired
Initial Knowledge	Well-understood technologies and design challenges; less uncertainty	Many knowledge gaps regarding technology, integration, and the design challenge
Finding Solutions	Iterate an existing design based on previous work or educated estimates, modifying it to achieve objectives and improve performance. If necessary, brainstorm new ideas.	Define a feasible design space, then reduce it by removing regions where solutions are proven infeasible or dominated.
Communication	Frequent, latest iteration of the “best” idea	Less frequent; sets of possibilities; broadcast knowledge for the team vice the next step
Integration	Synthesis and convergence through iteration. Disciplines given budgets and constraints, which can be reallocated to other disciplines	Intersections of sets along matching parameters
Selection	Select the “best one” based on a developed decision scheme. Prototype at the end to confirm the working solution.	Concurrent engineering. Eliminate inferior choices. Conduct low-cost tests along the way to generate flow-up knowledge that supports choices.
Optimization	Typical methods with fitness functions and preferences are invoked at any level of abstraction in the design. Typically, one or two parameters dominate the function.	Alternatives and disciplines design in parallel. Infeasibility and intersections drive global optimization.
Constraints	Maximize constraints in specifications to ensure functionality and interface fit.	Use minimum control specifications to allow optimization and mutual adjustment. Design decisions create constraints and requirements for subsequent analyses.
Risk	Centralized and managed with budgets and constraints.	Decentralized, everyone establishes feasibility before commitment, seeks robust solutions, and honors commitments and choices.

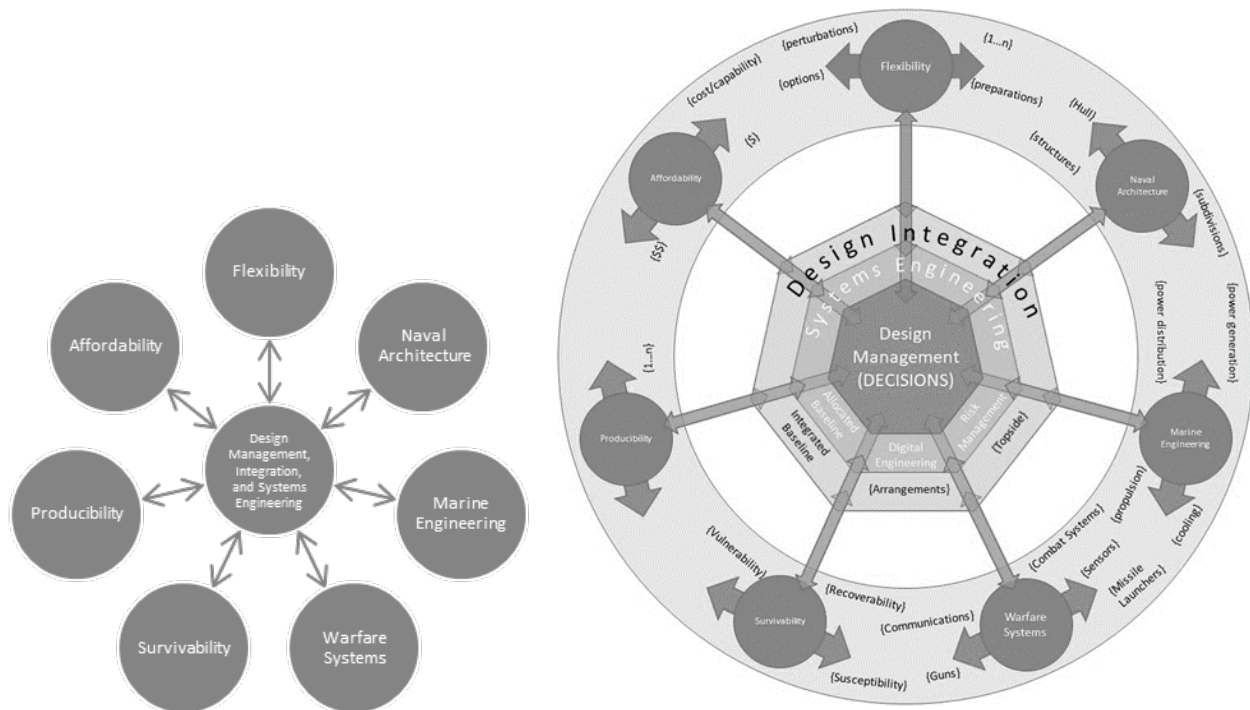

## DDG(X) SBD METHOD AND SCALE

In 2018, the U.S. Navy took action to begin the development of a new class of combatant ships to address uncertainty in future needs and accommodate potential future missions above and beyond those of the current DDG-51 and CG-47 classes (O’Rourke, 2023). A Requirements Evaluation Team analyzed suitable initial parameters. Then, it delivered them to the inaugural design team led by Higgins and Page as the Senior Ship Design Manager (SSDM) and Deputy Ship Design Manager (DSDM), respectively. Their initial charter was to further explore cost-capability trades and concept designs to inform the Capability Development Document. We decided that a set-based method was appropriate to manage the complexity and complicatedness of this undertaking in line with previous Navy efforts (Burrow et al., 2014; Garner et al., 2015). Excerpts from Page (2022) and Page et al. (2022) follow to provide the context for the organization, philosophy, and methodology created.

### Organization

Organizationally, the team used a hub-and-spoke model. This structure balanced the distributed nature of the U.S. Navy’s ship design organizations and our initial chosen sets. The SSDM and DSDM designated seven Functional Area Leads for systems engineering, naval architecture, marine engineering, warfare systems, survivability, flexibility, and affordability, as seen in Figure 3. Those leads were responsible for designated sets in their domains. Leadership planned to co-locate the team at a

design site for high-frequency communications and collaboration, but resources prevented that initially, and then COVID-19 precluded co-location. So, the set teams operated from their designated work sites in Pennsylvania, Maryland, Virginia, and Washington, DC, with little opportunity for face-to-face interaction. This lack of co-location presented an unanticipated opportunity to demonstrate the concurrent engineering aspects of Set-Based Design.

**Figure 3: Initial Design Team Organization and Scaled Design Team Organization**

With time, the team expanded, explored more sets, and the organization and process scaled. Figure 3 also reveals the scaled structure of the organization, which retains much of the foundational framework. The hub expanded and discretized the systems engineering and design integration functions distinct from design management. The spokes of the framework are now connected, forming a wheel representing the communications and negotiations delegated to the domains from the hub.

## Philosophy

The SSDM and DSDM created a design philosophy and promulgated it through a series of Design Guidance Memoranda (DGM). There were initially seven, but that has expanded to include many more. The topics include meeting minutes, routing processes, digital engineering strategy, testing and test objectives, margin management, team training, critical systems, and, of course, how to implement the set-based method for DDG(X). Fundamentally, the philosophy was to manage the risk inherent to the ship and the ship design process while delivering the attributes and characteristics of an affordable and flexible combatant that would serve the Navy for the next 60 to 80 years. The SSDM and DSDM perceived risk with knowledge capture, configuration control, an overly constrained design space, design rework, team communication, and a method unfamiliar to many within the Navy organization. These DGMs addressed those risks and others by instituting practices and providing foundational knowledge and desired behaviors.

The second DGM in the series was especially important because it communicated the SBD philosophy and process to the team. It promulgated the policy that every team member was empowered to retain a valuable portion of their trade space, and only the SSDM (or his delegate) could remove a portion of the design space for further consideration. It also included a requirement to document assumptions within the process and have them approved by the SSDM to avoid the risk of artificially limiting a region of the design space. The assumptions served as placeholders for data not yet known or available to the teams, and they had a potential to affect the boundaries and constraints of the analysis. It established the guiding principle to explore the various domains and sets using appropriate methods. It dictated that sets ought to be no bigger than necessary to analyze an appropriate level of abstraction to close a knowledge gap. The SSDM and DSDM also required the team to think through the metrics and criteria they would use in their analyses to drive to the next decision to avoid the risks of needless investigations that did not close a knowledge gap or extended studies that did not reach conclusions on time. The DGM also included a glossary of the

new terms representing this new way of thinking. It established the concept of a Set Review with the desired outcome of the Reviews being these decisions and approvals.

## Method

The next step in executing SBD with the DDG(X) design team was to meet with the functional area leads depicted in Figure 3 and their set team leads to discuss how to apply this method in their set. These meetings served several purposes, including training, calibration, brainstorming, and just plain storming (from the ubiquitous form-storm-norm-perform model of team dynamics). The group would discuss the first knowledge gaps to address in the design germane to their domain and move forward with agreement on the proper analysis to resolve that knowledge gap, the assumptions necessary to accomplish that analysis, and the metrics and criteria appropriate for the analysis. Reaching mutual understanding often required several meetings with leadership and set teams.

These meetings served as the basis for what became Set Reviews. The Set Review was a structured meeting that provided consistency to the presentation of information to the SSDM for decisions. The Review served other purposes, too. It reinforced training and developed the team's familiarity with our SBD process. Eventually, it was the forum where the design team discussed integration and the intersection of overlapping parameters across domains. For each Set Review, team leadership expects a set team to review eight fundamental elements. The DGM on SBD directed these elements to the team and provided a case example for them to follow.

Each Set Review started with the purpose of the study (i.e., which knowledge gap the team is addressing) and of the Set Review (e.g., interim review, approve assumptions, decision review, set reduction). Next, the Set Review shared the team's approach to closing the knowledge gap. Next, the Set Team briefed the assumptions necessary to use that approach. Subsequently, they communicated the criteria for developing their findings, conclusions, decisions, or recommendations. Then, with that background in place, the team could share the analysis and results followed by the outcomes (e.g., findings, conclusions, recommendations, and decisions to remove portions of the design space). After that, the team shared any uncertainty about the outcomes that may influence the outcomes or future analysis. Finally, the Set Review ended with the anticipated next steps, including further analysis within the current set, recommendations for the following knowledge gap or set to explore, or others.

To document the useable, and hopefully re-useable, knowledge, a successful Set Review culminated in a Design Decision Memorandum (DDM). These DDMs are critically important because they record the team's progress, capture the team's work, and record the outcomes of the Set Reviews for posterity. They were widely available to the team and the community of stakeholders surrounding this effort, including resource sponsors, requirement generators, subject matter experts outside the design team, and acquisition professionals. Of course, not every Set Review generated a DDM as the team instantiated this SBD process: through the first year, there were 66 Set Reviews and 26 DDMS (39%); through the second year, there were 139 Set Reviews and 75 DDMs (54%), and through the third year there were 156 Set Reviews and 86 DDMs (55%). In addition to the increase in successful outcomes with time, another important metric related to the process was a decrease in the time to achieve the first DDM, lowering from about 49 days in the first year to about eight days by the third year. In other words, when the team first presented a new set or analysis, it used to take almost two months of rework and adjustments to reach a satisfactory level of information for a successful outcome. However, by the third year, the Set Reviews were more productive as the team learned from each other and leadership the standards necessary for a successful Set Review.

## Risk and the First Sets

While the DGMs addressed many risks and set policies in place that answered many questions of the growing team, there was one other philosophical question to answer that did not necessarily belong in a DGM: Where do we start? In other words, what are the first sets? Do we start with every possibility in every set? The answer to this last question is emphatically "no." A naval vessel is sufficiently complex that doing so is impossible. The answer to the other questions, generalized to any naval vessel, is that it depends. Generally, the requirements will drive the answer. An aircraft carrier will have a different start than an amphibious vessel, which will have a different start than a submarine, which will have a different start than a combatant. Also, generally speaking, the answer is outside the Work Breakdown structure of the vessel. Instead, *knowledge gaps* are a vital concept that helps determine the first sets and subsequent sets. The SSDM and DSDM used the requirements, known risks, critical path analysis, external sources, and our judgment and experience with previous projects to derive knowledge gaps and thus the first sets.

One example of requirements dictating the first sets derives from the combat systems domain. The requirement stated that the ship would use the latest variant of the AEGIS combat system but incorporate a service life allowance to change and expand in the future (LaGrone, 2022). One might think there was little work left and few knowledge gaps; however, although that requirement defined some of the material solutions, the team still needed to determine the placement of the sensors in the suite

and define what service life allowance for the system in terms of computing power, space and volume, weight, arrangements, electrical power, and cooling. Of course, the initial placement of sensors depends on superstructure geometry, so this drove another of the initial set explorations due to the tight coupling between these parameters, which were equally undefined at the start. Therefore, warfare systems and combat systems were one of the first sets, and teams formed in this domain to explore these knowledge gaps.

An example of the critical path dictating one of the first sets is with the hull. Despite the fidelity of modeling tools available for hydrostatics and hydrodynamics of a vessel, the U.S. Navy still conducts model tests of hull forms at the Naval Surface Warfare Center, Carderock Division, to explore performance ranges, reduce risk, and confirm the expected performance under various conditions. This test requires building a properly scaled model (which takes time) based on the hull form's final dimensions, which requires analysis of many other coupled parameters throughout the rest of the ship design (and, therefore, also takes time). The testing takes time, as does analyzing the data and many other activities in this process. Knowing this, the hull form definition and testing was a critical path item and, therefore, one of the first sets explored.

Judgment and experience with previous projects led the SSDM and DSDM to include boat handling (the launch and recovery of the ship's boats) as one of the first sets. One may think this discipline should not entertain the same regard as the hull form, combat system placements, or power and propulsion architecture. However, in this case, experience from a previous ship class where boat handling systems had proven difficult and caused significant and expensive rework informed this process of the breadth of potential solution space and the varying degrees of impact on hull form and other major systems, revealing the potential risk that warranted early consideration of the boat handling subsystem. After all, the team had not yet ruled out any parameters with the hull form, arrangements, or other domains that may have removed the risky solution. Further, SBD allowed exploration in this domain for solutions that may have precluded the issues that developed in the previous class.

The SSDM and DSDM chose eleven initial sets and their constituent knowledge gaps. They were:

1. **Hull form** began by exploring three basic shaping choices that affected **survivability**. **Hull form** was also on the critical path because of model testing.
2. **Survivability** began with certain **susceptibility** studies and the gathering of attributes for **vulnerability**. This is a risk area for every naval vessel.
3. **Propulsion** began with the architecture: mechanical, hybrid, or integrated power. **propulsion** was also a risky area with the potential to be on the critical path due to land-based testing.
4. **Power distribution** began with its architecture, i.e., ring bus, zonal, and a few characteristics like voltage and power quality standards.
5. **Power generation** began with the type (gas turbine vs. diesel vs. combinations).
6. **Boat handling** started with the launch location of the ship's boats: side, astern, or both. This was a risk area from previous projects.
7. **Warfare system** began and tracked various characteristics of the delivered combat system (the Flight III combat system) and alternate future combat system characteristics that could be envisioned and added, such as directed energy weapons, new sensors, and new computing.
8. **Topside** began by exploring rough deckhouse size, shape, and location measures.
9. **Flexibility** began by establishing a framework for analysis and developing **uncertainty** to start the framework. It was a critical enabler of the ship and the design. This was the first time anyone had holistically and quantifiably analyzed it, so we felt strongly that it needed to be one of the first **sets** and that it should be its own **set**.
10. **Affordability** had eleven distinct studies informed by other sets and included cost specialists that helped quantify some of the cost-capability trades.
11. **Ships** was a set that represented balanced concepts. We used them to validate and integrate other **sets**.

This final set, the **ship** set, is particularly interesting because it is a set of synthesized, converged, and balanced designs. In other words, it is a set full of point designs.

## DDG(X) USE OF POINTS WITHIN THE SBD CONSTRUCT

The use of PBD within SBD may seem counterintuitive. After all, the summary comparison of the two methods presents a case in which the two have few similarities and many differences. That comparison and this article - so far - imply that the two methods are mutually exclusive. This section aims to dispel that thinking. When one carefully crafts the interactions of the two methods, they are complementary. Integrating the two methods requires mindful development of the point designs to fulfill the closure of particular knowledge gaps in a given set in a calculated way, similar to any other analysis a set team may conduct.

The team's discovery of this interaction was both reluctant and serendipitous. It emerged as a discovery due to the final two listed sets of our initial effort: **affordability** and **ships**. Early in the timeline of the design effort, the team's charter was to

explore cost-capability trades, which initiated the **affordability** set. In line with the process, discussions ensued to determine the proper analysis, metrics, criteria, assumptions, and approach to resolve the knowledge gaps and inform requirements regarding affordability. The team quickly realized that affordability, like many other emergent properties of a vessel, is a system-level attribute that is difficult to allocate cleanly to subsystems, but the team needed to evaluate cost and affordability at both discrete and integrated levels of abstraction. Many affordability attributes are tightly coupled with other design aspects, often non-linearly, such as speed, engines, and hull form that have cubic behaviors with resistance and discrete increases in cost due to engine sizing. This abundance of attributes certainly invoked SBD but created the conundrum of understanding affordability at the system (vessel) level to include the secondary and tertiary effects to cost that changing certain parameters and analyzing them may have. At this point, when trying to stand up an SBD method, creating point designs to understand cost and affordability seemed paradoxical. Reluctantly, the team moved forward with this approach, understanding that these points would be more tightly controlled and require faster creation than in previous efforts. The emphasis of the points was on realistic representation of the open design space across all domains while isolating a particular set or characteristic of interest.

Before this effort, including in the Requirements Evaluation Team, the Navy created point-based designs with a few exceptions (Burrow et al., 2014; Garner et al., 2015; Mebane et al., 2011). The Navy has a tool that synthesizes the various parameters of a vessel's design into a feasible solution or tells the user why the vessel will not synthesize. They also have a companion tool to change parameters within boundaries and constraints to produce many point designs rapidly and allow comparisons. It can produce 1,000-2,000 point designs per hour if run on high-power computers. This toolset enables a design space exploration based on boundaries at the moment in time coupled with the programmed code, but does not necessarily create new knowledge. The Requirements Evaluation Team generated 25,000 points during its exploration similar to the **ship** set the affordability team created, but none of those points were used in subsequent design phases with the DDG(X) team.

The DDG(X) effort did not require thousands of designs, though; it required carefully curated point designs that could be compared in all-else-equal techniques to generate knowledge that informed affordability measures. Therefore, each analysis required a unique study guide, a document usually a dozen pages or less that defined benchmark vessels, excursions from that benchmark, and what parameters were allowed to vary from one to the next. The combination of the benchmark vessel and the parameters varied as part of the study created the excursion that generated new knowledge of the design within the boundaries and constraints of the excursion. These study guides listed the approved assumptions and boundary conditions for each point design in the analysis. Collectively, all of these point designs constitute the **ship** set.

The **ship** set contains a few variations of point designs. One variation is called a benchmark. A benchmark vessel represents a synthesized vessel that incorporates decisions and outcomes from Set Reviews up to a certain point. Put another way; a benchmark incorporates the knowledge created and decisions made into a representative point design. Due to this approach, only known and approved knowledge structures (or known and approved assumptions) created new product structures. This limitation helped keep rework loops small and ensured that knowledge built upon itself as the process revealed the design. Depending on the knowledge sought in the open trade space, the process may require several related benchmarks. For instance, when exploring the major power and propulsion architecture, the team created one benchmark with a mechanical architecture, another with a hybrid architecture, and another with an integrated electric architecture so that knowledge creation happened across these architectures until the SDM made a down-select decision. That introduces the final variation of the **ship** set, an excursion. This type of point design allowed specific parameters to vary in controlled ways to help analyze the ship-wide impacts of these changing variables.

Another variation of the approach is that a benchmark vessel represents a synthesized vessel that reflects a portion of the ship set trade space, whereas a few benchmarks are developed and maintained to represent the total ship set trade space. Over time, these benchmarks are updated to incorporate decisions and outcomes from Set Reviews. When decisions and outcomes have not been completed (e.g., warfare system selection), different benchmarks will vary the sets they are designed with to ensure representation of the ship trade space. These benchmarks are then utilized to support the determination of the metrics that can only be determined from a synthesized vessel. When a particular set needs to understand total ship affordability or other metrics for comparisons within the set space being examined (e.g., power generation type – gas turbine or diesel), excursion concepts will be developed from the benchmarks that vary one set (e.g., diesel power generation set in an excursion from a gas turbine benchmark). The differences from the excursion concept to the benchmark represent the impact of the set variation, and that difference becomes the finding for that set's impact across the ship trade space. (e.g., diesel generators are much less power dense but more fuel efficient than gas turbines, increasing ship size to accommodate the diesel generators but reducing ship size on fuel demand; benchmark/excursion comparisons will identify the overall impact on affordability).

A practical example helps to illustrate these points and understand the different variations of point designs. Two of the cost-capability trades requiring more knowledge at the beginning were the top speed of the vessel and the architecture of the power and propulsion plant, specifically mechanical, hybrid, or integrated-electric. Naval engineers ought to recognize that 1) changing the propulsion plant architecture is not trivial, 2) changing speed changes costs in non-linear ways, and 3) the change

in cost for the change in speed will depend on the architecture. Therefore, the team created a coupled design study that varied each parameter to close this knowledge gap for the team and our stakeholders. At the time, the team had three benchmarks for each propulsion architecture within a common hull form with a common combat system and topside arrangement. Those benchmarks became the standard from which two excursion ships varied in their top speed (six new point designs total). These benchmarks and excursions are still only representatives of the open trade space: the team selected specific power generation and propulsion components that had not been locked in with design decisions, and the synthesized models included inherent assumptions on how to best trade hydrodynamics against installed power since that decision space was also still open. The results allowed the team and our stakeholders to compare three cost curves across variations in propulsion plant and top speed. The team could determine and report which plants were more affordable at which speeds. They could also reveal which plants were more sensitive to speed changes – an essential measure of uncertainty at this design stage. The team could couple this information with others like risk and technology readiness to help in the decisions regarding speed, cost, architecture, and others moving forward from that scenario. The speed and propulsion architecture decisions were made within the next year, resulting in a new benchmark that incorporated those decisions and others into a new synthesized and balanced reference vessel, finishing this practical example.

These benchmark and excursion point designs serve many vital purposes. First, one use case for these point designs within SBD is as a risk reduction measure. There are scenarios when schedules accelerate or time runs out for a given design phase. The benchmarks provide a balanced and synthesized design that *could* proceed to subsequent phases at any time since the benchmark presents a representative point that should meet all the requirements. The number of knowledge gaps unanswered dictates the uncertainty and risk in moving forward. The benchmarks also validate the requirements by showing one possible solution of many.

A second use case is in performing ship-wide comparisons and analyses when only select variables change. This purpose allows the design team to tease out second and third-order effects through the design and their cost implications. This case is essential in designing a naval vessel because of the tight coupling of the design parameters.

A third use case relates to the second: knowledge generation. When carefully curated and analyzed, the point designs generate knowledge on a ship scale to understand requirements and cost impacts. In the vein of knowledge generation, they also provide a means by which a design team can match their knowledge structure with the product structure, at least within the boundaries of the synthesis code, in this case. Further, the point designs allow a design team to test the boundaries of the design space. DDG(X) terms these tests “diversity of thought” exercises. When leadership or the team wants to challenge a requirement, assumption, or technology solution, the use of point designs in the manner relayed here provides a structure to conduct those tests, generate new knowledge, and potentially stretch the boundaries of the design space.

In essence, these point designs act as virtual prototypes, a purpose SBD encourages. However, while Toyota can afford to (and does) build physical prototypes of cars and subsystems, it makes less sense for the Navy or another ship owner to follow the same practice. Virtual prototyping allows the Navy to “build” a ship and create a digital engineering underpinning for the effort, with digital threads that can carry through into production and sustainment. The value of the prototype is limited in the same way as any model used is: one must understand the assumptions, code, and fidelity of the information involved.

One last case to note is that the point designs help transition SBD from theory to practice. The U.S. Navy had limited exposure to SBD, especially on a large scale for a combatant. Some stakeholders perceived a considerable risk in using SBD on such an important project without more of a track record for the method. These point designs grounded SBD by providing a sense of familiarity. At the risk of speaking for those stakeholders, they appreciated this approach and, for the first time in their careers, saw (literally seeing in the charts and data graphs presented) the effects requirements and assumptions had on cost and the other coupled parameters of the design. This approach was able to visualize a trade space for decision-makers that transparently presented the capabilities, limitations, and assumptions of the data and outcomes. The design team leadership had to carefully remind stakeholders, when appropriate, that these point designs were for knowledge regarding possibilities and causal relationships of parameters and results that lead to decisions but are not necessarily - *the* - solution (notwithstanding the first use case communicated above).

## CONCLUSIONS

While it may seem counterintuitive to use PBD within SBD, the two methods complement each other when constructed in ways that enable their interaction. For complex design challenges like naval vessels, using point design within SBD to generate knowledge and understand causal relationships in the tightly coupled and non-linear trade space benefits the effort. These point designs help reduce risk, act as virtual prototypes, and enable analysis of ship-wide impacts when only a few parameters change. DDG(X) created a preliminary ontology of point designs that suited the team’s purpose: benchmarks and excursions. These basic variations facilitated the team’s knowledge generation and matched their knowledge structure to the product structure in

repeatable and valuable ways. Though the DDG(X) team was reluctant to create point solutions as part of their SBD implementation, it proved a valuable practice worth repeating, with well over two hundred point designs created to explore the space, create knowledge, and reduce risk. The two methods are not mutually exclusive, and this approach can generalize to apply to any complex design undertaking.

# Beyond Jack-Ups: A Moonshot for Future Offshore Wind Turbine Installation Vessels for an Uncertain Market

J.J. de Ridder<sup>1,2,\*</sup>, J.D. Stroo<sup>2</sup>, and A.A. Kana<sup>3</sup>

## ABSTRACT

*This paper addresses the growing offshore wind market's demand for larger turbines in deeper waters by highlighting limitations in existing installation solutions and proposing a new concept with a floating monohull, named Moonshot, which will thus be different than traditional jack-up or semi-submersible crane installation vessel options. This paper discusses the design process, which combines Ulstein Rotterdam's Controlled Innovation and Blended Design to develop the concept. This process is used to explore various market scenarios to determine optimal vessel parameters. Results demonstrate how optimizing for financial performance or seakeeping behavior impacts the design. Moonshot's initial parameters are established, and its performance is compared to existing installation solutions.*

## KEY WORDS

Early-stage design; Complex design methods, Design space exploration; Offshore wind turbine installation; Seakeeping.

## INTRODUCTION

Today's society faces growing concern over climate change, which is primarily caused by the release of greenhouse gases and other hazardous emissions. Generating electricity and heat by burning fossil fuels causes a large part of global emissions (United Nations n.d.). To help mitigate the impacts of climate change, it is crucial to reduce the reliance on fossil fuels and transition to cleaner, renewable energy sources. One of those sources is offshore wind energy. As a result, offshore wind energy is a rapidly growing industry. The global wind market has experienced significant growth in recent years, with the total installed capacity increasing from zero in the 1990s to over 40 GW in 2020. This growth is expected to continue towards 630 GW in 2050 (Kuhn, et al 2023).

Due to the improvement in offshore wind energy and growing demand, the landscape of the offshore wind turbines is also changing. Analysis of 4C Offshore wind farm data (February 24, 2023) has been performed, revealing three major trends. The first is the increasing capacity of turbines. The turbine capacity has significantly increased over the last years and is expected to continue to increase. With the increasing capacity of turbines, the physical size of turbines also increases, making them larger and heavier. The second is the increasing distance from shore to the offshore wind farms (OWFs). The main reason for this is that available location near the coast, especially in the North Sea, are getting scarce (WindEurope 2020). Also, wind speeds are higher and thus more favorable (Nikitas, et al 2020). From 2011 to 2023, the average distance from land to OWF has more than doubled (NORWEP 2022). The third is the increase in water depths at OWF locations. The analysis showed that water depth was not more than 20 meters in 2010, while nowadays the water depth is almost 40 meters. The wind farm data showed that this number is expected to increase in the future.

Currently, wind turbine and foundation transportation and installation (T&I) is done by the same vessels. However, due to the increasing weight and size of foundations, which are growing faster than turbines, foundation installation work is shifting to purpose-built foundation installation vessels (FIVs) (Foxwell 2022). Wind turbine installation will therefore soon be done by dedicated wind turbine installation vessels (WTIVs). This research is thus focused on the process of wind turbine installation. Other research focused on understanding the driving factors behind offshore wind installation vessels includes van Lynden et al (2020). There are various ways of T&I for offshore wind turbines. Seven distinctive methods were identified for offshore wind turbine installation with vessels, as shown in Figure 1.

**Figure 1: Overview of common methods for offshore wind turbine installation, based on (Jiang 2021, Richmond et al 2018, EnergyFacts.eu 2019)**

The methods mainly differ on the number of onshore preassembled components and subsequently the number of required lifts. The method and degree of preassembly influences the number of offshore lifts. Since offshore lifts are risky and susceptible to delay or damage due to wind conditions, the preference is to minimize offshore assembly (Kaiser, et al 2011; Iberdrola n.d.). Also, from a cost perspective it is beneficial to reduce the number of lifts offshore. For example, (Robinson, et al 2022) state that if construction costs would be \$1 onshore, it is \$2 in port, and \$10 offshore. Despite, most offshore wind turbines are currently installed using method 2 – single blade with preassembled tower - (Asgarpour, 2016) because components can be transported more easily and deck space is used most-efficiently, reducing the number of required roundtrips (Kaiser, et al 2011). Method 7 is a novel installation method which combines the advantages of method 2 and method 6, ensuring efficient use of deck space, while also keeping the number of overboard offshore lifts as low as possible. The rotor nacelle assembly (RNA) is assembled on board of the vessel in a controlled environment with a dummy tower.

Regarding transportation of turbine components, there are two options. The first option is all-in-one, in which the installation vessel both transports and installs the turbine components. The vessel loads at the marshalling port and sails to the installation site. There, the components are installed by the same vessel. When empty, the vessel returns to the marshalling port, repeating the cycle (Vis, et al 2016). The second option is a feeder system, in which the WTIV stays at the OWF location and is supplied by feeder barges or vessels that shuttle between the marshalling port and OWF to be loaded and unloaded with turbine components. An advantage of this strategy is that installation vessel's productivity could be higher because it does not have to sail. However, lifting from another vessel at sea, which is moving due to waves, could be very risky (Vis, et al 2016), potentially damaging the fragile turbine components (Asgarpour 2016).

Currently, mostly jack-up vessels are used for wind turbine T&I (Asgarpour 2016). These vessels can elevate themselves above the sea surface with their legs to provide a stable (Nørkaer Sørensen, 1984) base for lifting operations and eliminate vessel and crane displacements due to waves and surges (Streatfeild, et al 2013; Attari, et al 2014). Analysis of the existing fleet of jack-up vessels used for wind turbine T&I with the 4C Offshore wind vessel database (March 10, 2023), showed that they will not be able to lift the next-generation turbines. Furthermore, the increasing water depths are a negative progression for jack-ups. The leg length of these vessel dictates the maximum working depth (Attari, et al 2014). In addition, because of their interaction with the seabed, they are dependent on soil conditions. A seabed survey must be done beforehand, requiring other vessels (Riviera Newsletters 2010), and these vessels cannot be deployed at all locations. In addition, lowering and raising the legs takes up a considerable amount of time (Uraz 2011), especially considering that this must be done at every turbine location and in port. This makes jack-ups very inefficient.

Alternatively, floating solutions are also sometimes used for wind turbine installation, such as semi-submersible crane vessels (SSCVs). A major drawback of these vessels is that their day rates are very high (Jiang 2021) and their capabilities exceed what is needed for offshore wind turbine installation (Kaiser, et al 2011), making them cost-inefficient. In addition, these vessels require a feeder system, despite having a substantial deck area. This is because SSCVs have a transit draft of 10 to 12 meters. Their maximum draft, during lifting operations, ranges from 25 to 32 meters (Saipem n.d.; Heerema Marine Contractors 2020), while the water depth at marshalling ports is typically not larger than 9 to 13 meters (Parkinson, et al 2022). As a result, SSCVs are not able to enter the marshalling ports to load turbine components, requiring a feeder system with all risks associated.

Multiple ways to address the gap between the existing wind turbine installation fleet and the market demands were investigated. Vessels currently on order or being built were found to be just larger jack-ups. Existing jack-ups are being retrofitted with larger cranes to be able to install the next-generation turbines. However, these approaches do not address the installation bottlenecks associated with jacking. In addition, several new concepts for future wind turbine installation were researched. These concepts were found to be mostly floating installation solution, relying on fully preassembled

installation methods, reducing the number of offshore overboard lifts. However, there are stability and seakeeping risks when sailing with a fully preassembled turbine (Herman 2002; Díaz, et al 2023). Most of the concepts were found to still have installation bottlenecks, such as the jacking or the need for a feeder system. Also, most concepts were found to have complex hull types, such as semi-submersibles or catamarans, which are expensive to build, leading to higher day rates (Djupevåg Eri 2015). Additionally, operational costs are generally higher for these hull types (Schouten 2018).

Based on the market, concept analysis, and previous development with industry partners, it was concluded that there is a need for a new cost-effective and efficient solution. This research proposes a new floating monohull vessel concept, called Moonshot, to address the gap between future market demand and current and near-term solutions. Monohulls generally have a large open deck area and are therefore capable of carrying a lot of cargo. Also, day rates are lower than for the other types of WTIVs (Jiang 2021). Also, they are capable of higher transit speeds than, for example, jack-ups and SSCVs (Djupevåg Eri 2015). But most of all, this vessel type would not have any of the mentioned installation bottlenecks. However, a floating monohull would be more susceptible to motions because of waves during the installation of the turbines, which is important to consider.

The aim of this research is to explore the feasibility of Moonshot and to investigate how it can be developed into a viable concept. Because of the unpredictable nature of the market it will operate in, it is important to explore the design space of Moonshot and elucidate optimal design parameters for both financial performance and seakeeping performance. The main research question of this paper is: “What should optimal design parameters be for the innovative Moonshot concept, a floating monohull vessel for offshore wind turbine installation, taking into account financial and seakeeping performance, while considering the uncertainties and evolving requirements of the offshore wind market?”

## DEVELOPING MOONSHOT

To design Moonshot, it is important to choose a suitable design strategy. Multiple design strategies were investigated. These included: point-based design, set-based design, systems engineering, systems-based design, and optimization-based design. Each of these design strategies were evaluated on several aspects that are important for the development of Moonshot, including: (1) applicability in ship design, (2) the degree of innovation the strategy enables, (3) optimization with a parametric ship model, and (4) flexibility in dealing with changing requirement and market uncertainty. None of the design strategies was found to meet all requirements. In response to this, two strategies developed by Ulstein Design & Solutions B.V. (UDSBV) were introduced: Controlled Innovation (CI) and Blended Design. When investigating these strategies, it was found that they are amalgamations of the main state-of-the-art design strategies.

CI was originally developed by Van Bruinessen (2016) as part of his PhD dissertation and is a strategy to evaluate functions and design aspects in the ship design process. The application of development packages for high-risk design aspects allows for knowledge generation and often results in new solutions and an improved design. Therefore, this method proves to be very useful when innovating in the realm of ship design. Blended Design was developed by Zwaginga (2020), Zwaginga et al (2021) and allows for multi-parameter optimization for many variations of a parent ship design within different (market) scenarios, while considering the lifetime financial performance.

The two strategies have been combined into one design strategy, suitable for the development of Moonshot. CI is used to determine the functions of Moonshot, as well as to establish the underlying design aspects. These design aspects are then evaluated to identify which ones require additional focus or extra knowledge. It is then important to differentiate between the design aspects that should be addressed in the development packages of the CI process and those that can be handled through Blended Design. The results obtained from the development packages will eventually serve as input or boundaries for Blended Design. The adopted design strategy for this research is shown in Figure 2 and described in more detail below.

**Figure 2: Schematic of the adopted design strategy for this research.**

## High-level objective, Functions, and Design aspects

Following the CI process, first the high-level objective of Moonshot was determined, which is that the design should aim to be competitive in the offshore wind market and be efficient. Secondly, the functions to reach the objective were established, which are: hull shape requirements, mission equipment for wind turbine installation, payload, station keeping, motion performance, mobility, and accommodation. Then, the associated design aspects to these functions were determined. The identified design aspects are shown in the first column of Table 1. Arranging the design aspects revealed that there were a lot of unknowns for the design aspects, including requirements for ship particulars, type of lifting equipment, and the number of turbines Moonshot should carry per roundtrip. Also, properties of the cargo are unknown.

## Design aspects evaluation

Table 1 shows the design aspect evaluation, in which all design aspects are ranked. The first step involves assessing the level of the uncertainty of each requirement of a design aspects. Uncertainty in this context refers to the likelihood of changes in the requirements. Thereafter, the expected impact of an aspect on the ship design is determined. The two scores are then multiplied. Design aspects with higher scores indicate greater risks to the ship design. To decrease these risks, it is crucial to reduce uncertainty of the high-scoring design aspects and generate more knowledge to establish the right requirements with more certainty. Following CI, these high-risk design aspects are covered in detail in development packages. However, not all aspects will be covered solely in the development packages, as some will be addressed through Blended Design. The table shows the evaluation of the identified design aspects and indicates whether the path of development packages or Blended Design is proposed for high-scoring design aspects.

**Table 1: Evaluation of the design aspects.**

	Uncertainty 1 = certain 5 = uncertain	Consequence Design 1 = low impact 5 = high impact	Score Design Aspect $U \times C \times 0.2$	Assigned solution
<b>Hull shape requirements</b>				
Hull type	1	5	1.0

<b>Accommodation</b>				
People on board	3	3	1.8	

## Development packages

Three design aspects were identified that should be covered in development packages to generate more knowledge, or before they can be incorporated in Blended Design, namely: the lifting equipment; the size, mass and CoG of components, and optimal deck layout.

### *Development package 1: Lifting equipment*

Since Moonshot will be a monohull and will install the turbine while floating, it will be susceptible to wave-induced motions. Therefore, the number of overboard lifts should be as low as possible to minimize risk. Therefore, the decision has been made to combine two installation methods to combine the benefits of those methods. The idea is to transport the turbine components separately, to allow for efficient use of deck space, and when at the installation location, assemble the turbine on board of the vessel. Then, the assembled turbine will be lifted overboard and installed on the turbine foundation. The right lifting equipment should be selected for this purpose. When looking at existing wind turbine installation vessels and future concepts, two types of vertical lifting mechanisms can be identified, free-hanging and guided (Figure 3).

**Figure 3: Visualization of lifting mechanisms: free-hanging lift (left) and guided lift (right).**

The two mechanisms have been evaluated on the five aspects in Table 2. The main advantage of a guided lift mechanism would be to prevent swinging loads, minimizing the risk of damage to the turbine components. However, the main drawback of this mechanism would be that it would not be flexible and could not be used for other lifting purposes, because the working area of a guided lift system would be very small. Therefore, a hybrid solution between the two lifting mechanisms is preferred, a crane that can do both, such as the Zephyr crane by Huisman. Therefore, this lifting solution is adopted on the concept for Moonshot.

**Table 2: Assessment of the different lifting mechanisms, including a hybrid solution.**

	Free-hanging lift	Guided lift	Hybrid solution
Sufficient lifting capacity			
Prevention of swinging loads			
Stored position during transport			
Flexible			
Acceptable			

#### **Development package 2: Size, mass, and CoG of components**

Information about the properties of next-generation offshore wind turbines is not available, resulting in uncertainty regarding the size, mass, and CoG of turbine components. To overcome this, an analysis into the properties of turbines has been conducted. A database was created with properties of 16 commercially available offshore turbine models of different sizes, and 7 generic reference offshore wind turbine models provided by research institutions. Spearman's rank correlation was used to determine the correlation between the various size and mass properties of the turbines. This showed that there is a strong correlation between all properties. The design of a wind turbine depends on the rated power, which is in turn linked to the squared rotor diameter (D). To understand the mass and size properties of turbines would scale with increased turbine capacity, scaling laws have been established with D as the independent variable. Two approaches, as described by (Sergiienko, et al 2022), were employed:

- 1) **Heuristic engineering fit** with  $y=cx^d+f$ , where x is the independent variable, and the exponent d is constant and based on expected geometric upscaling from physical laws or literature. Coefficients c and f are unknown, and f is non-zero for linear scaling;
- 2) **Best power fit** with  $y=ax^b$ , where coefficients a and b are unknown.

The coefficients were obtained by fitting curves, following the two approaches, through the data points from the wind turbine database. Then, the coefficient of determination ( $R^2$ ) was calculated to indicate how well the resulting curves fit the data. Eventually, the best fitting scaling law for each of the wind turbine properties has been established. These are shown in Table 3. When extrapolated, these can subsequently be used in Blended Design to estimate the size and mass of future turbine components. The center of gravity (CoG) location of the turbine components was estimated using literature and assumed for towers to be at 41% of the height (Quancard, et al 2019). The CoG of blades is located 35% from the blade root (Sørensen 1984) and for nacelles and hubs at the center of the components.

**Table 3: Scaling laws for each parameter based on a heuristic engineering approach and best power fit, based on the database with 23 offshore wind turbine models.**

Parameter	Heuristic engineering fit	R <sup>2</sup>	Best power fit	R <sup>2</sup>
$P_{rated}$	-	-	-	-
$D_{rotor}$	$5.98 \times 10^1 \cdot P_{rated}^{0.5}$	0.913	$6.02 \times 10^1 \cdot P_{rated}^{0.497}$	0.913
$L_{blade}$	$4.86 \times 10^{-1} \cdot D^1 + 0.113$	1.000	$4.89 \times 10^{-1} \cdot D^{0.999}$	1.000
$M_{blade}$	$1.16 \times 10^{-3} \cdot D^2$	0.903	$5.58 \times 10^{-3} \cdot D^{1.707}$	0.929
$L_{nacelle} + L_{hub}^*$	$8.23 \times 10^{-2} \cdot D^1 + 2.112$	0.819	$1.66 \times 10^{-1} \cdot D^{0.890}$	0.815
$B_{nacelle}^*$	$7.03 \times 10^{-2} \cdot D^1 - 4.433$	0.834	$1.47 \times 10^{-3} \cdot D^{1.658}$	0.882
$H_{nacelle}$	$6.13 \times 10^{-2} \cdot D^1 - 2.136$	0.719	$1.98 \times 10^{-2} \cdot D^{1.175}$	0.703
$M_{nacelle}$	$1.20 \times 10^{-2} \cdot D^2$	0.866	$1.59 \times 10^{-2} \cdot D^{1.947}$	0.867
$M_{hub}$	$2.76 \times 10^{-3} \cdot D^2$	0.584	$1.08 \times 10^{-3} \cdot D^{2.174}$	0.588
$L_{tower}$	$3.80 \times 10^{-1} \cdot D^1 + 39.328$	0.730	$4.27 \times 10^0 \cdot D^{0.622}$	0.735
$D_{tower}$	$3.89 \times 10^{-2} \cdot D^1 + 0.766$	0.888	$6.38 \times 10^{-2} \cdot D^{0.924}$	0.885
$M_{tower}$	$3.07 \times 10^{-2} \cdot D^2$	0.624	$5.89 \times 10^{-2} \cdot D^{1.880}$	0.626
$H_{hub}$	$4.68 \times 10^{-1} \cdot D^1 + 32.540$	0.822	$2.56 \times 10^0 \cdot D^{0.737}$	0.822

\*Only the direct and semi-direct drive turbines were used for this parameter.

### Development package 3: Deck layout

To investigate the optimal deck layout for Moonshot, eighteen different deck layouts were manually drawn with components for 15 MW turbines. The deck layouts differed with respect to crane, assembly, and installation location, as well as placement of the components on deck. Subsequently, all deck layouts were evaluated on the following aspects:

- Port logistics and transit
  - Loading
  - Transit
- Offshore operations
  - Tower lifting
  - Nacelle lifting
  - Blade lifting
  - Assembly lifting
- Capacity
  - Number of turbines
  - Efficient use of deck space
- Motion behavior
  - Assembly location
  - Installation location

An analysis was performed to establish local motions in the nacelle for two different loading conditions and at two different locations. The analysis was done for a case in the North Sea with a JONSWAP spectrum with  $\gamma=3.3$  at a significant wave height of 2.5 meters. The vessel was allowed to weathervane. For the analysis, software SESAM package by DNV was used. GeniE was used for creating a panel model, HydroD for modeling the environment and perform the hydrodynamic analysis in the frequency domain, using WADAM as a hydrodynamic solver.

All deck layouts were evaluated and scores on the various aspects were assigned. After evaluation, it was concluded that the best deck layout and crane position for Moonshot would be as shown in Figure 4.

**Figure 4: The selected optimal deck layout for Moonshot.**

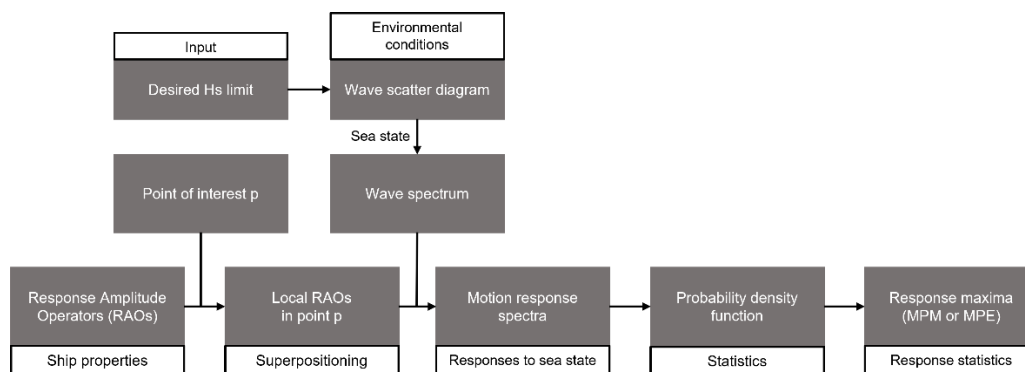

## BLENDED DESIGN FOR MOONSHOT

Blended Design is used to explore the design space of Moonshot and to elucidate the ship parameters based on financial and seakeeping performance. The existing model, as developed by Zwaginga (2020), Zwaginga et al (2021) generates a large number of unique design variations on a parent ship design by varying naval architectural parameters. For each of those design configurations, the lifetime financial performance is calculated within a simulated market environment. The model incorporates market uncertainty and different market scenarios can be considered to identify the optimal vessel size for evolving markets while balancing short- and long-term competitiveness. The current model could not directly be applied for the purpose of Moonshot as it cannot take into account seakeeping behavior and was originally designed for different vessel types, specifically heavy transport vessels (HTVs) and FIVs for monopile and jacket foundation T&I. In order to

adapt Blended Design for Moonshot, existing assumptions and functions needed to be updated or modified. Furthermore, new functionalities were added. Figure 5 visualizes the different parts of Blended Design and the connection between different functions of the entire model. The colors indicate what parts are added (green), unused (red), modified (blue), and left unchanged (white).

**Figure 5: Integration of functions for Moonshot in Blended Design.**

## Method for seakeeping analysis

**Figure 6: The approach to determine seakeeping behavior.**

similar. The trajectory of the RAOs calculated with the CFEs aligned with the behavior of the RAOs from HAS. The amplitudes of the motion RAOs appear to be around the same angular wave frequency, and the order of magnitude of the RAOs falls within the same range. Additionally, the area under each RAO curve was calculated and compared. The area is a measure of the transferred energy. This comparison is shown in Table 4.

**Table 4: Comparison of the areas under RAO curves for results from HAS and CFEs.**

			Wave heading angle

As displayed, the CFEs tend to underestimate the area under the RAO curves in comparison to the RAOs obtained from HAS. This implies that there is a difference in the total transferred energy across the entire range angular wave frequencies. The disparities between the two methods are most pronounced in beam seas. Also, a validation has been performed with another way to validate the RAOs from CFEs is to compare the standard deviation ( $\sigma$ ) of the resulting response spectra. This is because the distribution of the area under the RAO curves is also important to consider. Therefore, the differences in transferred energy do not provide the complete picture. To incorporate the distribution into the validation, response spectra were calculated for all RAOs in three different sea states with different wave peak periods ( $T_p$ ). A comparison for one of the periods is shown in Table 5.

**Table 5: Comparison of the standard deviation ( $\sigma$ ) of the response spectra at  $T_p = 7s$ , calculated using the RAOs from HAS and CFEs.**

The comparison showed that the error in the variances decreases as wave periods increase, or wave frequencies decrease. Overall, the variances from CFEs were lower than from HAS, but in the correct order of magnitude. Also, it is important to keep in mind the primary purpose of the method for determining the RAOs, which is to assess seakeeping behavior within Blended Design and predict the relative merits of various ship configurations. In this context, the method appears to be applicable. However, absolute results obtained from this method should be interpreted with caution.

### Local RAOs

RAOs are calculated in the CoG of a vessel. When linearizing for small motions, the independent RAOs can be translated to local motions in a point P through superposition. The phase angles of the RAOs are not known, so it is assumed for this research that the phases of all motions are such that the maximum motions occur at the same instance. This approach would yield the most conservative results. The resulting RAO in each of the three directions is then the sum of the associated RAOs in combination with the coordinates of point P with respect to the origin of the coordinate system, located at the CoG of the ship. For this project, point P will be located at the hub height in its installation position of the largest turbine every ship configuration can potentially carry in its lifetime in a specific market. This is visualized in Figure 7.

**Figure 7: Schematic of the location of point P for local motions.**

### Wave scatter diagram

A wave scatter diagram represents the joint probability of significant wave height ( $H_s$ ) and wave zero-up-crossing period ( $T_z$ ). The wave scatter diagram can be calculated for different worldwide locations and depends on multiple parameters. The values for those parameters have been derived using measurements and can be obtained from DNV-RP-C205 Environmental Conditions and Environmental Loads (Det Norske Veritas AS 2017). The seakeeping module is programmed such that different wave scatter diagrams can be considered, based on the input. For this research, zone 11 is used. The corresponding wave scatter diagram is presented in Figure 8.

When designing a vessel, it is common practice to aim for a certain workability or to set the limits up to which it can operate. Based on market research, it was decided that Moonshot should be able to operate up to  $H_s$  of 2.5 meters. This is highlighted by a black outline in the figure above and corresponds to a workability of more than 75 percent, which is acceptable. Of the sea states with a  $H_s$  of 2.5 meters, a  $T_z$  of 6.5 seconds is most occurring. For this research, this sea state (outlined in red) will be the sea state of interest.

**Figure 8: Wave scatter diagram calculated for zone 11 (North Sea).**

### Wave and response spectra

For this research, a JONSWAP wave spectrum will be used with a peak enhancement factor ( $\gamma$ ) of 3.3. The wave spectrum will be calculated for the sea state of interest for the specified zone in Blended Design, as explained earlier. After the wave spectrum is determined, the response spectra for each of the motion directions and wave headings can be established. The motion response spectrum describes the response to waves of a floating body at different wave frequencies.

*Response maxima*

To assess the seakeeping characteristics of the ship configurations, it is important to predict the highest response value within an irregular sea state within a certain time. This is done with probability distributions. A good approximation for the distribution of response maxima can be obtained using a Rice distribution function. This probability distribution depends on the variance ( $\sigma_s$ ) of the response spectrum and spectral width parameter ( $\varepsilon$ ). When the  $\varepsilon=0$ , the Rice distribution reduces to the Rayleigh distribution. For  $\varepsilon \leq 0.9$ , the most probable largest value in  $n$  observations of a random process, as given in (Bhattacharya 1973), is calculated by Equation 1 and 2.

$$n = \frac{T}{T_z} \quad [1]$$

$$\eta_n = \sigma_s \left[ 2 \ln \left( \frac{2\sqrt{1-\epsilon^2}}{1+\sqrt{1+\epsilon^2}} \cdot \frac{n}{\alpha} \right) \right]^{1/2} \quad [2]$$

The most probable largest value  $\eta_n$  depends on a risk factor  $\alpha$ . This factor is the probability that the extreme value will exceed  $\eta_n$ . For example, for  $\alpha=1$ , the most probable maximum (MPM) value is calculated. This is the most-likely maximum response that will occur within the specified time interval  $T$ . This interval is commonly 3 hours. The MPM response value typically has a 63 percent probability of being exceeded. On the other hand, with  $\alpha=0.01$ , the exceedance probability is only 1 percent, which is often referred to as the most probable extreme (MPE) response. An example of a probability density function (PDF) and cumulative distribution function (CDF) for  $n$  response observations is depicted in Figure 9. Also, the MPM and MPE values with an  $\alpha$  of respectively 1.0 and 0.01 are shown.

**Figure 9: Rayleigh PDF and CDF ( $\epsilon = 0$ ) for  $m_0 = 8.02 \cdot 10^{-4}$  and  $n=2,207$  waves ( $T_p=5.5s$ ).**

The decision of the value for  $\alpha$  depends on the acceptable risks and designer's decision. When looking at the MPM and MPE responses of the CDF above, it stands out that the difference between the two values is relatively low, respectively 0.114 and 0.142 meters. This depends on the steepness of the CDF and is thus directly related to the properties of the response spectrum. It should be noted that the response spectrum will be different for every wave heading, ship motion direction, and sea state. Therefore, the MPM and MPE values of other cases might be further apart, and when interpreting the results, it is important to keep in mind that the results are based on statistics and larger responses could occur. Thus, for this research, the decision was made to calculate the MPE ( $\alpha = 0.01$ ) responses, representing a more conservative approach. The calculation of MPE response values is executed for every wave heading. Ultimately, the MPE responses across the three directions (x,y,z) for all wave headings are determined. With these results, the worst MPE responses across the longitudinal, transverse, and vertical direction can be determined for every ship configuration.

### Validation of the module

To validate the output of the seakeeping module, the worst local MPE motion responses were calculated for an UDSBV design. These results were compared to the results from HAS under the same conditions as used in the module. The results were calculated for two different loading conditions, at both the assembly and installation position of the turbines, and for different sea states. Also, the validation was conducted for both a weathervaning and omnidirectional condition. The results demonstrated that the local MPE displacement of the two methods are comparable and within the same order of magnitude in the weathervaning condition. One of the validations, for  $T_p=6.2s$  is shown in Table 6.

**Table 6: Validation of weathervaning MPE motion-induced displacements from the seakeeping analysis module (SAM) with hydrodynamic analysis software (HAS).**

		Most probable extreme					
		Fully-loaded			Lifting last turbine		
Position	Method	Long. disp. [m]	Trans. disp. [m]	Vert. disp. [m]	Long. disp. [m]	Trans. disp. [m]	Vert. disp. [m]
Assembly location	HAS	0.77	0.15	0.26	0.94	0.25	0.32
	SAM	0.74	0.22	0.21	0.74	0.27	0.21
	Error	-4%	44%	-21%	-21%	10%	-33%
Installation location	HAS	0.84	0.15	0.27	1.01	0.25	0.32
	SAM	0.74	0.22	0.23	0.74	0.27	0.25
	Error	-11%	44%	-14%	-26%	10%	-24%

However, minor differences were observed, especially in longitudinal motion direction. This is likely because the simplified method does not consider coupling effects between motions and probably the omission of three of the six RAOs

does play a minor role. However, for the purpose of this research, the outcomes of the new module are considered acceptable. The validation of the omnidirectional condition showed that this method cannot be used for this type of environment. This is mainly a result of the large discrepancies in the RAOs in beam seas.

### Wind turbine mission module

The wind turbine mission module connects the wind turbine market within Blended Design with the ship configurations. The module determines the feasible number of turbines that can be transported and installed by each ship configurations. Given the diversity of turbine sizes in a market, this calculation is performed for every possible turbine size. The number of turbines is dependent on multiple constraints. The module calculates the number of turbines a ship configuration can carry for each of the constraints and then identifies the limiting factor that yields the smallest number of turbines that can be transported and installed. This procedure is depicted in Equation 3.

$$N = \min\{N_{CC}, N_A, N_{DWT}, N_{tot,tr}, N_{tot,lift}\} \quad [3]$$

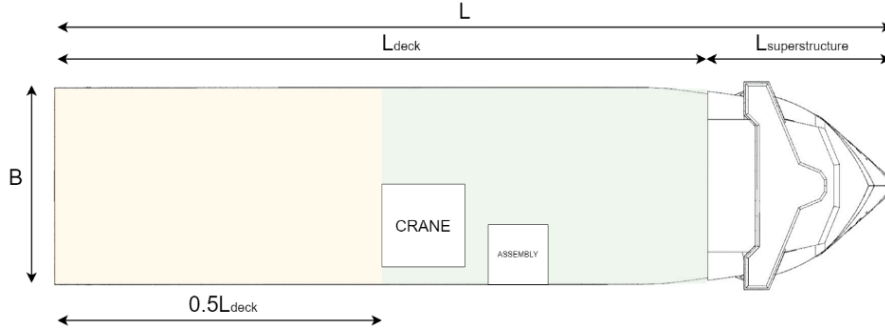

### Crane capacity constraint

The crane capacity of a ship configuration determines the maximum turbine weight that can be lifted, (see Equation 4).

$$N_{cc} = \begin{cases} \infty, & \text{if } m_{WTG} < \text{crane capacity} \\ 0, & \text{else} \end{cases} \quad [4]$$

### Deck area constraint

The number of turbines for different sizes, that could fit in the free deck space of a configuration is calculated. For the analysis, the deck area is divided into two parts (see Figure 10). It is assumed that the green area will be reserved for towers and nacelles with hubs. The yellow area, behind the crane, is designated for blade storage. White areas cannot be used.

**Figure 10: Division of deck area.**

The dimensions originate from the results from development package 2. To account for seafastening and ensure sufficient spacing, a margin of 1 meter around the nacelles is assumed. For towers, a square footprint of the tower diameter with an offset of 1 meter on each side is assumed. To account for unused space, a margin of 90 percent is adopted. The number of turbines, with this margin included, was found to better match realistic deck layouts. The number of turbines, based on towers and nacelles fitting in the green area is calculated according to Equation 5.

$$N_{A,1} = 0.9 \cdot A_{deck,green} / [(L_{nacelle} + 2) \cdot (B_{nacelle} + 2) + (D_{tower} + 2)^2] \quad [5]$$

Afterwards, the number of blades that fit within the width of the yellow part is calculated. Blades are assumed to be stacked in blade racks in pairs of three. The algorithm checks whether the width of all blade stacks does not exceed the breadth of the vessel and automatically adjusts the number of turbines if that is the case. This is depicted in Equation 6.

$$N_{A,2} = \begin{cases} B / (B_{blade} + 2), & \text{if } N_{A,1} \cdot (B_{blade} + 2) > B \\ N_{A,1}, & \text{else} \end{cases} \quad [6]$$

Based on the deck layout, blades are assumed to extend over the aft of the vessel. The estimated length that should fit on the length of the yellow part of the deck is set at 60 percent of the total blade length. A check is performed to verify if this requirement is satisfied. A margin of 5 meters between the aft of the crane and blade racks is assumed (Equation 7).

$$N_A = \begin{cases} N_{A,2}, & \text{if } 0.5L_{deck} - 5 \geq 0.6L_{blade} \\ 0, & \text{else} \end{cases} \quad [7]$$

### Deadweight constraint

The third limiting factor is associated with the deadweight available for cargo. The algorithm calculates the maximum number of turbines that can be accommodated within the vessel's deadweight. This calculation assumes that there is no ballast water used. The total mass of a single turbine is defined in Equation 8.

$$m_{WTG} = m_{tower} + m_{nacelle} + m_{hub} + 3 \cdot m_{blade} \quad [8]$$

The number of turbines is calculated using Equation 9. An allowance of 10 percent is assumed for the mass of seafastening.

$$N_{DWT} = DWT / (1.1 \cdot m_{WTG}) \quad [9]$$

#### **Transit and lifting stability constraints**

Blended Design calculates the maximum allowable KG value for both transit and lifting conditions of all ship configurations. Within the turbine mission module, the vertical center of gravity (VCG) for an increasing number of wind turbines of every size in the market simulation is calculated. It then checks if the VCG of the turbines is still below the allowable KG. If not, the vessel will be unstable and not be able to carry that number of wind turbines. The algorithm eventually finds the maximum number of wind turbines for which the KG value is still positive. Ballast water is incorporated in both cases. The VCG of ballast water is a fixed ratio of the depth. The mass of ballast water is calculated following Equation 10.

$$m_{bal} = DWT - N_{WTG} \cdot m_{WTG} \quad [10]$$

The VCG of the turbine components corresponds with the findings from development package 2. To determine the resulting VCG of these components, when they are in storage position on deck during transit, Equation 11 is used.

$$VCG_{comp} = D + \frac{3m_{blade} \cdot 0.5 \cdot 3h_{blade} + m_{tower} \cdot VCG_{tower} + (m_{nacelle} + m_{hub}) \cdot VCG_{nacelle}}{m_{turbine}} \quad [11]$$

The VCG of the deck cargo in transit and lifting condition is then calculated with the following Equations 12 and 13.

$$VCG_{tr} = \frac{VCG_{LSW} \cdot LSW + N_{tot,tr} \cdot VCG_{comp} \cdot m_{WTG} + VCG_{bal} \cdot D \cdot m_{bal,tr}}{\Delta_{tr}} \quad [12]$$

$$VCG_{lift} = \frac{VCG_{LSW} \cdot LSW + (N_{tot,lift} - 1) \cdot VCG_{comp} \cdot m_{WTG} + VCG_{bal} \cdot D \cdot m_{bal,lift} + z_{load} \cdot m_{WTG}}{\Delta_{lift}} \quad [13]$$

#### **Validation**

The module has been validated using a reference vessel from UDSBV. Validation has been performed for 8, 15, and 20 MW turbines. Deck layout drawings were made, and calculations were done to check whether the calculated number of turbines for every constraint for the different turbine sizes matches. The results were found to be the same, so it is assumed that the wind turbine mission module produces sensible results.

## **EVALUATING THE PERFORMANCE OF MOONSHOT**

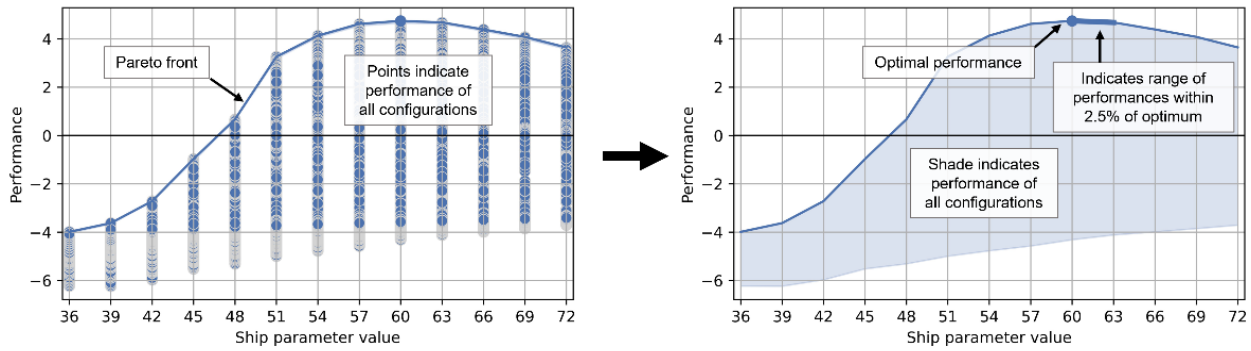

After the new modules were created and adaptations to Blended Design were made, the design space is explored to evaluate the performance of different ship configurations and to elucidate optimal design parameters for next phases of the design. Firstly, a design space was created by varying ship parameters. In total, the design space consisted of 158,340 unique ship configurations, as displayed in Table 7.

**Table 7: The created design space in Blended Design.**

Particular	Start	End	Step size	#
Length [m]	140.0	280.0	5.0	29
Breadth [m]	36.0	72.0	3.0	13
Depth [m]	10.0	19.0	1.0	10
Sailing speed [kn]	10.0	15.0	1.0	6
Crane capacity [t]	1,000	7,000	1,000	7
Block coefficient [-]	0.77	-	-	1
<b>Unique configurations</b>				<b>158,340</b>

The output from Blended Design is visualized in graphs that show the performance of all configurations for a specific ship parameter. A Pareto front is drawn through the best-performing configurations for every parameter. Figure 11 depicts the visualization of the how the resulting graph is constructed and how to interpret it. The optimal range is user-defined and is set to 2.5 percent for this research.

**Figure 11: Visual guide on how to interpret the result plots.**

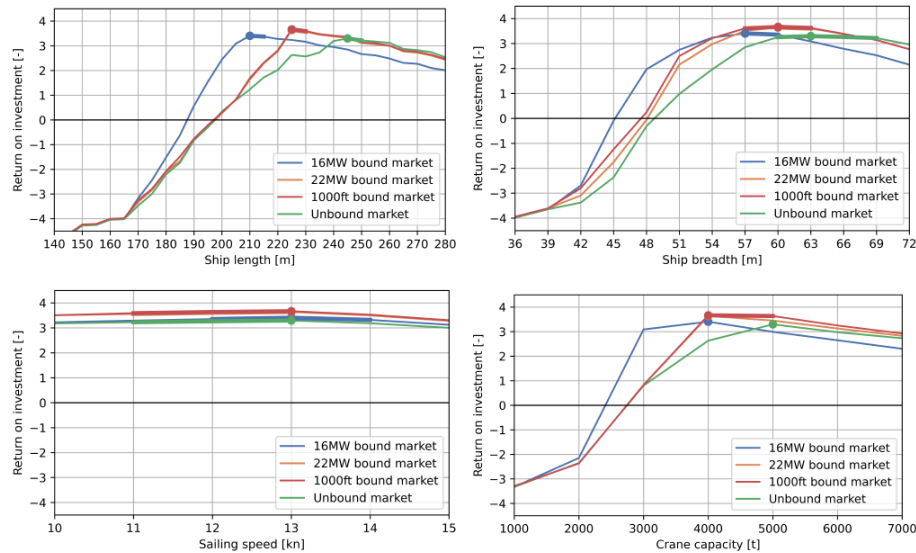

Firstly, the results from the financial performance analysis of all configurations within the design space is discussed. Secondly, the seakeeping performance will be presented.

## Financial performance

The influence of ship parameters on the financial performance has been investigated. Different scenarios have been incorporated in the analysis and optimal design ranges have been determined. The financial performance is measured in return on investment (ROI), which is the ratio between the net profit over the lifetime and the investment costs. The revenue of each ship configuration consists of an installation reward per installed MW. Thus, every vessel will be rewarded for the number of turbines and size of turbines it installs.

### Performance in different market scenarios

Figure 12 presents the financial performance in four different future markets. The unbound market assumes that the turbine growth is not limited. The 16MW bound market assumes that the turbines will not grow beyond the maximum turbine capacity of all offshore wind projects currently in operation, planned or within the Procurement, Construction, and Installation (EPCI) phase. The 1,000 feet bound market assumes that the growth of turbines is restricted to a tip height of 1,000 feet. This scenario has recently been proposed by the Netherlands Wind Energy Association (NWEA) (Rijntalder 2023). The maximum rotor diameter in this case would be around 280 meters (Netherlands Wind Energy Association 2023), which would correspond to a 22MW turbine. Once this capacity is reached, the size of turbine components is assumed to not further increase. Uncertainty in the mass of components is only considered in the third scenario. In the fourth scenario, the market would be bound to 22MW, but uncertainty in both the size and mass properties is considered. The difference in optimal design parameters for different market scenarios is clearly visible.

**Figure 12: Visualization of the results for the four market scenarios.**

### Influence of distance to port

Figure 13 presents the financial results for different distances between the OWFs and marshalling ports. The calculations for the different market scenarios were conducted with a distance of 140 nautical miles (NM). This distance was selected based on insights from literature, as it corresponds to the anticipated maximum distance to shore for future OWFs in 2026 (NORWEP 2022). To explore the impact of varying distance ranges, both shorter and longer distances were included. The short distance of 35 NM is based on current global maximum distances from (NORWEP 2022). The long distance is ten times that distance. The distance to port effects the ROI of different configurations. This is mainly due to the increasing

sailing distance, decreasing the number of turbines that can be installed. Larger vessels perform better as distance increases, which can be attributed to the increased cargo capacity, ensuring that they can take more turbines per roundtrip. The optimal sailing speed is the same for all distances, but the optimal range narrows down as distances increase, favoring faster configurations at large sailing distances.

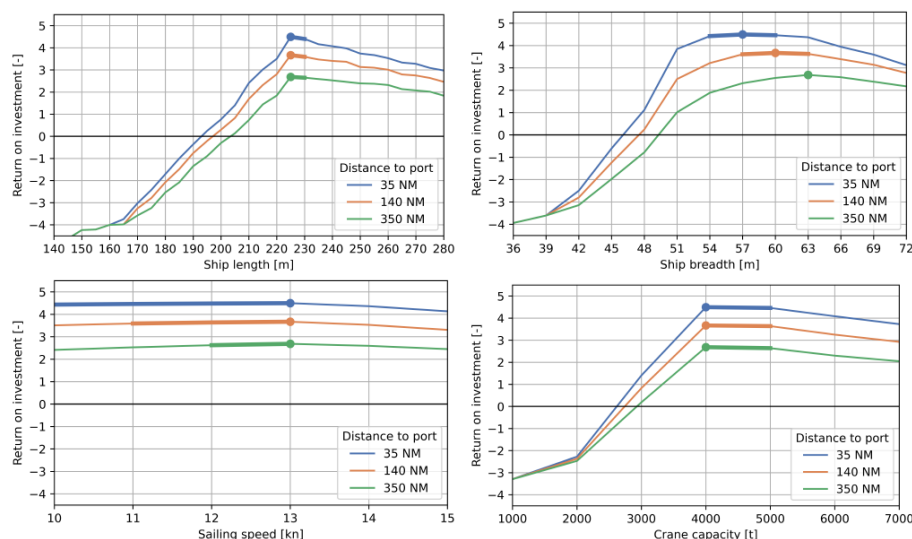

Figure 13: Visualization of the results of a 1,000ft bound market with three distances to port.

#### *Influence of splitting the turbine towers*

The turbine towers are assumed to be transported vertically and as one part. The towers are very heavy and tall, resulting in high VCGs. The number of turbines a ship configuration can transport and install could be constrained by five different limiting factors, including stability. Therefore, an analysis was conducted on the distribution of limiting factors across all feasible ship configuration, to gain insight in what drives the carrying capacity. Figure 14 presents a breakdown of the limiting factors for all feasible ship configuration and a distribution with distinction per turbine size.

Figure 14: Distribution of limiting factors for ship configurations (left) and aggregated per turbine size (right).

In most ship configurations, the limiting factor is the crane capacity. This is because the design space consists of configurations with crane capacities ranging from 1,000 to 7,000. As turbine size increases, crane capacity becomes more limiting. After that, deck area and lifting stability are the most limiting constraints. The fact that many configurations is limited by lifting stability, indicates that the deck area or deadweight, and thus the full potential of a lot of ship configurations is not completely used. The main reason why lifting stability is limiting in a lot of configurations is because of the high VCG of the turbine towers.

This led to investigating the effects of transporting the turbine towers as two smaller parts, rather than one large components. Splitting the towers in two parts would benefit the overall VCG of the turbine components. On the other hand, more deck area would be needed to transport one tower and more lifts would have to be performed when loading and installing the towers, doubling loading and installation times for tower parts. Figure 15 depicts how the limiting factors are distributed across the carrying capacity of all feasible ship configurations when the towers are transported as two parts.

**Figure 15: Distribution of limiting factors for ship configurations (left) and aggregated per turbine size (right) with towers transported as two parts.**

As shown in the figures above, the lifting stability constraint is a less dominant limiting factor for the carrying capacity of wind turbines. The share of the deck area limiting factor among all configurations has significantly been increased. This shift suggests that the carrying capacity of the ships is used more efficiently. The difference in carrying capacity when the tower is divided into two parts, for one of the configurations in the design space is visualized in Figure 16. The two plots depict the number of turbines that can be transported according to the five constraints for every turbine size. It also shows the main limiting factor for every turbine size and the resulting capacity.

**Figure 16: Visualization of limiting factors and number of turbines for the two tower strategies.**

To assess the benefits of the transportation strategy, a financial performance analysis was conducted. The goal is to determine whether the advantages of transporting the towers as two parts outweighs the negative consequences. The financial performance is depicted in Figure 17. As visible, the ROI of all configurations is lower when the towers are divided into two parts instead of being transported as single components with a high VCG. Therefore, it can be concluded that there is no financial benefit in carrying the towers as two parts.

**Figure 17: Visualization of the results for two different tower transportation strategies in a 1,000ft bound market. The distance to port is 140 NM.**

## Seakeeping performance

The influence of various ship parameters will be investigated, and optimal design configurations will be determined for best seakeeping performance. The calculations have been performed for a significant wave height of 2.5 meters. The performance is measured in local MPE responses, as explained earlier. The lower the responses, the better. The local responses are calculated at the hub height of the largest turbine a ship configuration can possibly transport and install during its lifetime. This is during offshore operations, so when the vessel is station keeping. The ship is assumed to weathervane, meaning that it is allowed to align the bow with the incoming environment. This improves seakeeping and reduces the power required for dynamic positioning. While weathervaning, the environment is assumed to be at 180 degrees with an offset of 30 degrees to both sides, as visualized in Figure 18.

**Figure 18: Wave headings during weathervaning with an allowed offset of  $\pm 30$  degrees.**

### *Weathervaning displacements*

Figure 19 shows the MPE motion-induced displacements in each of the three motion directions for different ship parameters. The results reveal that the longitudinal motion response is most dominant. This can be attributed to the environment while weathervaning, where waves are primarily coming in at the bow of the vessel. The main contributor to the longitudinal response is the pitch motion, which is lower for increasing ship lengths. Increasing the breadth does not really influence the MPE motion responses. In transverse direction, the main contributor to the motion displacement is the roll motion. However, roll motion is quite low due to the weathervaning and the used method for determining the RAOs. The used method neglects coupling effect between motions, disregarding for example roll motion due to pitch. Regarding vertical direction, the foremost contributor to the motion displacement is the heave motion in combination with pitch and roll. The results show that the vertical motion decreases for longer ships. This could be because the heave motion RAO shift to lower wave frequencies for longer ship. This results in lower RAO values at the same wave frequency for longer ships. When looking at breadth, relatively constant lines are observed. This is because heave motion is not significantly influenced by ship breadth with the used calculation method. In addition, due to decoupled motions and the weathervaning, the roll motion is also very little influenced by increased breadth.

The influence of depth on the motion behavior of configurations is not straightforward. As depth increases, so does the maximum draft of a configuration, leading to an increase in displacement, which affects the motion behavior. However, an increase in draft leads to a decrease in sectional hydrodynamic damping ( $A$ ) and the Smith correction factor ( $\kappa$ ) in the method from (Jensen, et al 2004), influencing the forcing functions for heave ( $F_3$ ) and pitch ( $F_5$ ), subsequently affecting heave and pitch RAOs. Additionally, increasing depth and draft affect stability in several ways. Draft affects the  $GM_T$  value of a ship configuration, impacting stability and the behavior of the roll RAO. An increase in depth at the same breadth reduces the B/D ratio, crucial for establishing the GZ curve, which determines the transverse stability. Stability influences the maximum turbine size the configurations can transport and install and, consequently, dictating point P in which local responses are calculated. In general, increasing depth results in decreased MPE motion displacement in all directions, as reflected in Figure 19.

Crane capacity has limited influence on motion behavior. The lines for all three directions remain relatively constant because the best ship configurations with optimal motion behavior are independent of crane capacity. For instance, the 'best' configurations for longitudinal motions have low to moderate breadth and the highest depth, providing the best motion behavior in the longitudinal direction. But due to their low B/D ratio resulting from the combination of breadth and depth, their stability is typically poorer, limiting their ability to handle larger turbine sizes in the market. For these smaller sizes, the point P where motions are calculated is closer to the CoG of the vessel, resulting in lower longitudinal motions.

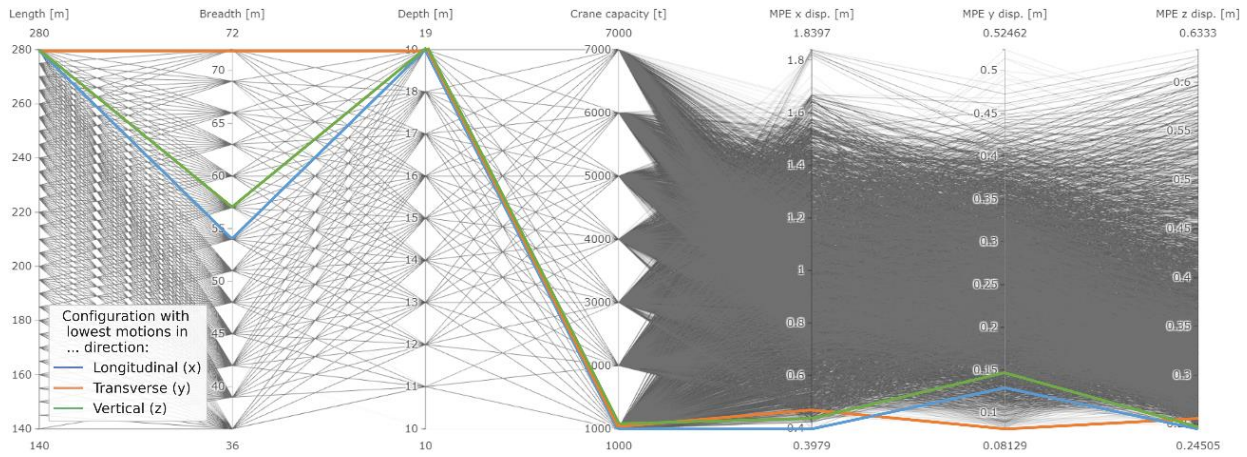

**Figure 19: Wave headings during weathervaning with an allowed offset of  $\pm 30$  degrees.**

The model behavior explained above is not the most elegant way to design a vessel, but the model does achieve the objective of finding the configurations with the best seakeeping behavior. This model behavior, while effective, can be considered undesired and should be considered when evaluating motion behavior or optimizing a vessel on motion performance.

Figure 20 presents a parallel coordinates plot of the motion performance. The plot shows all possible configurations with their MPE motion responses in all three directions. Three combinations of ship parameters have been highlighted. These three configurations would have the lowest MPE displacement for one of the three directions. These three optimal ships would be very large, with the smallest crane possible. The model selects these configurations as the best one, because it can only lift the smallest turbines, with point P for motion calculation closest to the CoG of the vessel. Considering the findings from financial performance and the best configuration in terms of motion performance, a large gap between the best ship configuration for Moonshot is found. This gap will be addressed later.

**Figure 20: Parallel coordinates plot of motion performance.**

### ***Weathervaning accelerations***

The accelerations during weathervaning have also been evaluated. Just as the MPE displacements, the MPE accelerations were also calculated in point P for the three directions. These three components were then translated to a resultant MPE acceleration vector using Equation 14.

$$MPE \ a = \sqrt{(MPE \ a_x)^2 + (MPE \ a_y)^2 + (MPE \ a_z)^2} \quad [14]$$

Figure 21 depicts the resulting MPE acceleration vector in relation to displacement of all configurations. To prevent damage to wind turbines, suppliers prescribe limits on acceleration in the nacelle during T&I. The acceleration limit is typically  $0.5g$  ( $\sim 4.9 \text{ m/s}^2$ ) (BVG Associates 2019). As demonstrated in the figure, the local MPE acceleration for all configurations remains well below this specified limit. Consequently, accelerations in the nacelle are not deemed to be a major concern.

**Figure 21: Visualization of the MPE acceleration vector results.**

## Combining seakeeping and financial performance

As previously highlighted, conflicting optimal ship configurations emerge when optimizing for either financial performance or seakeeping performance. To reconcile this discrepancy between the two objectives, a financial penalty will be imposed on configurations exhibiting inferior seakeeping behavior. This penalty will be in the form of an added cost for motion compensation, which is a supplement to the base cost for the main crane. The unit of this metric is €/t.m), encompassing both the crane capacity and the cumulative MPE displacement in longitudinal, transverse, and vertical direction, measured in meters. While the metric might not be documented in existing literature, it aligns well with practical considerations. It is reasonable to expect that cost of lifting equipment would increase with increasing motion compensation requirements. Moreover, the inclusion of crane capacity in the metric is also logical, as a motion compensation system for higher crane capacity would likely be more complex and larger, inherently being more expensive.

As this metric is not documented in existing literature, there is no reference for quantifying the cost of motion compensation. Consequently, a range with different cost levels has been assumed. This range spans from €0 to €10,000/(t.m). The resulting ROI for these different cost levels is depicted for different ship parameters in Figure 22. As displayed, the ROI decreases for increasing cost levels for motion compensation. What stands out, is that the optimum for length shifts to longer configurations. This indicates that at a certain point, the higher cost of investing in and operating a longer ship surpasses the increased cost for motion compensation of shorter vessels.

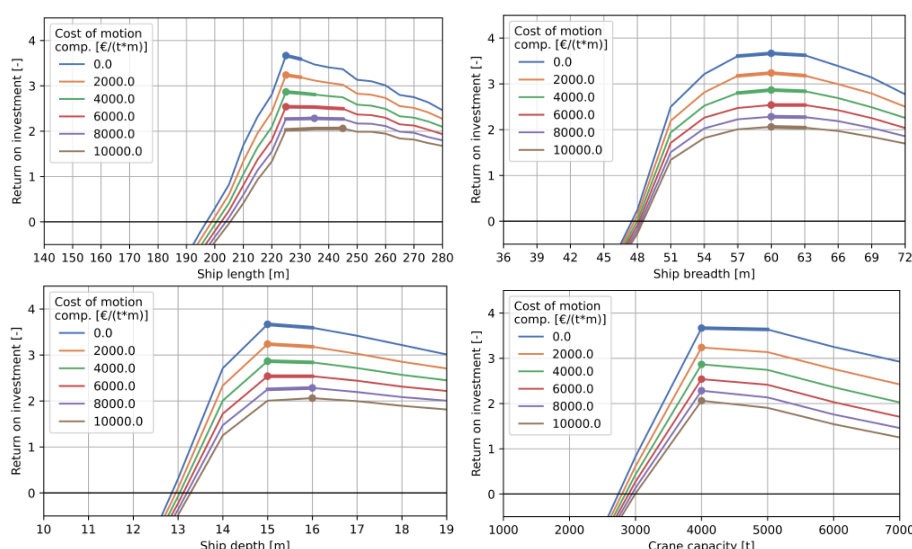

Figure 22: Visualization of the financial results with motion performance penalty in a 1,000ft bound market with an operational  $H_s$  limit of 2.5 meters.

## Optimal design ranges for Moonshot

Considering all findings, optimum design ranges for the ship have been established. These findings for different scenarios are summarized in Table 8. The initial design parameters can be chosen according to client preferences or based on a designer's perspective. The initial design parameters, as chosen by the author, are displayed in the last row of the table.

Table 8: Summary of optimal design parameters for Moonshot.

Scenario	Length [m]	Breadth [m]	Depth [m]	Sailing speed [kn]	Crane capacity [t]
<b>Financial performance</b>					
16MW bound market	210-215	57-60	14-15	12-14	4,000
22MW bound market	225-230	60-63	15	11-13	4,000
1,000ft bound market	225-230	57-63	15-16	11-13	4,000-5,000
Unbound market	245-250	60-69	16-17	11-13	5,000
<b>Distance to port<sup>+</sup></b>					
35 NM	225-230	54-60	15	10-13	4,000-5,000
140 NM	225-230	57-63	15-16	11-13	4,000-5,000
350 NM	225-230	63	16	12-13	4,000-5,000
<b>Seakeeping performance<sup>*,*</sup></b>					
Weathervaning x-displacement	280	54	19	11-13	1,000
Weathervaning y-displacement	280	72	19	11-13	1,000
Weathervaning z-displacement	280	57	19	11-13	1,000
<b>Motion compensation<sup>*,*</sup></b>					
€2,000/(t.m)	225-230	57-63	15-16	11-13	4,000
€6,000/(t.m)	225-245	60-63	15-16	11-13	4,000
€10,000/(t.m)	225-245	60-63	16	11-13	4,000
<b>Initial design parameters</b>	<b>230</b>	<b>63</b>	<b>16</b>	<b>12</b>	<b>4,000</b>

\* in a 1,000ft bound market with a 140 NM distance between port and OWF. ° for a maximum significant wave height of 2.5 meters. + in a 1,000ft bound market scenario.

## BENCHMARKING THE DESIGN

Previous results indicate that the Moonshot could be a viable alternative for offshore wind turbine installation. However, the question arises whether it measures up against existing technologies. To benchmark, a version of Moonshot has been designed to directly compete with the largest jack-up design in the market, the NG-20000X (GustoMSC n.d.). This jack-up has a capacity of four 20 MW turbines (4C Offshore n.d.). Blended Design has been used to explore the design space and determine the ship parameters for the direct competitor, the 20MW Moonshot. This Moonshot concept is designed to operate in a market with only 20 MW turbines for only one year. 1,532,160 ship configurations were investigated. Firstly, optimal design ranges were determined with cost for motion compensation levels of €0 to €10,000/(t·m). The actual cost would probably be somewhere in that range. The results are shown in Figure 23.

**Figure 23: Visualization of the financial performance results for the 20MW Moonshot.**

The optimal design ranges reveal an overlap when looking at the two different cost levels. An optimal displacement for both cost levels can be found around 70,000 tonnes. Following a slightly different approach then earlier, the displacement will be fixed at this value to find the optimal ship parameters for best seakeeping performance within this displacement. The results from this analysis are shown in Figure 24. Based on the results from both the financial and seakeeping performance, an optimal configuration can be selected.

**Figure 24: Visualization of the seakeeping performance results for the 20MW Moonshot with a fixed displacement.**

After selecting the optimal configuration for the 20MW Moonshot, the day rate, number of installed turbines per year, and the cost per installed MW were extracted from Blended Design. The same metrics were calculated for the NG-20000X jack up, an SSCV, and Huisman's windfarm installation vessel concept. The number of turbines installed per year for those

solutions was determined based on estimated cycle times of the operational cycles. With an assumed day rate, derived from literature or internal knowledge at UDSBV, the cost per installed MW was calculated. These values were then compared to the installation cost per MW of the 20 MW Moonshot.

**Table 9: Comparison of different installation solutions to benchmark Moonshot.**

Parameter	NG-20000X	SSCV	Huisman's WIV concept	20 MW Moonshot
Sailing speed [kn]	11	10	12	13
Cargo capacity (20 MW turbines) [-]	4	-	-	5
Workability [-]	0.6	0.6 <sup>+</sup>	0.6 <sup>+</sup>	0.78
Day rate installation vessel [€/day]	375,000	750,000	750,000	260,000*
Day rate feeder vessels [€/day]	-	2x 50,000	2x 50,000	-
Day rate harbour crane [€/day]	-	32,000	32,000	-
Installed turbines per year [-]	110	165	179	180
Cost per installed MW [€/MW]	50,900	80,100	73,900	21,500*

\* Profit margins are not reflected in the day rates and installation cost per MW of Moonshot, whereas in the others it is included.

<sup>+</sup> Actual workability of the installation vessels is higher. However, it is assumed that the workability is dictated by the offshore transfer from the feeder barges or vessels.

The benchmarking revealed that Moonshot is a more efficient and cost-effective solution, capable of installing a larger number of turbines per year at a considerably lower cost per MW compared to other solutions. The results of the benchmarking show the potential of Moonshot in comparison to other solutions as a competitive and cost-efficient offshore wind turbine installation solution. Above all, since Moonshot is a floating solution and has no interaction with the seabed, it would remain feasible in areas where jack-up vessels might no longer be feasible in the future. Overall, these findings underscore the cost-effectiveness and competitive advantage of the Moonshot concept in the offshore wind industry, positioning it as a promising solution for the evolving demands of the sector.

## CONCLUSIONS

This paper introduced a novel installation solution for offshore wind turbine installation, named Moonshot. The development process involved a combination of UDSBV's Controlled Innovation and Blended Design. With Controlled Innovation functions and design aspects were identified. An evaluation of design aspects revealed the ones that required special attention. These included the choice of lifting equipment, size and mass properties of wind turbine components, and the deck layout. Since Moonshot is a monohull solution that will install turbines while afloat, it would be more susceptible to waves than other existing WTIVs. Therefore, seakeeping assessment is deemed to be important. Modifications to the Blended Design model were made to accommodate Moonshot's unique characteristics and to assess seakeeping performance. With Blended Design, different scenarios were analyzed on both financial and seakeeping performance to explore the design space of Moonshot and elucidate optimal design parameters. The results revealed a disparity when optimizing for financial or seakeeping performance. To balance these factors, a penalty mechanism was introduced, resulting in new optimal ship configurations. Furthermore, Moonshot was benchmarked against other wind turbine solutions, such as jack-ups and SSCVs. Blended Design was used to determine optimal design parameters for a direct competitor. Then, the cost per MW of the other solutions was compared to the optimal 20 MW Moonshot. The comparison showed that Moonshot could be a viable alternative in the offshore wind turbine installation sector.

## CONTRIBUTION STATEMENT

**J.J. de Ridder:** Conceptualization; formal analysis; investigation; methodology; project administration; validation; visualization; writing – original draft. **J.D. Stroo:** Conceptualization; resources; supervision; writing – review and editing. **A.A. Kana:** Conceptualization; supervision; writing – review and editing.

## ACKNOWLEDGEMENTS

This work was performed as part of the MSc thesis for the lead author, (de Ridder 2023). The thesis was performed in Marine Technology at Delft University of Technology and the authors would like to acknowledge both Delft University of Technology and Ulstein Design and Solutions B.V. for their support of this research.
