# Digital Sailmate: Enhancing Safety through Low-Cost Stability Monitoring in Artisanal Fishing

Nathan Manojlovic Smith<sup>1\*</sup>, Priscila Melo<sup>1</sup> and Simon Benson<sup>1</sup>

## ABSTRACT

*Despite overall mortality decreasing, offshore fishing remains one of the riskiest work-based activities worldwide. For example, fishing communities in East Africa have a 43-fold higher rate of drowning than the general population. A lack of safety culture and knowledge around vessel stability contributes to this issue. Formal safety measures can be difficult to enforce, especially in small scale and subsistence fishing activities dominated by small artisanal boats. Digital technologies hold potential to effectively improve fishing safety. A digital safety device based on commonly held and relatively low-cost consumer products such as smartphones can provide increasing information to fishers enabling more informed safety decisions to be taken during vessel use. This paper proposes the algorithms for a prototype device to monitor stability of fishing vessels, with focus on the capabilities of low-fidelity data in stability assessment. The findings of experimental results at model and full scale are presented. The research indicates that an inclining test can be carried out with minimal training or knowledge base to allow an adequate stability assessment of a vessel before departure on a fishing trip. This baseline measure can then be used to track stability whilst underway as vessel motion is recorded and processed continually updating the stability assessment.*

## KEY WORDS

Safety; Fishing vessels; Digital Technology; Stability; Accessibility.

## INTRODUCTION

Globally, offshore fishing remains one of the most dangerous occupations (Jensen et al., 2014; Roberts et al., 2021; Womack, 2003) and is especially hazardous for artisanal fishers in low- and middle-income countries (LMICs). Willis et al. (2023) estimate the global mortality rate at over 100,000 fishers a year. Insufficient vessel stability, leading to capsizing, is a key aspect of this safety crisis. This research proposes that providing more information about the stability condition of a vessel enables fishers to make more informed decisions on operational safety. This information can be collected, analysed, and then communicated to fishers via a low-cost digital device that measures and monitors vessel stability.

The paper links the problem of fishing boat safety due to loss in stability to the opportunity that low-cost consumer level digital technology provides. The premise of this research is that low fidelity data may be used for stability assessment in a low-cost system. The focus of the paper is the initial testing of a prototype device with the ability to both measure stability in a controlled procedure and monitor vessel stability during normal operations.

The case study for this project investigates artisanal fishing vessels in East Africa. Tests are carried out in two environments, model scale testing in laboratory wave tanks and a full-scale pilot study on a fishing boat in a harbour. The model scale tests demonstrate some of the difficulties in applying a sensor to measure the underlying natural roll period of a vessel in a discrete frequency wave train such as is generated in a smaller wave tank. The full-scale study demonstrates improved results from real wave environments and suggests the applicability of the approach to develop a full featured safety application.

## BACKGROUND

### Fishing Boat Safety

In high-income countries (HICs) mortality rates of fishers are over 100 per 100,000 fisher-years (Sindall et al., 2022). Mortality rates in low- and middle-income countries (LMICs) are not as well documented and are estimated to range from 2 to 5 times more than the mortality in HICs (Sindall et al., 2022). Regardless of the economic development of the country, in both LMICs and HICs most deaths are associated with capsizing of boats, due to bad weather conditions or economic pressures resulting in fishers overloading vessels or going out in conditions unsuitable for their vessels (Sindall et al., 2022).

This study focuses on Kenya as a case study location. The fishing industry in Kenya employs over 60,000 fishers directly and 1.2 million indirectly through fishing, production, and supply chains. The areas of fish production in Kenya are the coast and open sea, freshwater lakes, such as Lake Victoria, rivers, and man-made dams. Across the country, use of traditional canoes, small dhows (*mashua*) and outriggers dominates, with less than 10% of these being motorised (Kimani et al., 2018). Examples of these vessels can be seen in Figure 1.

**Figure 1: Typical Artisanal Vessels. Mid-size dhows (top left, bottom left), large sailing dhow (top right), small canoe (bottom right)**

There is a lack of data on drowning fatalities in East Africa, especially among coastal communities with many studies based around Lake Victoria. There have been several studies into the epidemiology of drowning around Lake Victoria, using techniques such as verbal autopsies (Opemo et al., 2014). Such techniques can be difficult to scale up from communities to a regional level and there remains a lack of official figures. Fishing communities in East Africa were found to be at a higher risk of drowning with a 43-fold higher incidence of drowning than in the general population (Whitworth et al., 2019), which was mostly associated to the lack of safety equipment such as life jackets (97% of cases) and the inability to swim. Many of these cases were likely initiated by a capsizing or other stability driven event.

The annual estimated number of deaths on Lake Victoria has been reducing from between 3000 and 5000 in 2014 (International Federation of Red Cross and Red Crescent Societies, 2014) to around 1500 in 2020 (Watkiss et al., 2020).

The reduction was mostly attributed to greater use of life jackets and a trend for larger boats. Although it is not known how many boats capsize due to loss of stability, around two thirds of drowning deaths a year can be attributed to the weather conditions (Watkiss et al., 2020).

## Stability Challenges

The risks within fishing which can lead to drowning include combinations of human and physical factors. One fundamental risk is that the boat is compromised during fishing operations through capsize or damage, thereby putting the crew at risk of entering the water. Stability can change quickly during onboarding of a catch bringing extra weight into the boat and moving the centre of gravity upwards. Associated risks around swimming ability and the lack of personal flotation devices means that capsize is a significant risk factor for drowning. Measures to improve the stability characteristics of fishing vessels can therefore reduce drowning risks.

Stability related accidents have the most casualties as they often happen suddenly meaning crew cannot access safety devices such as lifejackets. For this reason, it is important that vessels have their stability conditions assessed before coming up against potentially dangerous conditions. Vessels under 24 metres have a much higher rate of accidents caused by stability conditions than larger vessels which are generally better equipped to deal with adverse conditions due to the size of the vessel and crew training. Although crews of small and medium vessels can assess the stability of the vessel, this is in most cases based off previous experience and it may be difficult to assess a reduction in stability (Míguez González et al., 2012).

The most common issues on fishing vessels that lead to stability problems are changes in weight distribution, operational situations, weather situations and dynamic instabilities (Míguez González et al., 2012).

- **Changes in weight distribution** leading to change of location of centre of gravity. This can be from changes in structure, equipment or the use of spaces that are not tracked and recalculated leading to potentially dangerous loading conditions. This may include changes in ballasting and any modifications made to vessels.
- **Operational situations** such as inappropriate or overloading the vessel, raising the centre of gravity. Additionally suspended loads or fishing gear may change stability conditions particularly in the case of nets grounding the will cause loss of stern freeboard.
- **Weather situations** such as water intake in heavy rains – especially relevant on small open vessels. Breaking waves are particularly dangerous in beam seas, and high winds will create greater heel angles which in both cases vessels with a reduced stability condition will be more susceptible to capsize.
- **Dynamic instabilities** related to the interaction of the vessel underway and waves such as parametric resonance where the vessel will experience high amplitude rolling motions, losses of stability or steering capacity due to sailing in following seas or quartering seas.

## Digital Safety Devices

Digital devices with safety features for personal use are becoming increasingly prevalent, such as sensors in smartwatches able to contact emergency services after a fall is detected. Decreasing cost and increasing sophistication has allowed development of technologies integrating into workplaces and everyday life. Access to technology such as smartphones is now prevalent in LMICs and presents opportunities to develop safety features useful for hazardous activities such as fishing.

Access to mobile phones is increasing in Kenya, with 94.6% of the population owning or having access to a SIM card, (Van Hove & Dubus, 2019). The use of smartphones is lower, with 33.9% of the phone owning population having smartphones and 52.8% owning basic phones (text and call features only) (Jelassi & Martínez-López, 2020; Krell et al., 2021; Van Hove & Dubus, 2019). This statistic is likely to increase rapidly as smartphone technology becomes further accepted, especially amongst younger people.

There are several existing technologies to estimate a boat's stability based on gyroscopic motion and baseline information about a vessel. The SKIPPER software gives updating stability condition with risk level for vessel and the maximum recommended wave height. To use the software information about the hull form, tanks and holds, flooding points, decks, minimum freeboard, lightweight and other ship particulars need to be inputted (Míguez González et al., 2012). This makes it effective on industrialised vessels where a stability matrix as seen in Womack (2003) would become too large and complex. Needing a large amount of data about the vessel makes the software more difficult to set up on traditional fishing boats where much of the data needed is unlikely to be known. Building from this paper, the Kora Kora mobile application uses a similar concept focusing on Indonesian fishing vessels (Grech La Rosa et al., 2022). This uses an app to measure roll period to collect data which can be used to provide a measure of vessel stability which is then presented in a traffic light system.

Another study proposed a device to monitor draft and stability from a vessel rolling motion, this found the current waterline of the vessel through the roll motion then made use of the displacement-draught curve to find total displacement. When a given limit is reached the device detects this and alert the crew (Sakib, 2015). This method requires a displacement -draught curve for the vessel which is not a realistic prerequisite for artisanal vessels in LMICs. The existence of these technologies show the potential for linking the issue of fishing boat safety due to the loss in stability with the opportunity presented by low-cost consumer level digital technology.

## METHODOLOGY

### Approach

The core principle of this research is that a vessel's roll motion, measured by a gyroscope, can be directly linked to vessel stability through the estimation of the metacentric height. This link, which is an established naval architecture technique, is explained in the following subsections. The novelty within this research is to apply this technique using a low-cost consumer device such as a smartphone, single board microcontroller or computer, and without the direct intervention of a stability expert. The device will give fishers an insight into the stability condition of the vessel allowing them to visualise significant changes in stability and make more informed decisions during operations.

The device requires capability to monitor motions for three types of tests:

- **Inclining Test:** A well established and widely used method for finding vessel metacentric height (GM). Found by moving weights to create heel angles and recording the angle change.
- **Roll Test:** Commonly only used on smaller vessels such as fishing vessels. A heel angle is created, and the vessel then allowed to oscillate. Generally considered less accurate than the inclining test but can be more accessible in a practical environment.
- **Continuous Monitoring:** Using the same principles as the roll test, a device can continuously measure the roll period and provide an immediate estimate of a vessel's stability condition.

In this paper a device, detailed below, is tested at two scales and locations. Firstly, a series of model scale wave tank tests using a 1 metre length model of an artisanal fishing boat, and secondly a full-scale pilot test in a harbour using a 5 metre length open deck fishing boat. Further tests will be undertaken on typical artisanal fishing boats in Kenya but are not reported in this paper.

### Stability Tests

#### *Principles.*

The metacentric height, GM, is a measure of static stability on a floating object. It defines the distance between the object's centre of gravity and the stability position known as the metacentre. When GM is greater than zero a boat is considered stable, meaning it will return to its upright equilibrium position. Maintaining sufficient positive GM, also to account for dynamic effects, is an important criterion for vessel safety. For larger ships GM is part of a regulated stability assessment which accounts for different loading conditions, damage, dynamic effects, and additional aspects such as wind loading. For smaller boats, especially in LMIC settings, assessing GM may not be a regulatory requirement, but it still provides a fundamental practical measure of stability and motion behaviour.

A larger GM gives more initial stability but also a shorter roll period (Biran, 2003), commonly known as being stiff. Conversely a lower GM causes the vessel to roll more slowly, known as being tender. For a vessel to be considered safe the GM needs to be positive with margins depending on boat type and operational area. The requirements for measuring GM depend on the boat type and the country it is operating in.

For example, the Maritime and Coastguard Agency in the United Kingdom issue guidance for fishing vessels under 15 metres registered length. The guidance advises exciting the vessel externally using a rope, once the vessel is rolling sufficiently the motion is allowed to decay and the average time of each oscillation is taken and is compared to the beam of the vessel to determine its safety (Maritime & Coastguard Agency, 2022).

#### *Inclining test.*

The inclining test is a well-established and widely used method to find GM for a vessel in its 'as built' condition and whilst in service. This is essential for ships to meet regulatory stability criteria. The test is conducted by moving known weights a given distance across the ship to create a small angle of heel. The angle of heel is found by recording the position of a pendulum or angle meter before and after the weight is moved. This can then be fed into an equation to find GM for small

angles of heel. This method will be used to find GM using the inclining test feature of the device. The GM can then be used to validate results and compare accuracy during further testing.

### ***Roll test.***

The roll period stability test is performed by creating a heel angle on a vessel and allowing oscillation at the natural roll frequency. On small vessels this is done by the crew moving to one side of the vessel to induce the heel angle and then moving back to the centre line to allow the vessel to oscillate or by using a rope to induce a roll motion. From this the roll period is measured and GM can be estimated. This is generally a less accurate measure of GM than the inclining experiment due to the estimation of the roll radius of gyration. However, it is a more accessible method with simpler analysis required to produce a result. For this reason, it is often used for small vessels, particularly fishing vessels (Maritime and Coastguard Agency, 2009).

The Weiss formula (Weiß, 1953, as cited in Kobylinski & Kastner, 2003; Santiago Caamaño et al., 2022; Grech La Rosa et al., 2022) as shown in Equation 1 can be used to find the natural roll frequency,  $\omega_0$  :

$$\omega_0 = \frac{\sqrt{g * GM}}{k_{xx}} \quad [1]$$

Where  $k_{xx}$  = the total roll radius of gyration in meters [m],  $GM$  = metacentric height in meters [m] and  $g$  = acceleration due to gravity  $\left[\frac{m}{s^2}\right]$ .

As seen in Santiago Caamaño et al. (2019) and Grech La Rosa et al. (2022), the roll radius of gyration can be estimated as:

$$k_{xx} = 0.4 * B \quad [2]$$

Where  $B$  = vessel beam in meters [m]. By rearranging for the metacentric height this method enables an immediate estimate of vessel stability in uncontrolled environmental conditions. Therefore, it can potentially be used to predict progressive changes in different settings, such as during operations where the vessel loading condition may change or weather-related instabilities. This technique will form the basis of the prototype algorithm.

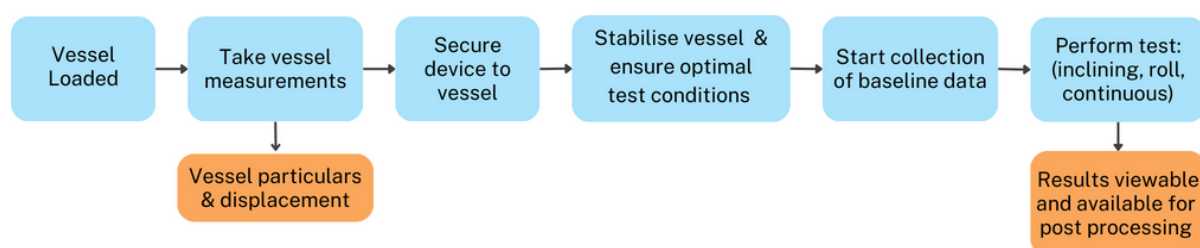

### ***Continuous monitoring.***

The continuous monitoring function uses the same principles as the roll tests but requires a more elaborate data processing approach. As the vessel carries out normal operations the device monitors the roll motion of the vessel. As shown in this study, the estimation of natural roll period from a continuous signal is challenging. It requires an algorithm to find consistent peak frequencies through signal analysis such as Fast Fourier Transform (FFT). The tracking of these peak frequencies over time can then be used to detect significant changes that may occur due to a shift of the centre of gravity, for example in the case of loading a vessel with a catch of fish when out at sea. It is important to detect these changes quickly as when the vessel is suddenly put in adverse conditions the change in stability can rapidly lead to capsize.

## **Experimental Flow**

Figure 2 describes the experimental flow of the prototype device for all three types of stability test (inclining test, roll test and continuous monitoring). The first step is to first ensure the vessel is loaded in its normal operating condition prior to testing. Then the appropriate measurements of the vessel are taken to estimate displacement. The prototype is securely fastened to the vessel on a flat surface with the gyroscope appropriately aligned to the centreline of the vessel. The vessel is allowed to settle before testing begins and ideally weather conditions should be calm. Baseline motion data is collected to allow the device to calibrate itself. One or more of the three tests is then performed. The output can then be immediately used, for example to provide an alert. It is also saved for later analysis.

**Figure 2: Experimental Flowchart**

## The Device

To measure roll motion on a vessel using a low-cost system operated by the fisher, a device with the following criteria is needed (Table 1):

**Table 1: Device Requirements and Capabilities**

Requirement Description	Requirement value	Prototype Device Specification
Measurements	Gyroscope to measure roll motion	MPU-6050 Accelerometer and Gyroscope
Cost	Low	Approx. £70 - £150, dependant on setup (addition of screen, fans etc.)
Power	< 10W	Variable, with a maximum draw of 6W
Sample rate	Adjustable, with capability of at least 100 Hz sample rate.	Sample rate set in algorithm. Capable of 1kHz sample rate.
Timescales	Storage capacity for several days of continuous measurement	32GB SD card capable of storing raw data for over 100 days of continuous running.
Size	Portable and small. Larger devices should have a carry case with handle.	157 x 82 x 41 mm in case without screen (no handle) 270 x 246 x 124 mm in case with screen (with handle)
Scale	Suitable for both model and full-scale measurements.	Yes
Environmental protection	Waterproof case	Hard, buoyant, waterproof case
Battery	Sufficient for 1 day operation on a single charge	2 x 5000mAh will power Pi for up to 19 hours

The ambition of the present study is to apply the experimental flow on a cross platform smartphone app. However, this adds layers of unnecessary complexity in the initial prototyping stages. Therefore the prototype device is based on a Raspberry Pi single board microcomputer. The advantages to choosing this device are that it is easily accessible, simple to use, robust and low cost. Additionally, it is capable of both collecting and processing large datasets on the same device. It comes set up with an operating system (OS) and graphical user interface (GUI) making the initial set up of the device simple.

The Raspberry Pi is coupled with an MPU-6050 accelerometer and gyroscope unit, a low-cost sensor capable of measuring angular acceleration and rotation around 6 axes. The MPU-6050 is a Micro-Electro-Mechanical Systems (MEMS) module, the angle data produced by the unit may be considered low fidelity data, similar to that produced by a mobile phone. The Raspberry Pi is fixed within a waterproof case with the gyroscope fixed to the Pi alongside a battery and a charging cable.

To complete the experimental flow, shown in Figure 2, data is collected from the device and converted into degrees, then is filtered to remove noise and extreme values. The clean data is then ready for Fast Fourier Transform (FFT) analysis of the signal. The Fourier transform converts a signal from the time domain to the frequency domain enabling detection of the underlying natural roll period of the vessel.

## Model Tests

Initial testing of the device was applied on a model scale fishing boat. It was considered important to test on a model relevant to the case study in East Africa so that the algorithm can be better tuned to the characteristics for these hull shapes. Vessels in the case study are noticeably different in style to many HIC settings in terms of the hull form shape, the powering (sails, motors etc) and the type of fishing operations (trawling vs line fishing).

The model used was a 20<sup>th</sup> scale model of a proposed 21 metre traditional Kenyan fishing dhow designed by the Flipflop project (Flipflop Project, 2017). The model was 3D printed enabling a lower cost yet accurate representation for stability and motion experiments. The model has a waterline length of 1.064 metres and is ballasted using metal weights fixed to the hull and deck. The vessel particulars are shown below in Table 2.

**Table 2: Model and full-scale particulars**

Vessel Particular	Full-scale	Model-scale
Water Line Length [metres]	21.38	1.064
Beam [metres]	6.75	0.338
Draught Amidships [metres]	2.50	0.125
Volume of Displacement [ <i>metres</i> <sup>3</sup> ]	17.66	0.017

The model has one full wooden deck and a second partial deck at midships to allow for a standardised vertical movement of weights to simulate multiple loading conditions across different tests. Figure 3 shows the 3 different loading conditions relative to each other:

- Low Position: Weight on vessel deck (baseline)
- Mid Position: Weight on top of foam blocks on vessel deck (decreasing value of GM by 2.4%)
- High Position: Weight on top of second deck (decreasing value of GM by 20%)

**Figure 3: Model weight positions: Low (baseline), Mid (+60mm), High (+210mm)**

For each inclining test, it was ensured that the model was in the correct loading condition and all weights were securely fixed. The inclining weights were placed on the deck with the prototype device and an inclinometer. To validate results from the prototype device the inclining tests were initially run both through the prototype and manually using the inclinometer.

Model testing was carried out at Newcastle University across the Wind Wave Current Tank (WWCT) and the Towing Tank (TT) shown in Figure 4, which have the dimensions shown in Table 3:

**Table 3: Testing facilities main parameters.**

Parameter	Towing Tank	Wind Wave Current Tank
Length [metres]	37	11
Width [metres]	3.7	1.8
Water Depth [metres]	1.25	1.0
Wave Period [seconds]	0.5-2.0	0.8-4.0
Wave Height [metres] (period dependant)	0.02-0.12	0.02-0.2

**Figure 4: Model in Testing Facilities, Newcastle University. Wind Wave Current Tank (left), Towing Tank (right)**

## Full-Scale Tests

The vessel used for the full-scale pilot study was an Arran 16 displacement hulled boat, as seen in Figure 5 with particulars shown in Table 4 (Arran Boats, 2023).

**Table 4: Arran 16 Particulars**

Vessel Particular	Value
Length [metres]	4.88
Beam [metres]	1.98
Draft [metres]	0.30

**Figure 5: Arran 16 used for full scale testing.**

The full-scale tests were completed in Beadnell Harbour, Northumberland, UK in August 2023. The vessel was moored at bow and stern. The weather conditions were mild with a gentle breeze and small waves, as can be observed in Figure 5. The tide was continuously coming in during the tests. The boat was set up for deployment of marker buoys and contained several inflatables and anchors. The outboard engine was not fitted.

## RESULTS AND DISCUSSION

The first stage of testing was to complete inclining and roll decay tests for the model in the 3 different loading conditions. This allowed validation for the results from wave testing. The inclining tests and roll tests were repeated before further phases of testing to ensure consistency of positions throughout. The model testing was divided into 2 phases, the first phase tested the device in regular waves using a commercial motion tracking system (Qualisys) as a baseline to investigate the accuracy of motion data collected from the device. The second phase tested the device in irregular waves with the aim of highlighting the natural roll frequency of the model. The final stage of testing presented is a full-scale pilot study, showing the validity of the methodology at full scale.

### Model Scale Inclining Tests

Inclining tests were completed in a small basin using a standard approach. The model was loaded in the three different weight positions as described previously (Figure 3). Four small inclining weights of 200 grams were added and 5 repeats were carried out for each position. The device was used alongside a separate digital inclinometer for validation. The average GM was calculated and is shown in Table 5. The radius of gyration,  $k_{xx}$ , was estimated at 0.135 metres using Equation 2. The values for GM and  $k_{xx}$  were used in Equation 1 to estimate the roll frequency for each weight position.

**Table 5: Inclining Tests and Roll Period**

Weight Position	Displacement [kg]	$k_{xx}$ [mm]	GM from Inclining Test [mm]	Roll Frequency (Estimated) [Hz]	Roll Frequency (Measured) [Hz]
Low	17.8	135.2	85*	1.08	1.10
Mid	17.8	135.2	83	1.06	1.04
High	17.8	135.2	68	0.96	0.98

\*The models low position GM value was slightly changed from the WWCT tests (WWCT: 0.086m, TT: 0.085m) due to changes to the device setup, namely a new battery and case however the positioning of the weights was the same.

Roll decay tests were completed by exciting the model from the port side by pushing down, when the roll was sufficient, data collection was started, and the roll motion was allowed to decay. This was repeated 5 times ensuring that each decay test produced 5 complete oscillations. The data was collected using the device to record the roll periods and verified with a stopwatch. The device then produced an FFT plot and the roll frequency presented as the 'Roll Frequency (Measured)' in Table 5. An example of one of the roll period tests with plots of the roll angle and FFT is shown in Figure 6.

**Figure 6: Roll Decay Test Results for Low Position. Roll angle (left) and FFT plot showing roll frequency of 1.10Hz (right)**

The results of the inclining and roll tests show that the measured roll frequency is within a window of the estimated roll frequency and the device can pick up changes of GM in model scale. As seen in Figure 3, the difference between the Low and Mid positions is 60mm, under a third of that between the Low and High (210mm) representing a 2.4% and 20.0% reduction of GM respectively. For the change between the Low and the Mid positions the device did not produce a clean enough signal to say with certainty that the device could pick up slight changes of GM. However, the difference between the Low and High positions was clear and the measured roll periods reflected the estimated roll period and showed an evident change in the stability condition of the vessel.

## Model Scale Wave Tests: Phase 1

The purpose of Phase 1 was to investigate the accuracy of data capture from the device in comparison to a commercial system. The Wind Wave Current Tank (WWCT) at Newcastle University was selected for this first phase of testing. This allows testing in a wide range of regular waves. The WWCT has a commercial motion capture system, Qualisys, that records the vessel motion through the tracking of 4 reflective spherical targets using 2 cameras set at either end of the test area.

The vessel was placed in ‘Low’ position and moored in the tank as shown in Figure 7. The GM was calculated at 0.086m from inclining tests conducted at the beginning of testing. The expected roll frequency for this setup was 1.08Hz.

The model used is of a vessel designed for use on the Kenyan coast and for ocean-going trips, so it is likely to encounter a range of operating conditions from calm inshore waters into the Indian Ocean and subject to heavy seas. A test matrix made up of 9 regular waves was selected and is shown in Table 6. These waves were chosen to represent a scaled representation of the wave heights and frequencies that the full-scale vessel is likely to encounter. All the waves tested are shown in Table 6 with the ratios of wavelength over the model water line length and breadth of the model. The wave lengths were measured in the centre of the tank test area where the model was located. The results of 3 of these tests (indicated by \*) are presented in Figure 8 with the nominal waves.

**Table 6: Phase 1 Test Matrix showing nominal wave frequency and height alongside ratios of wave length to model waterline length and breadth**

Wave Frequency [Hz]	Wave Height [m]	Wave Length/ $L_{WL\ model}$	Wave Length/ $B_{model}$
* 0.8	0.01	2.69	8.46
0.8	0.02	2.49	7.83
0.8	0.03	2.39	7.53
1.0	0.01	1.48	4.64
* 1.0	0.02	1.55	4.87
1.0	0.03	1.69	5.33
1.25	0.01	0.98	3.10
1.25	0.02	1.02	3.19
* 1.25	0.03	1.05	3.29

**Figure 7: Scaled plan view of the test setup in the Wind Wave Current Tank.**

The vessel was placed at beam seas and moored from the bow and stern to 4 points on the tank. The sampling rate of the device was set to 33Hz and the data collection was started remotely through a VNC server to start it simultaneously with Qualisys and the wave probe.

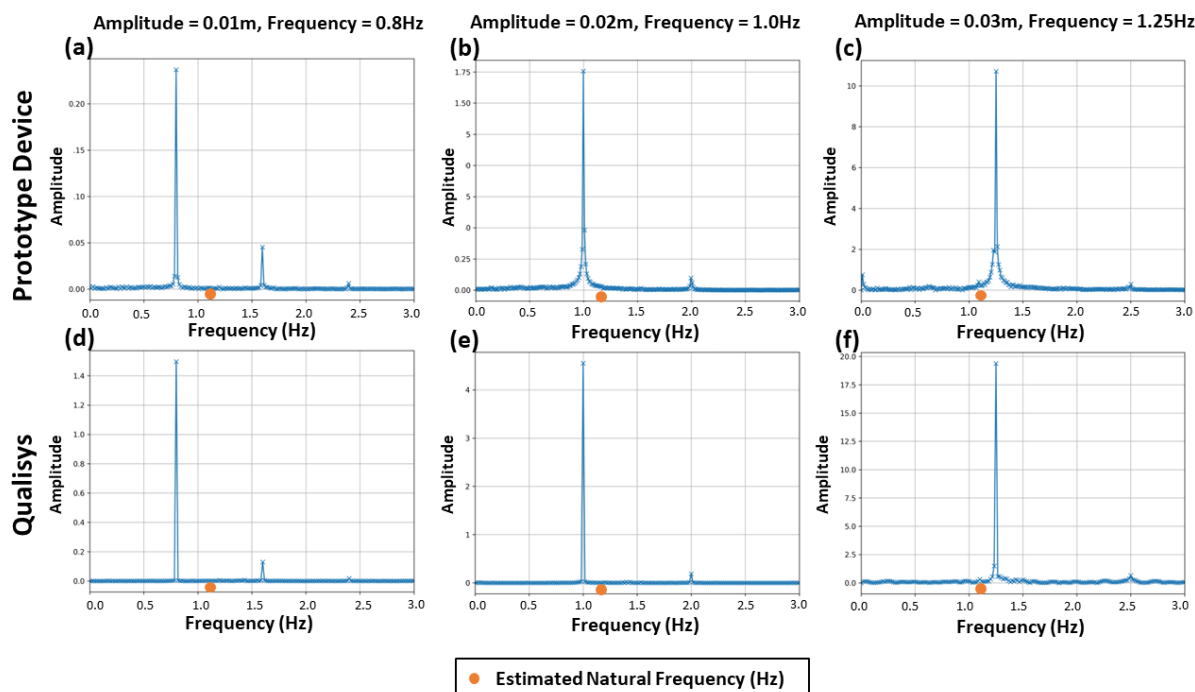

FFT analysis was carried out on the data collected by both the device and Qualisys. The peak frequencies for the tests are shown in Figure 8. The model’s motion was entirely dominated by the wave frequency. As can be seen in Figure 8 there was no significant difference between the nominal wave frequency and the recorded peak frequency for both the device and Qualisys, with the peak nominal wave frequencies being 0.8 Hertz (8a, 8d), 1.0 Hertz (8b, 8e) and 1.25 Hertz (8c, 8f). For each of these, the vessel roll frequency is the same as the wave frequency.

Most notably, Figure 8 shows the alignment of the two data acquisition methods, with the device showing peaks at the same frequency and with comparable clarity to Qualisys. The data from the device has greater amounts of noise surrounding the peaks, however this noise remains low relative to the amplitude of the peak. This noise is due to several factors: lower fidelity raw data from the device, the effect of electrical noise from the environment, greater amount of processing of raw device data and lower sampling rate of the device in comparison to Qualisys. These factors are likely the cause of the lower peak amplitude seen in the FFT from data collected by the device. The effect of the reduced sampling frequency

should be diminished at full scale due to the longer roll periods resulting in a higher number of data points per roll period giving greater definition than at model scale.

Overall, the results from the WWCT show there is no significant difference between the two acquisition methods with both detecting the same peak frequencies. The signal using lower fidelity data produces lower amplitude peaks with more noise however the effect of this is minimal as the peaks are easily identifiable, showing the validity of the device methodology. The first phase of the model scale testing ensured the accuracy of the data produced by the device, the second phase builds upon this to identify the natural roll period using irregular waves and more complex wave spectra.

**Figure 8: Comparison of FFT graphs for the two acquisition methods, the prototype device (a, b, c) and Qualisys (d, e, f) for a sample of 3 nominal sine waves described in Table 7. The estimated natural frequency is denoted by the orange dot above the x axis for each subplot.**

**Table 7: Nominal and Recorded Wave Data**

Nominal Wave		Average Recorded Wave Probe Data		Subplots in Fig.8
Amplitude [m]	Frequency [Hz]	Amplitude [m]	Frequency [Hz]	-
0.010	0.800	0.010	0.800	a, d
0.020	1.000	0.013	1.000	b, e
0.030	1.250	0.039	1.249	c, f

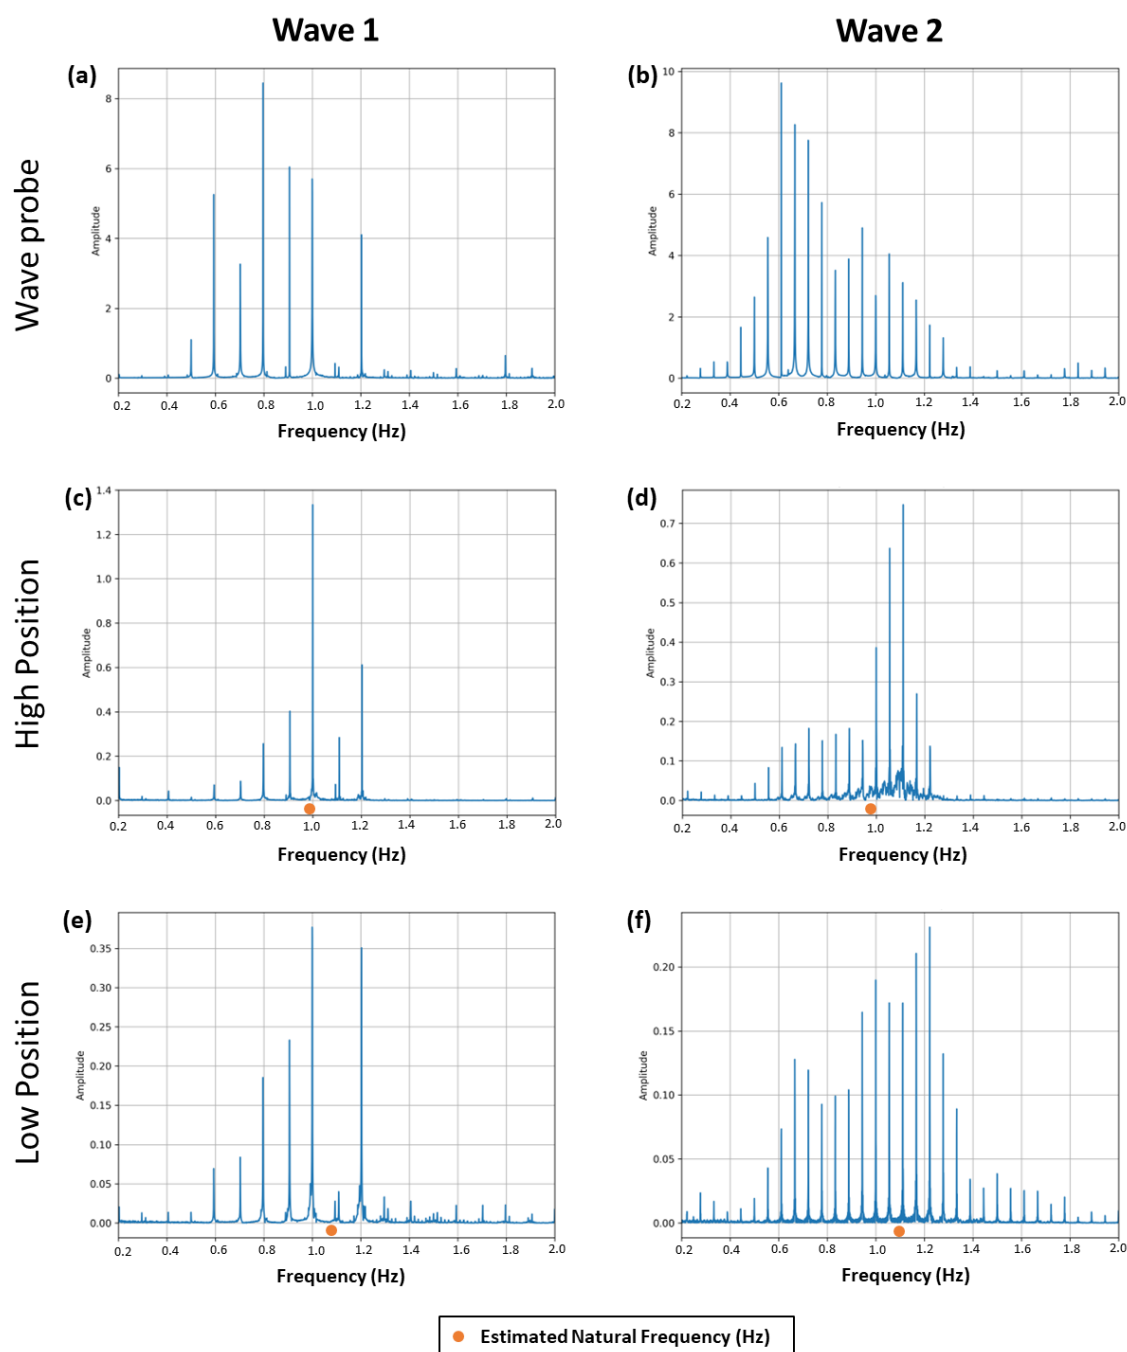

## Model Scale Wave Tests: Phase 2

The Towing Tank at Newcastle University was selected for the second phase of model testing due to the greater length and breadth of the test area. Initially, the model was moored first in 4-point mooring in beam seas as in the WWCT and regular waves were used. As these results were consistent with the WWCT it could be said that the difference made by the tank size was minimal. The vessel was then modelled as being ‘at anchor’ using a mooring line attached to a lead weight at the bottom of the towing tank, this mooring line was measured to ensure that the model vessel would not be able to make contact with the sides of the towing tank, the set up can be seen in Figure 9.

**Figure 9: Scaled plan view of the test setup in the Towing Tank.**

The intention in the second phase was to create more complex wave forms and allow waves to disperse over the tank length and mix, for this reason the test duration was also extended to 20 minutes. Two quasi wave spectra were created using combinations of wave fronts, sine waves, modified JONSWAP spectra and white noise, and are presented below in Figure 10a, &10b, denoted by Wave 1 and Wave 2.

**Figure 10: FFT results from Phase 2 testing. The 2 quasi wave spectra: Wave 1 (a) and Wave 2 (b) are shown with the vessel motion for each Wave 1 (c, e) and Wave 2 (d, f). The estimated natural frequency is denoted by the orange dot above the x axis for each subplot.**

The model setup remained the same as in Phase 1 of model testing and the model was tested in 2 of the loading conditions shown in Figure 3:

- Low Position: Weight on vessel deck (GM: 85mm, estimated roll frequency: 1.08Hz)
- High Position: Weight on top of second deck (GM: 68mm, estimated roll frequency: 0.96 Hz)

Figure 10 shows the FFT analysis of the model roll motion analysis data for the 2 loading conditions; high (10c, d) and low (10e, f) for 2 wave spectra; Wave 1 (10a, c, e) and Wave 2 (10b, d, f). The FFT plots for the vessel roll motion (10c- f) are shown alongside the FFT plots for the wave probe data (10a, b). The estimated natural roll frequencies for each position are denoted by the orange dot above the x axis.

Looking at the data from Wave 1 (Figure 10, left), initially it appears the natural roll frequency has been picked up for the high position, as there is a clear peak at 1.0Hz and roll frequency estimated at 0.96Hz and measured at 0.98 Hz from roll decay tests. However, as the same frequency of 1.0Hz is also the peak frequency in the low position it is clear this is a vessel response to the wave frequency.

For the more complex wave, Wave 2 (Figure 10, right) again the natural frequency of the vessel is not clear. The highest amplitudes seen are around 1.1Hz for the High position and 1.2 Hz for the Low position, around 0.1 Hz higher than the estimated roll frequency. The data recorded on the device across all tests has a negative skew whereas both waves have a positive skew. This shows general shift away from vessel motion being dominated by the wave frequencies in the Towing Tank in comparison to the Wind Wave Current Tank. Although the peak frequencies had moved away from the wave frequencies the two could not be said to be independent of each other, this is more evident in the more complex wave, W2.

Across all 4 tests the FFT plots have a more similar shape for each wave rather than each position suggesting the wave frequencies have far greater affect in the model than the weight position. This suggests the results from the towing tank show a continuation of issues faced in the Wind Wave Current Tank, with the natural roll frequency not being seen in continuous monitoring of the vessel motion. As this may be due to unrepresentative conditions using unidirectional waves a small pilot study was conducted.

## Full Scale Tests

A pilot study was conducted at full scale using a vessel in the local area to investigate whether issues present in model scale would still present at full scale. To test this a series of tests were conducted, each with a duration of 5 minutes, allowing different loading conditions to be assessed. The vessel used was a 4.88 metre Arran 16, described previously in Table 4. The vessel was moored on a beach at bow and stern in a similar fashion to the mooring lines used in first phase of model testing. During the testing the tide was continually coming in and there were slight changes in the wind and waves during the time of testing, but both remained calm.

The peak frequency over time graphs are shown for the following tests in Figure 11:

- Test 1: 2 people in vessel (Added Weight: 130kg), walking around vessel randomly.
- Test 2: 2 people in vessel (Added Weight: 130kg), rocking vessel to create constant roll motion.
- Test 3: Vessel empty, vessel allowed to roll freely.
- Test 4: Vessel empty, constant roll motion induced externally.

**Figure 11: Comparison of peak frequencies over time for 4 test conditions.**

The peak frequency found from the FFT analysis is plotted against time in Figure 11, with the FFT using a 50 second 'window' of data, updating itself every 10 seconds. No significant change in peak frequency within each test was expected to be seen as test conditions remained stable and no change in the position of the centre of gravity, G, was made. Although there is variation in the peak frequency detected, there remains a clear difference between the two loading conditions, with

Tests 1 and 2 having a roll frequency of around 0.7 Hz and Tests 3 and 4 around 0.9 Hz. As can be expected the Tests 2 and 4, where roll motion was constant, had almost no change in recorded roll frequency. For Tests 1 and 3 there is expected to be a greater effect of environmental conditions such as wind and waves and this is reflected in Figure 11, where both tests have more variation of recorded peak frequency in comparison to Tests 2 and 4. The results from these tests showed a clear difference between peak frequencies for the 2 loading conditions and the device was able to pick up differences between these, as well as pick up peak frequencies clearly out of laboratory conditions dealing with the effects of waves, wind and tidal currents.

This pilot study showed that the device could collect and process roll data for a full-scale vessel to a sufficient level of accuracy. Therefore, the device shows potential for use on fishing vessels in small scale and subsistence fishing, where there is a need for lower cost devices.

## CONCLUSIONS

This project has laid the foundations for further work investigating how low-cost digital technology can be used to assess the stability of fishing vessels in artisanal settings. The results of a prototype device have been presented from both model and full-scale testing.

The first phase of model testing has shown that low fidelity data can be used to measure roll motion in a comparable fashion to a commercial system. However, in regular waves unrepresentative of ocean waves the natural roll frequency of the model was not detected. The second phase of model testing aimed to create more realistic waves through quasi wave spectra, the vessel motion here was a clear response to the waves rather than simply reflecting the wave frequencies however this still did not allow the natural roll frequency to be detected.

The full-scale pilot study was successful in detecting the natural roll frequencies of the vessel and detecting changes in the roll frequency and therefore the vessel GM. Although work to refine the model scale testing remains, the results from full-scale tests are promising, demonstrating real-life applications. While further development is needed to make a full functioning device for everyday use, this study has effectively demonstrated proof of concept.

## FUTURE WORK

Further work into model testing should take place to resolve issues around wave frequency domination and investigation into the minimum value of GM before the stability condition of the vessel becomes dangerous should be carried out to determine alert levels for the device.

Full-scale testing is planned to take place on a traditional East African fishing boats and complete stability testing will also be carried out. This will include an inclining test and full lines plan. Alongside this the device should be used in its inclining test feature and then using the roll test to investigate error margins between a comprehensive stability test and this device.

Further development of the prototype device with a more user-friendly Graphical User Interface (GUI) will take place, whilst also investigating the potential to integrate the proposed technology and algorithms into regular smartphones. These are increasingly owned and used by fishers, and provide an opportunity to efficiently implement the technology. However, there are anticipated difficulties in the use of a smartphone which may include the robustness of the sensor architecture and setting a steady sampling speed, especially when the phone's processor is completing background operations.

Additionally, the creation of a vessel database to aid understanding of East African fishing boat forms will improve the device algorithms and support improve estimation of key parameters such as displacement and ensure the estimated radius of gyration is suitable.

# Leveraging a Small Dataset to Predict Nonlinear Global Loads

Kyle E. Marlantes\* and Kevin J. Maki

## ABSTRACT

*In this work, a hybrid machine learning method, which uses ML strategies to model high-order force components within a low-order equation of motion, is considered in the context of the global wave-induced loads of a ship in irregular waves. It is shown that the method can make predictions in a range of wave conditions even when the training data set only includes a single seaway. The proposed method offers a data-leveraging technique which may be useful in the design space, where a small data set derived from a high-fidelity source can be leveraged to make similar fidelity predictions in a larger number of wave conditions.*

## KEY WORDS

Wave-induced; global loads; shear forces; bending moments; hybrid machine learning

## INTRODUCTION

Global wave-induced loads are an important consideration in the design of ship structures. Often, shear forces and bending moments are estimated using rules-based distributions or simplified quasi-static methods (Payer and Schellin, 2013). Though practical for early-stage design, research has shown that real-world measurements can exceed rules-based predictions (Andersen and Jensen, 2014). In many cases, linear frequency-domain hydrodynamic tools such as strip theory are used (Payer and Schellin, 2013). However, it is well-known that such low-fidelity methods can underpredict the maximum bending moment (Wu and Hermundstad, 2002), (Rajendran et al., 2016), (Gaspar et al., 2016), sometimes by as much as 32% when considering long-term responses (Parunov et al., 2022a), and compensating with large safety margins may lead to an over-designed structure (Parunov et al., 2022b).

Nonlinear global loads are predominantly a second-order effect (Juncher and Terndrup, 1979), (Marlantes and Taravella, 2019) and strongly related to the body-nonlinear hydrodynamic forces, so it is necessary to use nonlinear numerical models. However, high-fidelity computational hydrodynamic tools, such as Reynolds Averaged Navier-Stokes (RANS) CFD methods or nonlinear potential flow methods, especially if coupled to a structural solver, suffer from a high computational cost, making it impractical to evaluate a large number of wave conditions (Hirdaris et al., 2014), (Temarel et al., 2016). As a result, body-nonlinear methods, which model the Froude-Krylov and hydrostatic restoring forces nonlinearly, are popular tools, as the nonlinearity from these forces capture much of the difference between hogging and sagging bending moments (Guedes Soares, 1991), which is especially evident in ships with large flare (Rajendran et al., 2016). One promising approach for high-fidelity methods is to use design waves, such as the Design Loads Generator proposed in Alford (2008) and

Alford et al. (2011) or the Critical Wave Groups method in Anastopoulos and Spyrou (2016), which greatly reduce the simulation time required. The role of simulators in design is enticing, but without the ability to identify “edges” in the design space, their usefulness is reduced (Schellin et al., 2015). Developing new computational methods which preserve nonlinearity, but are inexpensive to evaluate in a large number of wave conditions, is important to advancing simulation-based design (Hirdaris et al., 2014).

In recent years, machine learning (ML) methods have been explored to reduce the computational cost of predictions, but the accuracy of most ML methods is reduced when making predictions in wave conditions which differ from the original training dataset, and most data-only methods require a large amount of training data (Portillo Juan and Negro Valdecantos, 2022). Hybrid machine learning methods, which combine physics with ML techniques, have been shown to reduce the training data requirements (Willard et al., 2020). However, few examples of hybrid machine learning methods applied to global wave-induced loads are found in the literature. Several examples of data-only methods, such as the work of Moreira and Soares (2020), Hou et al. (2024), and Kwon et al. (2022) have been given, and a recent, and novel, approach in Wang and Ti (2024) which considers the wave-induced loads on bridge structures with arbitrary shapes. Several studies also take a probabilistic approach, such as the Bayesian models described in Zhu and Collette (2017). However, most studies focus on structural health monitoring in real-time, fatigue monitoring, or structural event detection. Moreover, most of these studies considered in-situ applications where data is plentiful, which often precludes their use in a design or analysis scenario, especially for unusual designs.

In this work, the hybrid machine learning method of Marlantes and Maki (2022) is considered in the context of the global wave-induced loads problem. The method relates a high-fidelity and low-fidelity model by a force correction that is modeled using an artificial neural network. To illustrate, Eq. (1) is the high-fidelity model, indicated by the superscript  $(h)$ , and the solution to this differential equation is the high-fidelity state  $\ddot{z}^{(h)}$ . This model might be a RANS-CFD simulation or a fully-nonlinear three-dimensional panel method, but in general, the high-fidelity model is assumed to be both more accurate and significantly more expensive to evaluate. Eq. (2) is the low-fidelity model—a model that is inexpensive to solve but lacks accuracy—indicated by superscript  $(l)$ , where the solution to the equation is the low-fidelity state  $\ddot{z}^{(l)}$ .

$$m\ddot{z}^{(h)} = f^{(h)} \quad (1)$$

$$m\ddot{z}^{(l)} = f^{(l)} \quad (2)$$

Adding and subtracting the low-fidelity force model  $f^{(l)}$  from Eq. (2) from the right-hand-side of Eq. (1) results in a force correction term  $\delta$ , as shown by Eq. (4).

$$m\ddot{z}^{(h)} = f^{(l)} + f^{(h)} - f^{(l)} \quad (3)$$

$$m\ddot{z}^{(h)} = f^{(l)} + \delta \quad (4)$$

An analytical model for  $\delta$  may not be available, so it is modeled using an artificial neural network, which introduces an error  $\epsilon = \delta - \delta^*$ , where  $\delta^*$  is the approximate force correction obtained by the trained model. Considering this error, Eq. (4) becomes Eq. (5). A solution to Eq. (5) will yield an approximate high-fidelity state  $\ddot{z}^*$  which will approach  $\ddot{z}^{(h)}$  as  $\epsilon \rightarrow 0$ .

$$m\ddot{z}^* = f^{(l)} + \delta^* \quad (5)$$

Both recurrent neural networks like Long Short-Term Memory (LSTM) and simpler feed-forward densely-connected multi-layer networks have been used to model  $\delta$ , but it is found in Marlantes et al. (2023) that relatively small, simple networks are sufficient for ship hydrodynamics problems, with the added benefit that they are inexpensive to train and evaluate. The

primary consideration when designing the network is to accommodate numerical integration of Eq. (5). To this end,  $\delta$  is modeled as a function of  $k$ -length discrete sequences of prior state  $\{z\}_{n-k-1}^n$ ,  $\{\dot{z}\}_{n-k-1}^n$ ,  $\{\ddot{z}\}_{n-k-1}^n$  and the wave elevation  $\{\eta\}_{n-k-1}^n$ , where the current time is  $t^n$ . Therefore, the state and wave elevation comprise the input features of the neural network and the output is simply  $\delta^{*,n+1}$ .

In this paper, Eq. (5) is extended to the global loads problem by means of classical rigid beam theory. Of specific interest is how well the method performs in wave conditions which differ from the training dataset, and the role that the low-fidelity forcing model  $f^{(l)}$  plays in this behavior. This property, known as generalizability, is critical to using data-driven simulation methods in a design scenario, where limited data is the norm. The ability to train a model of  $\delta$  on a small, initial dataset, and then make predictions of wave-induced loads at similar fidelity in many additional wave conditions could provide considerable insight into the performance of a design.

## THEORY

The classical model of global shear forces and bending moments assumes the hull behaves as a single rigid beam, as shown in Figure 1. While this model is greatly simplified, it will be used as the basis for this work as it encompasses the essential physics. The total length of the beam  $L$  is taken as the principle length of the vessel under consideration. We restrict the hull girder to move only in the vertical direction,  $z$ , such as in the heaving motion of a vessel in a seaway, reducing the problem to a single degree-of-freedom (DOF) system. As a consequence, any effect pitch motion may have on the nonlinear shear and bending moment is not considered. This simplifies the formulation of the hydrodynamic forces as they will depend only on heave motion and wave elevation, and will not have any coupling into rotation, which may alter the amplitude, frequency, or phase of the response.

**Figure 1: Hull girder as a rigid beam. The physical mass distribution  $m(x)$  is time-invariant. The hydrodynamic force distribution  $f(x; t, z, \dot{z})$  is shown at an instant in time  $t$ .**

The dynamics of the rigid hull girder shown in Figure 1 follow Eq. (6), where the total physical mass  $M$  is the integral of the longitudinal mass distribution  $m(x)$  and is assumed to be time-invariant. The total hydrodynamic force  $F(t; z, \dot{z})$  varies with time  $t$  and is nonlinear with respect to the state variables  $z, \dot{z}$  and is found by integrating the sectional hydrodynamic forces  $f(x; t, z, \dot{z})$  over the length of the hull. Note that because the beam is rigid and moving only in heave, the vertical acceleration  $\ddot{z}$  is pulled out of the integral on the left-hand-side of Eq. (7).

$$M\ddot{z} = F(t, z, \dot{z}) \quad (6)$$

$$\ddot{z} \int_0^L m(x) dx = \int_0^L f(x; t, z, \dot{z}) dx \quad (7)$$

The total force  $F(t; z, \dot{z})$  is nonlinear, high-fidelity, and assumed to be exact. Following the method outlined in the introduction, the high-fidelity total force  $F(t, z, \dot{z})$  can be expressed in terms of a force correction  $\Delta(t, z, \dot{z})$  to some inexpensive and low-order forcing model  $F^{(l)}(t, z, \dot{z})$ , given by Eq. (8). Similarly, the low-order total force  $F^{(l)}$  and force correction  $\Delta$  are the integral of their sectional counterparts  $f^{(l)}$  and  $\delta$ , respectively.

$$F(t, z, \dot{z}) = F^{(l)}(t, z, \dot{z}) + \Delta(t, z, \dot{z}) \quad (8)$$

$$= \int_0^L f^{(l)}(x; t, z, \dot{z}) dx + \int_0^L \delta(x; t, z, \dot{z}) dx \quad (9)$$

The instantaneous vertical shear force  $V$  at time  $t$  at a section  $x = s$  balances the difference between the inertial forces  $I$  and hydrodynamic forces  $F$  acting on the hull girder up to  $s$ , as given by Eq. (10). The internal bending moment is found by a nearly identical process after including the lever-arm  $(x - s)$  in the integrand, so for brevity it will not be presented here. We extend the same force-correction approach from Eq. (8) to the vertical shear force and bending moment. The resulting expression for shear is given by Eq. (12).

$$V(s; t) = I(s; t) - F(s; t, z, \dot{z}) \quad (10)$$

$$= \ddot{z} \int_0^s m(x) dx - \int_0^s f(x; t, z, \dot{z}) dx \quad (11)$$

$$= \ddot{z} \int_0^s m(x) dx - \int_0^s [f^{(l)}(x; t, z, \dot{z}) + \delta(x; t, z, \dot{z})] dx \quad (12)$$

The sectional low-fidelity forcing model  $f^{(l)}(x; t, z, \dot{z})$  and force correction  $\delta(x; t, z, \dot{z})$  in Eq. (12) are the same terms as in Eq. (9). Therefore, we restrict our focus to the sectional forces at  $x = s$ , and express the dynamics of a section as Eq. (14), which is simply the two-dimensional version of Eq. (6). If the sectional forces  $f^{(l)}$  and  $\delta$  are modeled, the shear force and bending moment will follow.

$$m(s)\ddot{z}_s = f(s; t, z_s, \dot{z}_s) \quad (13)$$

$$= f^{(l)}(s; t, z_s, \dot{z}_s) + \delta(s; t, z_s, \dot{z}_s) \quad (14)$$

While a solution of Eq. (14) will yield a  $\ddot{z}_s$  that is indeed different than  $\ddot{z}$ , due to the rigid body assumption, it differs by only a constant factor equal to  $L$ . Therefore, a solution to Eq. (14) captures the same underlying dynamics of the global problem and an investigation of Eq. (14) will allow us to make conclusions about Eq. (10). In the remainder of this work, we will focus primarily on Eq. (14), as it is the fundamental building block of the global loads problem.

## Duffing Equation

To investigate the choice of  $f^{(l)}$  on the performance of the method, a forced Duffing equation is used as a theoretical model of the sectional hydrodynamic force  $f(s; t, z_s, \dot{z}_s)$ , as it captures the salient features of the nonlinear hydrodynamics problem of a ship in waves. The Duffing equation model is given by Eq. (15), where  $c_1$  and  $c_3$  are the linear and cubic hydrostatic restoring coefficients,  $b_1$  and  $b_2$  are the linear and quadratic hydrodynamic damping coefficients, and the wave excitation forcing due to irregular waves is expressed as a summation of harmonic wave components. The wave excitation is made nonlinear by including the state  $z_s$  in the amplitude, modified by a coefficient  $\alpha$ .

$$m(s)\ddot{z}_s = \sum_i (\zeta_i - \alpha z_s) \cos(k_i s + \omega_i t + \phi_i) - c_1 z_s - c_3 z_s^3 - b_1 \dot{z}_s - b_2 \dot{z}_s^2 \quad (15)$$

The wave component amplitudes  $\zeta_i$ , wave numbers  $k_i$ , and angular frequencies  $\omega_i$  are sampled from a generic wave energy spectrum  $S(\omega)$  given by Eq. (16), where  $H_s$  is the significant wave height and  $\omega_p$  is the peak frequency. The component phase angles  $\phi_i$  are selected randomly from the range  $[-2\pi : 2\pi]$ .

$$S(\omega) = H_s^2 \frac{5}{3} \frac{\omega_p^4}{\omega^5} \exp\left(-\frac{5}{4} \left(\frac{\omega_p}{\omega}\right)^4\right) \quad (16)$$

To cast Eq. (15) in the form of Eq. (14), we must choose a model for  $f^{(l)}(s; t, z_s, \dot{z}_s)$ . This choice will determine the physics that are solved directly versus what must be learned by the ML model for  $\delta_s$ . Five different low-fidelity forcing models are proposed, given by Eqs. (17)-(21), with Eq. (17) having the most physics retained (and consequently the least physics that must be learned in  $\delta_s$ ). In Eq. (21), the entire forcing function must be learned by the ML model.

$$\text{Model A:} \quad f_A^{(l)}(s; t, z_s, \dot{z}_s) = \sum_i \zeta_i \cos(k_i s + \omega_i t + \phi_i) - c_1 z_s - b_1 \dot{z}_s \quad (17)$$

$$\text{B:} \quad f_B^{(l)}(s; t, z_s, \dot{z}_s) = -c_1 z_s - b_1 \dot{z}_s \quad (18)$$

$$\text{C:} \quad f_C^{(l)}(s; t, z_s, \dot{z}_s) = -c_1 z_s \quad (19)$$

$$\text{D:} \quad f_D^{(l)}(s; t, z_s, \dot{z}_s) = \sum_i \zeta_i \cos(k_i s + \omega_i t + \phi_i) - c_1 z_s \quad (20)$$

$$\text{E:} \quad f_E^{(l)}(s; t, z_s, \dot{z}_s) = 0 \quad (21)$$

To further illustrate the differences in the low-fidelity forcing models, Table 1 shows the force contributions that are modeled analytically and those that are data-driven for each choice of forcing model  $f^{(l)}(s; t, z_s, \dot{z}_s)$ .

**Table 1: Forces retained as physics (P) in  $f^{(l)}(s; t, z_s, \dot{z}_s)$  or learned by ML in  $\delta_s$**

		Forcing Model				
Force Description	Term	A	B	C	D	E
Linear Restoring	$c_1 z_s$	<b>P</b>	<b>P</b>	<b>P</b>	<b>P</b>	ML
Nonlinear Restoring	$c_3 z_s^3$	ML	ML	ML	ML	ML

Linear Excitation	$\sum_i \zeta_i \cos(\cdot)$	<b>P</b>	ML	ML	<b>P</b>	ML
Nonlinear Excitation	$\sum_i -\alpha z_s \cos(\cdot)$	ML	ML	ML	ML	ML

## RESULTS

The Duffing equation is configured using  $m(s) = 1.0$ ,  $c_1 = 1.0$ ,  $c_3 = 0.01$ ,  $b_1 = 0.1$ ,  $b_2 = \alpha = 0$  so that the only nonlinear term is the cubic restoring force. For a given significant wave height  $H_s$  and peak frequency  $\omega_p$ , the wave elevation  $\eta_s$ , and time series of nonlinear state  $z_s$ ,  $\dot{z}_s$ ,  $\ddot{z}_s$  and force correction  $\delta_s$ , are generated by solving Eq. (15) numerically. This is done to generate training data which are used to train the ML model for  $\delta_s$ . In addition, testing data are also generated, but these data are used to verify the performance of the trained models and are not used during the training process, as is discussed later in this section.

Throughout the study, each of the five low-fidelity forcing models given in Table 1 are considered. In all time series, a time step of  $\Delta t = 0.1$  s is used. Also, when sampling the wave spectrum to create  $\eta_s$ , the sample frequency bandwidth is taken

such that the repeat period of the resulting summation is equal to the length of the time series.

An ML model consisting of a feed-forward, densely-connected neural network with 2 hidden layers, 30 nodes per layer, and ReLU activation functions is trained for each  $\delta_s$  corresponding to each low-fidelity forcing model  $f_s^{(l)}$ . In this work, a stencil length  $k = 5$  is used, per the recommendations outlined in Marlantes et al. (2023). The reason a small  $k$  is effective in this case is because the nonlinear force components are functions only of the instantaneous state variables  $z_s$  and  $\dot{z}_s$ . Each model is trained for a total of 1000 epochs until the training loss no longer improves, however, only the weights from the epoch with the lowest loss are retained as final weights. The training time for each model is approximately 1 minute on a modest computing platform.

The average  $L_2$  error,  $L_\infty$  error, given by Eqs. (22) and (23), respectively, are used to evaluate the accuracy of the time series predictions in terms of RMS and extreme values.

$$L_2 = \sqrt{\frac{\sum_i^N (\hat{x} - x)^2}{N}} \quad (22)$$

$$L_\infty = \max(|\hat{x} - x|) \quad (23)$$

However, such measures are sensitive to small phase errors. As a more powerful measure of performance, the Jensen-Shannon divergence (JSD), as given by Eq. (24), is used to estimate the entropy of the predicted response pdf relative to a known reference pdf.  $P$  is the reference distribution and  $Q$  is the model distribution, both being pdfs, and  $M$  is the mixture. The Jensen-Shannon divergence is based on the Kullback-Leibler divergence  $D$ , given by Eq. (25), which is a measure of the relative entropy between the model distribution  $K$  and the reference distribution  $M$ , both defined over the domain  $\chi$ . It can be thought of as a measure of information loss, or expected surprise, if a certain distribution is used to model a reference distribution. A lower JSD means the model is closer to the reference, with a divergence of zero meaning the two distributions are identical.

$$JSD(P\|Q) = \frac{1}{2}D(P\|M) + \frac{1}{2}D(Q\|M) \quad (24)$$

$$M = \frac{1}{2}(P + Q)$$

$$D(K\|M) = \sum_{x \in \chi} K(x) \log \left( \frac{K(x)}{M(x)} \right) \quad (25)$$

The  $L_2$ ,  $L_\infty$ , and JSD metrics will be evaluated on predictions of the sectional acceleration  $\ddot{z}_s$  as it captures both the accuracy of the force integral on the right-hand-side of Eq. (9), as well as the inertial force of the entire beam to a constant factor.

## Training Data Size

We wish to use the smallest training dataset possible, so the influence of training dataset size on prediction accuracy is first investigated. Using a significant wave height  $H_s = 1.0$  and a peak frequency of  $\omega_p = 1.0$ , irregular wave records of  $\eta_s$  ranging in total length of 10 s up to 1000 s are generated, and the corresponding responses  $z_s$ ,  $\dot{z}_s$ ,  $\ddot{z}_s$ , and the force correction  $\delta_s$  are computed. Using this data, an ML model is trained for each low-fidelity forcing model in Table 1. The trained models are used to make predictions of the response in 1000 s of irregular waves with the same  $H_s = 1.0$  and  $\omega_p = 1.0$ , but with different random phase angles. For each model, the  $L_2$ ,  $L_\infty$ , and JSD are computed. Figure 2 shows the prediction errors vs

training dataset size for each low-fidelity forcing model. Note that the training dataset size is given as the number of Zero-Up-Crossings (ZUCs) in the wave record, as this is a more meaningful measure of response encounters than time alone.

**Figure 2:**  $L_2$ ,  $L_\infty$ , and  $JSD$  prediction errors for each low-fidelity forcing model over increasing training data size measured in wave record Zero-Up-Crossings (ZUCs). Predictions are in irregular waves  $H_s = 1.0$ ,  $\omega_p = 1.0$ , with random phase angles that differ from the training dataset.

Figure 2 shows that prediction errors of the five different models converge at roughly the same rate relative to the size of the training dataset. Datasets of approximately 50 ZUCs and larger yield similar prediction errors, with the exception of model E, which requires at least 100 ZUCs.

### Generalizability in $H_s$

Training data is generated for two different significant wave heights,  $H_s = 0.7$  and  $H_s = 1.0$ , at a peak frequency of  $\omega_p = 1.0$  for a total time series length of 500 s, or about 108 ZUCs to correspond with the findings in Figure 2. The time series for the state variables  $z_s$ ,  $\dot{z}_s$ ,  $\ddot{z}_s$ , and wave elevation  $\eta_s$  are shown in Figure 3.

**Figure 3:** Training data time series for Duffing equation:  $m(s) = 1.0$ ,  $c_1 = 1.0$ ,  $c_3 = 0.01$ ,  $b_1 = 0.1$ ,  $b_2 = \alpha = 0$ , in irregular waves:  $H_s = 0.7$  and  $H_s = 1.0$ ,  $\omega_p = 1.0$ .

Figure 4 shows the corresponding  $\delta_s$  for each low-fidelity forcing model for the training data case  $H_s = 1.0$  and  $\omega_p = 1.0$ . Note the difference in magnitude of  $\delta_s$  between the models, where  $\delta_{E,s}$  encompasses all of the hydrodynamic forces.

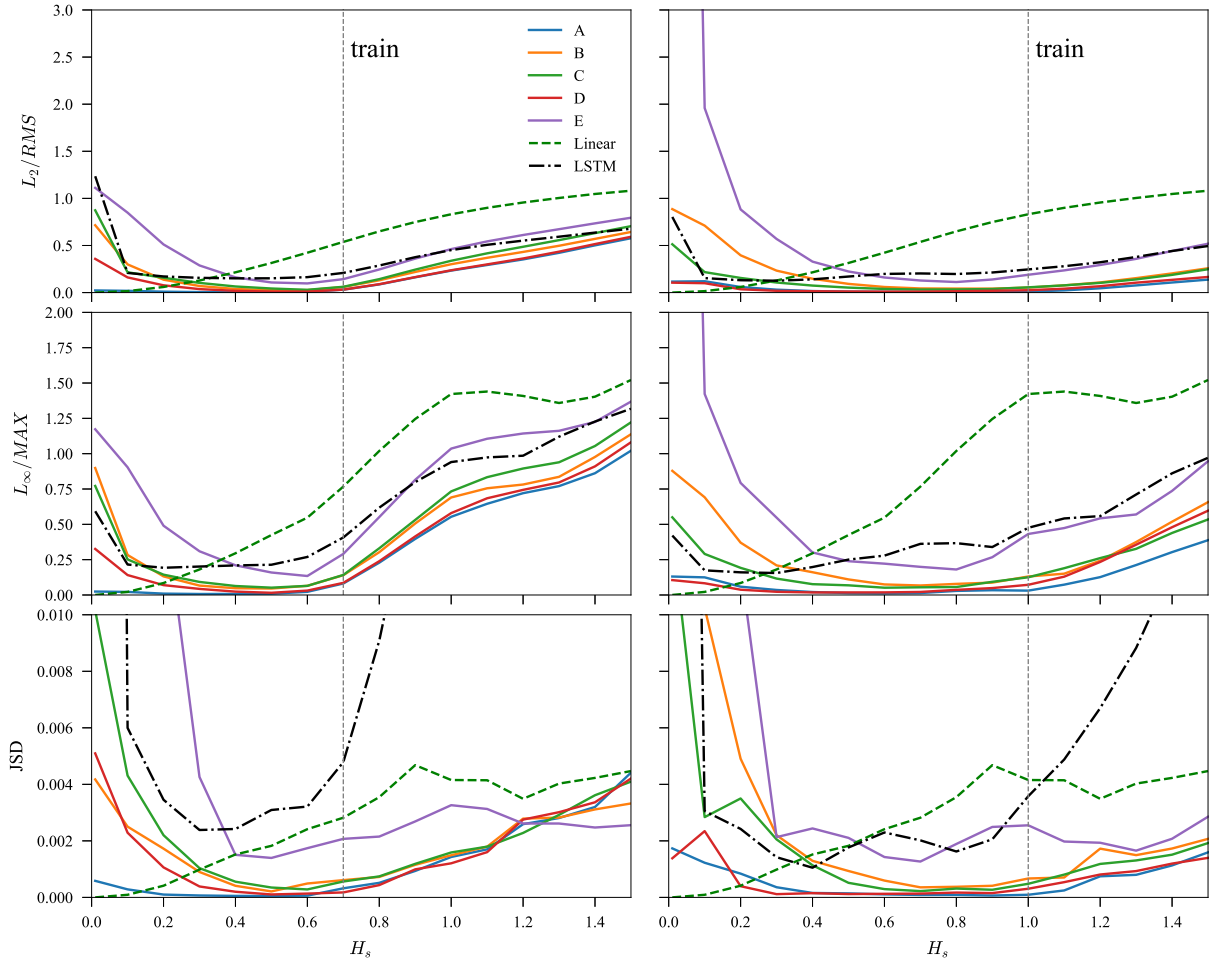

**Figure 4: Training data for force correction  $\delta_s$  for the five different low-fidelity forcing models  $f_j^{(l)}$ ,  $j = A, B, C, D, E$  in irregular waves:  $H_s = 1.0$ ,  $\omega_p = 1.0$ . The time series is given only from 200 s to 400 s so that the difference between the models is easier to distinguish, however, the pdfs are generated from the entire 500 s time series.**

Training data for two different  $H_s$  are shown in Figure 3, however, only one realization will be used for training at one time. This represents the minimum useful training dataset: 100 ZUCs in a single  $H_s$ . ML models for each of the five low-fidelity forcing models are trained at each wave height, to investigate any difference the training  $H_s$  may have on the performance of the models when making predictions.

As a benchmark, a Long Short-Term Memory (LSTM) neural network is also trained using a sequence-to-sequence paradigm, where the entire wave elevation  $\eta_s$  is used as the input to the network, and the output is the corresponding responses  $z_s$ ,  $\dot{z}_s$ , and  $\ddot{z}_s$ . LSTM networks and their variants are widely used in literature on data-driven modeling of marine dynamics (Xu et al., 2021), (Silva and Maki, 2022), and may be the predominant data-driven model for time series modeling. Due to its popularity, the LSTM is chosen for comparison. The network is composed of 4 hidden layers with 50 cells per layer to mimic the models used in Xu (2020). The model is trained for 200 epochs, until the loss plateaus at a value less than 1%. The best weights during the training process are restored at the end of the training process. The training time for the LSTM network using the data in Figure 3 is approximately 2 hours on a modest computing platform.

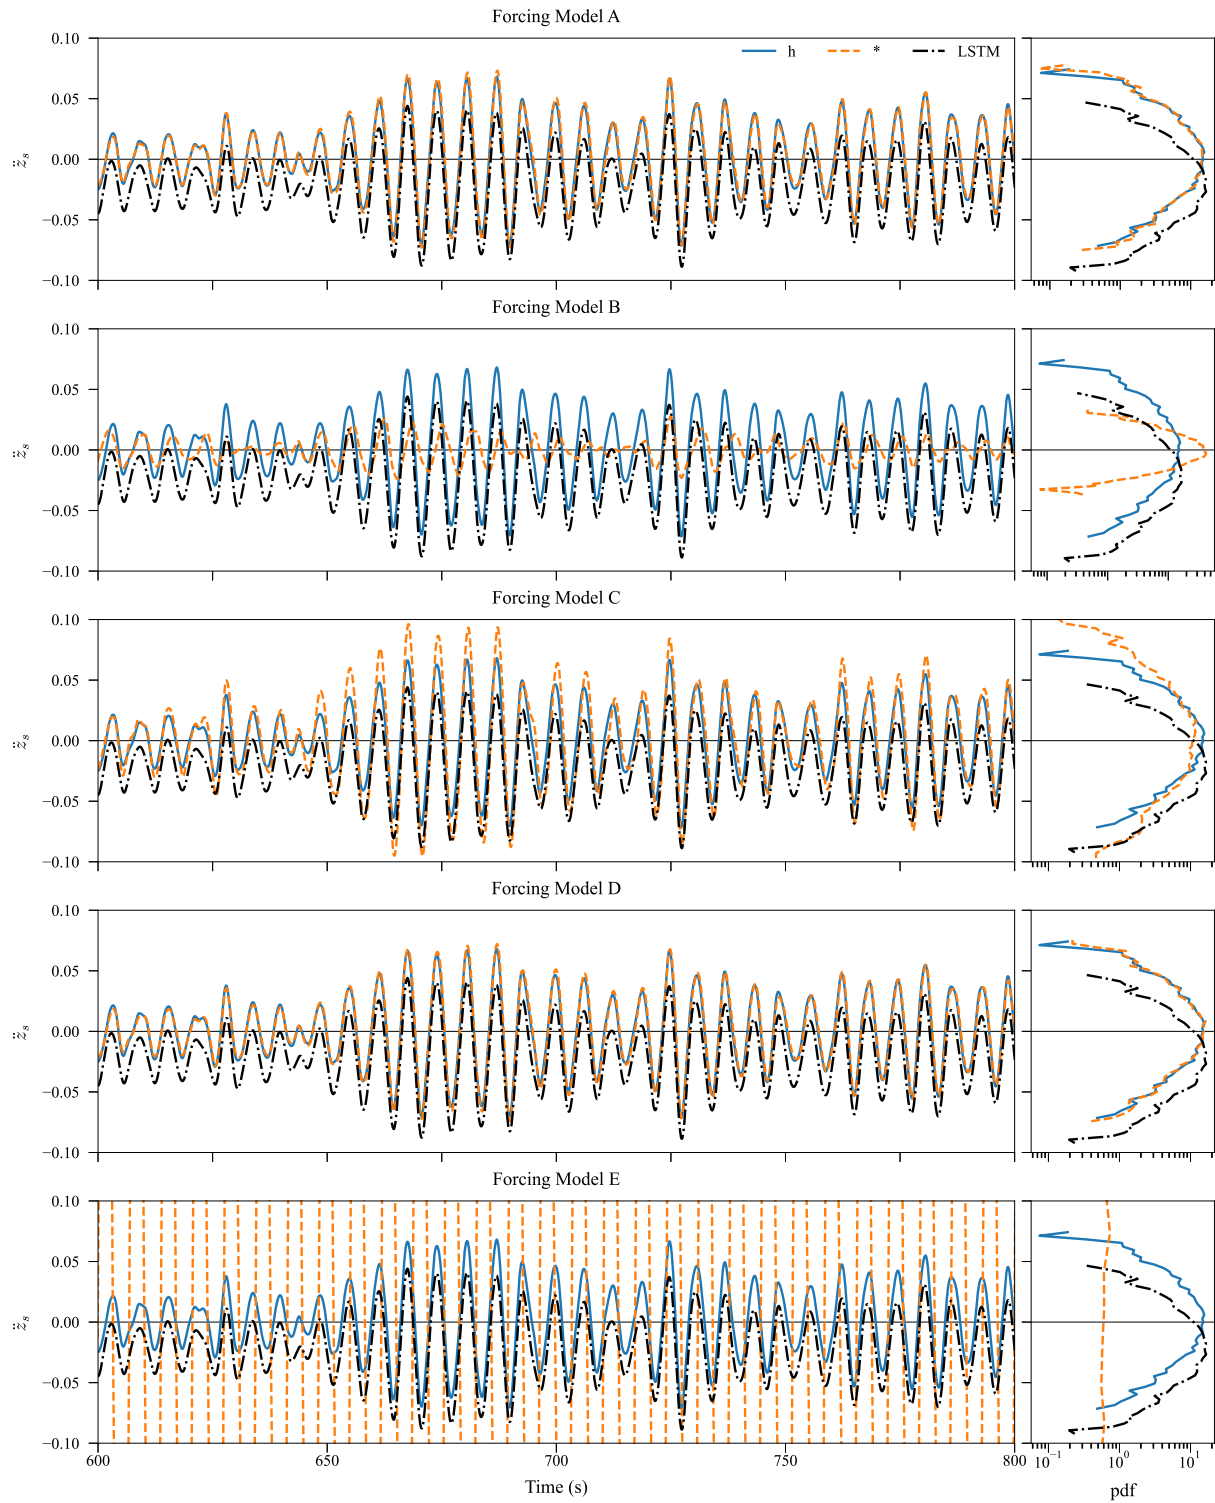

A testing dataset is generated for a range of significant wave heights  $H_s$  from 0.01 to 1.5 and a peak frequency  $\omega_p = 1.0$  over 1000 s of time. The component phase angles  $\phi_i$  are selected randomly to differ from the phase angles used in the training dataset. Each trained ML model is used to make predictions of the responses in each  $H_s$  from the testing dataset. Using Eqs. (22) through (24), the  $L_2$ ,  $L_\infty$ , and JSD metrics for the predictions are computed over the last 900 s of time series, omitting the first 100 s as it is a transient region. Figure 5 shows the performance metrics for each low-fidelity forcing model, the LSTM predictions, and a benchmark linear model, over the range of test significant wave heights. The wave height that was used for training is marked by a vertical line in each figure.

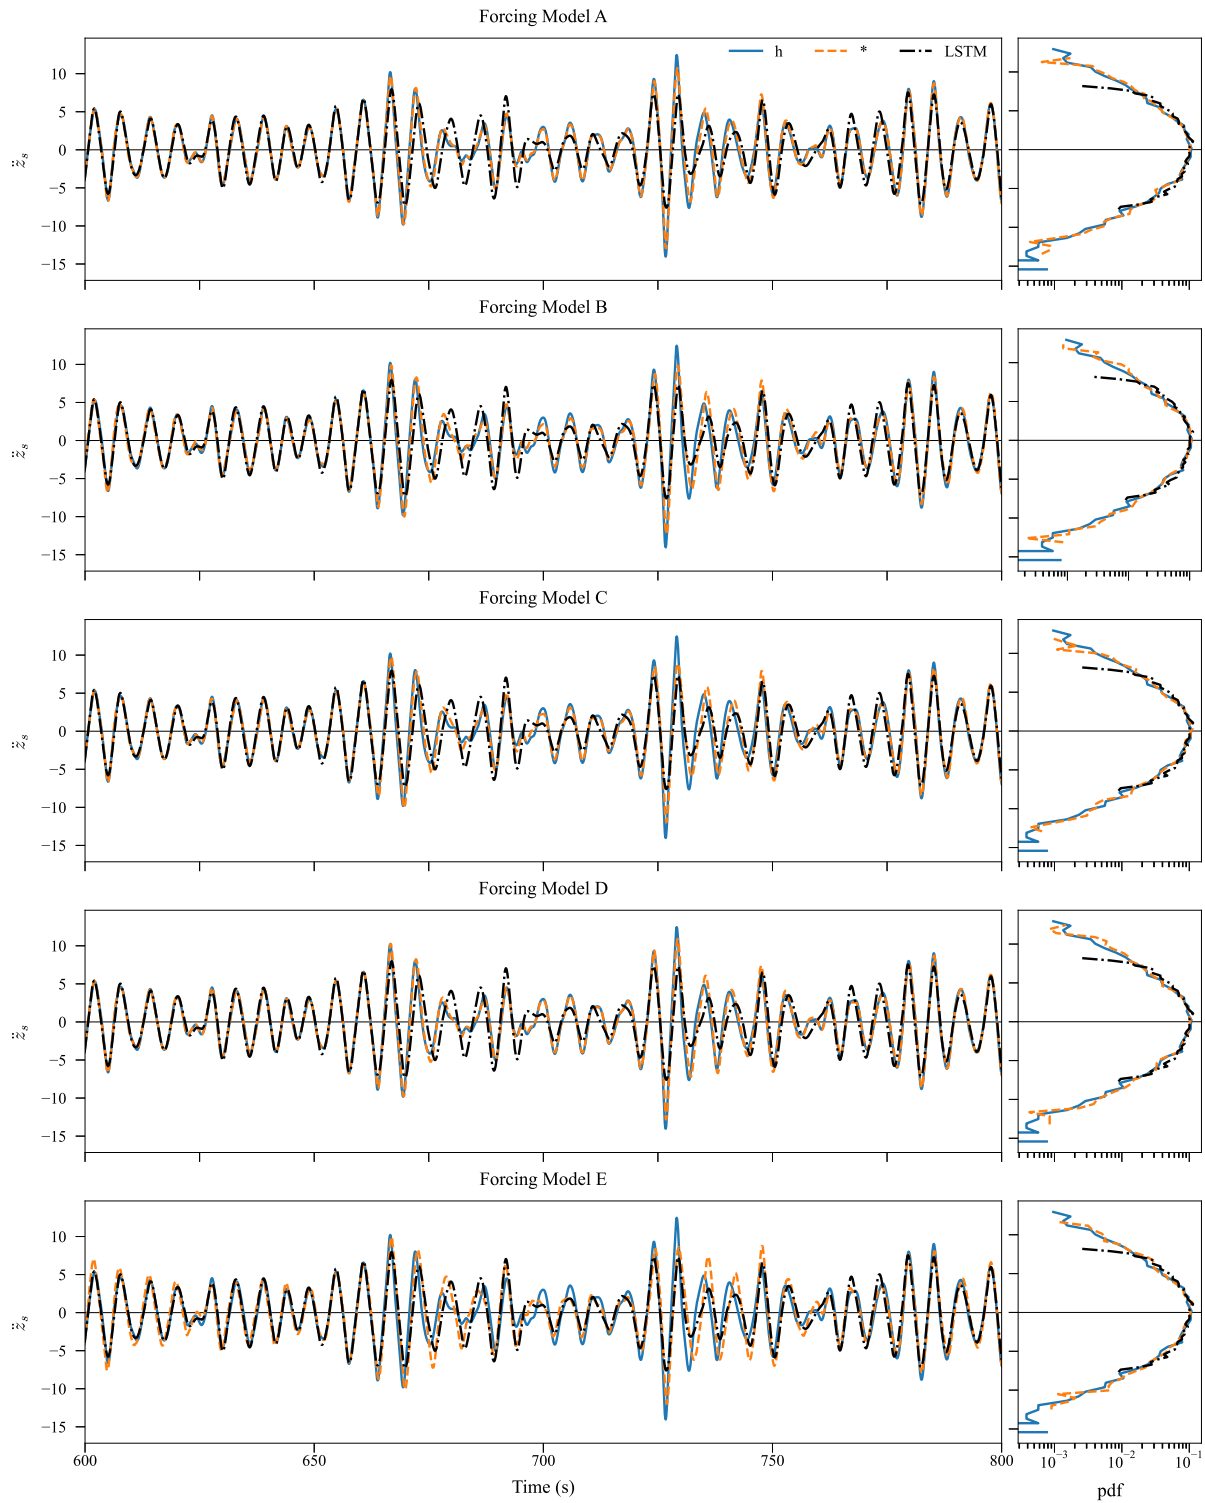

**Figure 5:**  $L_2$ ,  $L_\infty$ , and JSD error metrics for predictions of  $\ddot{z}_s$  for different low-fidelity forcing models over a range of  $H_s$ . The left panels correspond to models trained using  $H_s = 0.7$ , and the right panels  $H_s = 1.0$ . Results from the LSTM predictions are also shown for comparison. The linear model is also included to show how the linear error decreases to zero in the limit of small significant wave heights.

Figure 5 shows model A—the model that retains the most physics—performs better than the other models, and the LSTM benchmark, in nearly all wave conditions. This suggests that the more physics that are retained as analytical terms in the model, i.e. not data-driven, the generalizability of the model is improved. This is especially evident at low wave heights, where the low-fidelity physics enforce the correct dynamics at the linear limit. The  $L_2$  and  $L_\infty$  errors from the LSTM predictions are roughly in line with model E, which is perhaps intuitive as it is almost a purely data-driven model as well. Training in larger  $H_s$  seems to reduce prediction errors in larger  $H_s$ , while slightly increasing prediction errors at low- $H_s$ . However, this difference is greatly reduced in models which retain more physics.

To emphasize the performance of model A further, Figures 6 and 7 give the time series and pdfs of the predictions for each forcing model and the LSTM benchmark at the smallest  $H_s = 0.01$  and the largest  $H_s = 1.5$  significant wave heights. It is shown that the LSTM model struggles in both extremes, especially to predict the tails of the distribution. In comparison, models A and D perform well for both cases. Model E performs the worst, greatly over-predicting the response in small  $H_s$ , appearing as rapid, but stable, oscillations. Consider the pdf for model A at  $H_s = 0.01$  in Figure 6 and note the sensitivity of the JSD to small errors in the predicted distributions, as this proposed model fits qualitatively well to the reference distribution, but the small errors in the tails are magnified in Figure 5.

**Figure 6: Predictions of  $\ddot{z}_s$  in irregular waves  $H_s = 0.01$ ,  $\omega_p = 1.0$  using the proposed method with different low-fidelity forcing models. Each model is trained in irregular waves with  $H_s = 1.0$ ,  $\omega_p = 1.0$ . Results from an LSTM prediction are also shown for comparison. Only 200 s of response is shown for clarity, however, the distributions encompass the entire 1000 s time series.**

**Figure 7: Predictions of  $\ddot{z}_s$  in irregular waves  $H_s = 1.5$ ,  $\omega_p = 1.0$  using the proposed method with different low-fidelity forcing models. Each model is trained in irregular waves:  $H_s = 1.0$ ,  $\omega_p = 1.0$ . Results from an LSTM prediction are also shown for comparison. Only 200 s of response is shown for clarity, however, the distributions encompass the entire 1000 s time series.**

## CONCLUSIONS

The results of this study show that the neural-corrector method of Marlantes and Maki (2022) can be extended to the global loads problem and provide predictions in a range of irregular wave conditions that differ from the original training dataset. It is also found that retaining low-fidelity physics greatly improves the generalizability of the model. The accuracy of the predictions exceeds that of an LSTM benchmark when trained on an equivalent training dataset, especially in preserving the tails of the response distributions. The fact that a simple, feed-forward neural network as used in the proposed method offers improved performance over a typical LSTM model is largely due to the inclusion of low-fidelity physics in the formulation. A well-tuned linear model intrinsically captures much of the important dynamics of the problem, so that the ML correction must learn only higher-order terms, as shown in Marlantes and Maki (2022), such that a much simpler network is adequate. Finally, the proposed method, when including the most physics in the low-fidelity forcing model, requires a dataset of responses encompassing only 50 - 100 irregular wave encounters.

This work considered the responses of only a single section of the global loads problem. To implement multiple sections in unison, there are two possibilities: training a single model with multiple output nodes corresponding to a spatial discretization of  $\delta(x; t, z, \dot{z})$  at different longitudinal locations; or, training multiple models with single node outputs—such as done in this paper. In the former case, the output nodes must respect the integral on the right-hand-side of Eq. (9), which could be enforced in the loss function during training.

# Supplementing Industry-Specific Dynamic Positioning Requirements to Network Theory

E.L. Scheffers<sup>1\*</sup> and P. de Vos<sup>1</sup>

## ABSTRACT

The trend towards fully autonomous navigation or reduced manning concepts, coupled with increased integration and interdependence of onboard systems due to the shift towards sustainable fuels and ever-increasing electrification and automation, has stressed the significance of ship systems' reliability. These developments reinforce the demand for a clear assessment of the robustness of main and auxiliary systems in early-stage ship design. Network theory offers a promising approach to address this demand. However, current graph measures do not align with industry-specific requirements for improving system robustness. This study aims to augment robustness evaluation components, such as modularity (independent subsystems), redundancy and reconfigurability, with additional considerations specific to Dynamic Positioning (DP) applications in the maritime industry. The enhanced robustness evaluation components are translated into graph measures. By employing these graph measures, different systems can be compared with respect to robustness, enabling informed decision-making in the trade-offs typical to early stages of the design process (e.g., cost versus redundancy). The proposed methodology combines the principles of network theory and industry-specific DP requirements to provide a comprehensive framework for evaluating the robustness of ship systems. System reliability can be assessed by integrating the identified robustness components and incorporating them into the graph measures. The early findings of this study show the potential to improve ship design processes by providing a systematic and quantifiable approach to enhance robustness.

Onboard Distribution Systems; Dynamic Positioning Regulations; Ship Design; Network Theory; Robustness; Reliability; Design Heuristics

## INTRODUCTION

Safety and reliability are two of the most essential aspects in the process of ship design, as becomes particularly clear in the regulations for ships with Dynamic Positioning (DP) capability. A common way to express different levels of reliability for DP systems is by specifying the so-called "DP class" of the vessel. A Dynamic Positioned Vessel (DP Vessel) is:

*A unit or a vessel which automatically maintains its position and/or heading (fixed location, relative location or predetermined track) by means of thruster force (ABS (2021)).*

The DP class regulations are subsequently based on increasing degrees of redundancy within the system. The high and

\* Corresponding Author: E.L.Scheffers@tudelft.nl

well-defined redundancy facilitating maintaining a position is essential in the continuous operation of, for example, wind-turbine installation vessels, crew supply vessels and other offshore operations vessels because it increases the availability of the ships in more challenging conditions.

The first step of a theoretical DP system approach is to define the underlying principles of the system requirements. All requirements share a common goal: to increase the system's overall reliability. The number of definitions in this study, especially due to its interdisciplinary character, is high; the aim is to be explicit in the meaning of discussed concepts. Therefore, Table 1 provides an overview of reliability-related concepts from a marine engineering perspective. In Table 2, the right column contains the assumed working principle related to the system requirement. Most requirements are based on "component redundancy", whilst the aspects "distribution redundancy" and "independent subsystems" are both applied once.

The DP System is the complete installation necessary for dynamically positioning a vessel including, but not limited to the power system, thruster system, DP control system and independent joystick system (ABS (2021)). Regulations encompassing DP subsystems have been explicitly defined by IMO since 1994. The IMO acknowledges equipment class 1,2 and 3. The ABS levels of class notation, DPS-1, DPS-2 and DPS-3 are in line with the IMO classes and are stricter with regard to robustness requirements with an increasing level of DP class notation. Table 2 shows an overview of DP system requirements by subsystem and DP level (Clavijo et al. (2022)). The right column shows the related reliability principles, explained hereafter. In the development of these rules, experience and expert advice have been of leading influence. Therefore, we can consider the DP rules to be mainly based on empirical evidence, i.e. a posteriori knowledge. If we can design a framework in which we can understand the theoretical concepts behind the regulations, we can develop a priori knowledge with theoretical evidence. This understanding could aid in increasing the design space and possibly safer systems. The interdisciplinary scientific study of networks enables the use of tools or metrics based on graph theory. Network theory combines ideas from e.g. mathematics, physics and computer science to understand networks better. These networks can represent the system topology of the aforementioned DP subsystems. Using a network representation allows for system analysis in early design stages since the network can be defined using very limited To the authors' knowledge, no prior studies exist on the comparison between empirical DP regulations and theoretical network metrics.

**Table 1:** Robustness and Reliability Concepts

Concept	Definition
Robustness	The ability of distribution systems on board of (war)ships to withstand perturbations during system operation (Vos de & Stapersma (2018))
Reliability	The ability of a system to function as required without fault under given conditions during the given period quantified as the probability that a system will not fail or malfunction (Makoto ITO (2022))
Resilience	The ability of a system to withstand failure and to continue operations following failure (ABS (2021))
Redundancy	Ability of a component or system to maintain or restore its function when a single fault has occurred (ABS (2021)) The extent of degradation the structure can suffer without losing some specified elements of its functionality (Kanno & Ben-Haim (2011))
Component Redundancy	Achieved by the installation of multiple components (ABS (2021))
Distribution Redundancy	The presence of "independent alternative paths between source and demand nodes which can be used to satisfy supply requirements during disruption or failure of the main paths" (Goulter (1987))
Independent subsystems	Two or more component groups, each of which is capable of individually and independently performing a specific function (ABS (2021))

## Paper Outlook

A comparison between empirical DP regulations and theoretical network metrics is a new approach. Therefore, the focus of this paper is 1) to provide a clear outline of the assumptions made to enable the comparison, 2) to introduce a selection

**Table 2:** Subsystem requirements (Clavijo et al. (2022)) and the corresponding reliability principles

Subsystem (Item)	Minimum system requirements			Reliability Principle
	Class 1	Class 2	Class 3

Backup control station	No	No	Yes	

of network metrics and their working principles, and 3) to discuss the comparison and future research directions. The paper starts with the "translation" from system diagrams to networks and the related assumptions (Section "Method: Network Definition"). The next Section introduces a selection of reliability network metrics, classified using the theoretical reliability principles which are deduced from the DP regulations (Section "Method: Network Reliability Metrics"). The method, consisting of the network definition and reliability metrics, is applied to a case study of two DP systems (Section "Case Study"). Concluding this paper, we will discuss the results, reflect on the approach and draw final conclusions (Section "Conclusion")

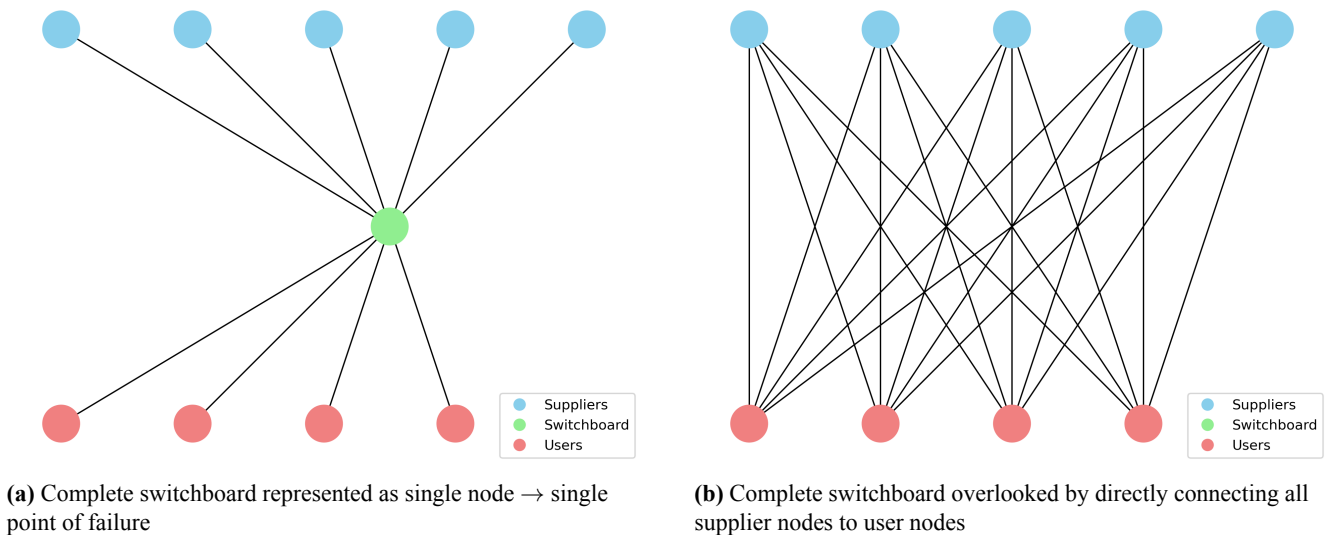

## METHOD: NETWORK DEFINITION

The DP System is the complete installation necessary for dynamically positioning a vessel (ABS (2021)). The following components or machines are always present in a DP system: electric power generation components such as engine-generator sets, multiple levels of electric power distribution via switchboards and distribution boards, electric converters, electric motors driving thrusters, a control system and finally, non-propulsion-related electric power consumers. When a comparable level of detail is maintained, most steps in translating a system to a network topology are straightforward. In each graph representation  $G$  of a network, components like generators, thrusters and converters are represented as nodes or vertices  $V$ ; pipes, shafts and cables are represented as links or edges  $E$  so that a network becomes a combination of nodes and edges  $G(V, E)$ . The networks are assumed to be simple undirected, unweighted connected graphs, meaning that the network 1) does not contain two or more connections between a pair of nodes, there are no self-loops (connections starting and ending at the same node), 2) the edges are undirected (the start point and end point can be considered interchangeably), 3) all edges have weight 1, and 4) all nodes are connected via one or more paths (Newman (2010)). The first three of these network properties result in a simplified network representation, only considering the network properties present in the logical architecture representation as defined by Brefort et al. (2018). The edges are undirected because edge direction is considered a temporal aspect and, therefore, part of the operational architecture. Certain aspects, however, are more subjective in their representation approach. Therefore, they are explained separately in the following sections.

### Distribution system components

The switchboard is a less straightforward component within the translation from system diagram to network topology. A switchboard as part of an electric system diagram is often represented as a (double) line or bar with different connecting lines entering and exiting this bar. The two extreme approaches to modelling a switchboard are shown in Figure 1a and Figure 1b respectively: the entire switchboard as a single point of failure. Meaning that, if something fails within the switchboard, in the model this is approached by a failure of the entire switchboard. The other extreme is disregarding the switchboard altogether and connecting the supplier nodes directly to all possible user nodes, as if the system is a complete bipartite graph (Newman (2010)). A failure within the switchboard influences a certain connection between this supplier and user but does not influence any of the other connections. Other approaches are, in terms of reliability, found between these extremes.

In this study, the switchboards are an essential part of the analysis since they are explicitly mentioned in the regulation overview in Table 2. Therefore, they must be included in the network. Considering switchboards as nodes within the network is in line with the node differentiation approach by Vos de (2018), who considered converter nodes (like generators) and hub nodes (like switchboards). This is approached by having the switchboards present as nodes connected to other nodes that represent the switchboard input and output ports. Whenever a switchboard is split by a switch or a bus-tie, a second node is added to the switchboard.

**Figure 1:** Extremes of distribution component network representations

## Control system

The control system is taken into consideration separately as part of simplifying the network representation. The control system is an essential part of the network; however, it is of such a different nature that it cannot automatically be compared using the same tools as the physical system components and connections. Moreover, the design freedom to determine the topology of the control system is so significant that the subjective choices made influence the network too significantly. This case study considers values of the network including and excluding the control system.

## Spatial considerations

An important part of improving resilience is by placing redundant components in separate compartments. This spatial aspect is, within this study, only taken into consideration when it is explicitly present in the system diagram. This differentiation between spatial system design and logical system design is in line with Brefort et al. (2018) and his division between functional architecture, logical architecture and physical architecture in the analysis of onboard systems.

## METHOD: NETWORK RELIABILITY METRICS

### Component Redundancy

This reliability aspect refers to redundancy achieved by the installation of multiple components performing a certain function (ABS (2021)). In this study, we do not apply system diversification (using different yet functionally similar components) to prevent common cause failures from happening. The following two network metrics have been selected to be a proxy measure for component redundancy: effective resistance (Ellens & Kooij (2013)) and maximum flow (Newman & Girvan (2004)).

### Effective Graph Resistance

Following the approach of (Ellens & Kooij (2013)), component redundancy facilitates parallel paths within a network and, therefore, increases with decreasing graph resistance. The effective graph resistance is based on the number of paths (parallel) and the length of paths (series) between different sets of nodes, which indicates the vulnerability of the connection between those nodes Ellens et al. (2011). In line with electrical resistance, a lower value suggests an "easier" flow between nodes. Therefore, we assume that the component redundancy increases with a decreasing graph resistance. Moreover, the effective graph resistance strictly decreases when an edge is added (Ellens & Kooij (2013)). The resistance between two nodes can be calculated using standard series and parallel resistance calculations. If each edge has a resistance  $r = 1$  Ohm, two nodes ( $a$  and  $b$ ) connected by a single path of length 2 have a resistance of

$$r_{a \rightarrow c} = r_{a \rightarrow b} + r_{b \rightarrow c} = 1 + 1 = 2 \text{ Ohm} \quad (1)$$

Where  $r_{a \rightarrow c}$  is called the effective resistance or resistance distance between node  $a$  and  $b$ . Adding an extra path between these respective nodes of length 3 gives

$$\begin{aligned} \frac{1}{r_{a \rightarrow c}} &= \frac{1}{r_{a \rightarrow b} + r_{b \rightarrow c}} + \frac{1}{r_{a \rightarrow d} + r_{d \rightarrow e} + r_{e \rightarrow c}} = \frac{1}{2} + \frac{1}{3} = \frac{5}{6} \\ r_{a \rightarrow c} &= \frac{6}{5} \text{ Ohm} \end{aligned} \quad (2)$$

The effective graph resistance  $R_G$  or Kirchhoff index is the sum over all pairs  $i, j$  of nodes. And can be calculated as (Ellens & Kooij (2013))

$$R_G = \sum_{1 \leq i \leq j \leq N} R_{ij} = N \sum_{i=2}^N \frac{1}{\lambda_i} \quad (3)$$

Here,  $N$  is the number of nodes in the network and  $\lambda_i$  is the  $i$ -th eigenvalue of the Laplacian matrix  $L$ , which is defined as  $L = D - A$ . The degree matrix  $D_{N \times N}$  contains the degree (number of edges connected a node) on the diagonal so  $D_{i,i} = \text{degree of node } i$ . The adjacency matrix  $A_{N \times N}$  has, generally speaking, non-zero values where nodes are adjacent (connected by an edge). In this study, we assume the networks to be undirected, unweighted graphs, thus  $A_{i,j} = A_{j,i} = 1$  if node  $i$  and  $j$  are connected. Since we assume the networks to be connected as well, only the first Laplacian eigenvalue  $\lambda_1 = 0$ . Therefore, the sum of the eigenvalues starts at the second eigenvalue  $\lambda_2$ .

Note that effective graph resistance as an indicator of component redundancy is currently still subject to active academic discussion. This statement is in fact applicable to all graph metrics discussed here and their corresponding maritime reliability principles, as this is part of ongoing research.

### Maximum Flow

The idea of component redundancy is to avoid single points of failure in the system. This translates to 'bottlenecks' when the system is considered as a flow network. These bottlenecks can be calculated using cut sets: a set of nodes or edges whose removal will disconnect a specified pair of nodes (Newman (2010)). The weight of each edge can physically be interpreted as the length or the capacity of that edge. Here, the capacity of each edge is set to 1 since we assumed the network to be unweighted; the primary reason for this assumption is the fact that length or capacity of the connections are unknown (as will very often be the case in early stages of ship/system design). This gives us the following definition for maximum flow: the maximum flow between a given pair of nodes in a network is equal to the sum of the capacity of the edges of the minimum edge cut set that separates the same two nodes (Newman (2010)). Calculating the maximum flow of a given network is an NP-hard problem; its value is approached using an algorithm. Algorithm 1 shows a basic greedy algorithm in order to explain an approach to  $f_{\text{textmax}}$ . In this study, maximum flow as approached by the push-relabel algorithm (Goldberg & Tarjan (n.d.)), which is further explained in (Roughgarden (2016b)) but will not be detailed here. Most DP systems are required to have more than one source node (e.g., the generator sets) and more than one sink node (e.g. thrusters). Therefore, a synthetic source and sink node are added in the calculation of this metric, respectively connected to all "actual" source nodes and all "actual" sink nodes.

**Distribution Redundancy**

Distribution redundancy refers to how well the redundant components can be utilised within the network. This aspect borders on reconfigurability: if a connection fails, can we still reach all relevant components via a different path? Therefore, the focus in selecting an appropriate metric for this aspect is on measures that express cycles, triangles and other cyclic topologies. The first metric we considered was the meshedness coefficient (Yazdani & Jeffrey (2012); Buhl et al. (2006)), which is the fraction between the total and maximum number of independent loops in a planar graph. This is a metric that has been applied to, i.a., water distribution networks (Yazdani & Jeffrey (2012)) and urban road networks (Buhl et al. (2006)). However, since onboard systems are designed within a three-dimensional space, we cannot guarantee that all networks are planar (can be drawn on a plane without having any edges cross (Newman (2010))). Therefore, the meshedness coefficient cannot be applied to onboard systems. Two other measures, however, can be applied to undirected non-planar networks: the clustering coefficient and the cycle basis.

**Clustering Coefficient**

In real-world networks, two properties are often found: a high clustering coefficient and robustness to random node failures. This clustering refers to the idea that "my friends are likely to be friends"; an expression for the triangle density within the network. Triangles facilitate two ways of reaching a certain point within the network, which we consider as distribution redundancy. Thus, the local clustering coefficient  $c_i$  of node  $i$  is defined as the number of edges among neighbours of  $i$  divided by the possible number of edges among its neighbours (Ellens & Kooij (2013)). The global clustering coefficient (over the complete network) is either expressed as the average of the local clustering coefficients or as six times the number of triangles divided by the number of triples (three connected nodes). In this study, we have chosen to apply the second definition for its focus on the complete network:

$$\tilde{c}_G = \frac{6 \times \text{triangles}_G}{N_2 - W_2} = \frac{\text{trace}(A^3)}{\sum_{i=1}^N d_i(d_i - 1)} \quad (4)$$

Where  $\tilde{c}_G$  is the global clustering coefficient of network  $G$ ,  $N_2$  is the number of walks of length 2 (all sets of three connected nodes:  $e_{a \rightarrow b}, e_{b \rightarrow c}$ ),  $W_2$  is the number of closed walks (same begin and end node),  $A$  the adjacency matrix and  $d_i$  the degree of node  $i$ .

### Circuit Rank

The second proxy for distribution redundancy is an extension of the clustering coefficient: the circuit rank or cyclomatic number Berge (2001). This metric provides the number of closed loops in the network that provide the base for all loops present and is equal to the number of independent cycles. The rank indicates a minimum number of edges to be removed to lose all cycles within the network and can therefore be considered as a minimum redundancy boundary. The circuit rank  $r_G$  is calculated as

$$r_G = E - V + C \quad (5)$$

Where  $E$  is the total number of edges in  $G$ ,  $N$  the number of nodes and  $C$  the number of connected components, which  $C = 1$  in case of a connected network.

### Independent Subsystems

The last reliability aspect is perhaps most directly related to network metrics. Having two or more component groups capable of individually and independently performing a specific function can be seen as a specific network partitioning with additional requirements. Network partitioning is the grouping of nodes in communities or partitions. The quality of this network division can be expressed as modularity (Newman & Girvan (2004)). To maximise modularity is to maximise the difference between the actual number of edges in a community and the expected number of such edges (Traag et al. (2019)). Again, we need an algorithm to approach the optimal network division. The Leiden algorithm is applied to partition the network (Traag et al. (2019)). The main disadvantage of this current network-based modularity approach is that the different functions of the components are not taken into account when determining the communities.

## CASE STUDY

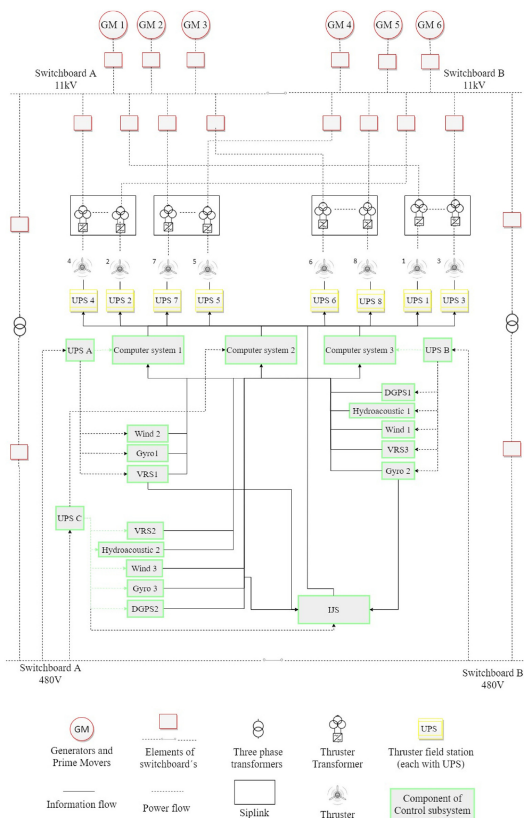

The case study consists of two Dynamic Positioning Systems of class level 2 and 3. The systems are defined by Clavijo et al. (2022) and initially used to perform a Reliability, Availability and Maintainability (RAM) analysis. This is a theoretically defined system based on literature and system knowledge. In future work the authors aim to apply the network analysis to real-world systems. Figure 2 shows the two considered systems, each consisting of a power subsystem (red), thruster subsystem (yellow), and control subsystem (green).

As mentioned in Section "Control system", the control system is regarded separately in this work. Figure 3 presents the corresponding network representation of the complete DP2 system. This figure shows the difference in structure between the power and thruster subsystems versus the control subsystem; the degree distribution is clearly completely different. Due to this difference in nature, the DP system is analysed both including and excluding the control system components.

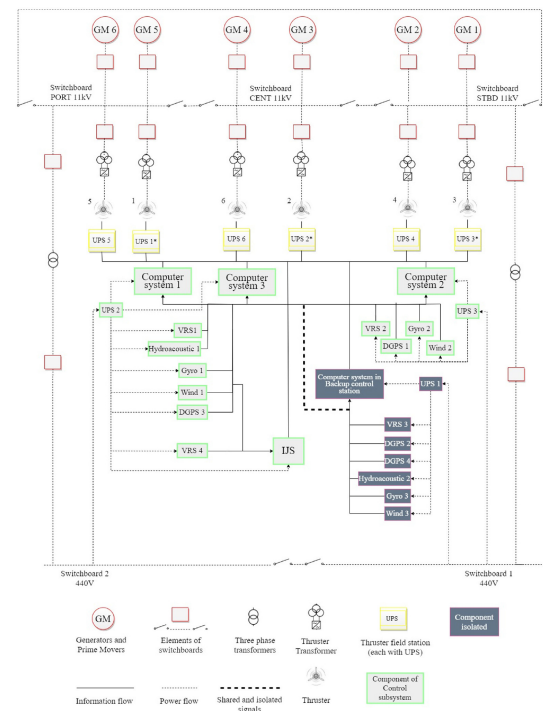

In line with the assumptions made in Section Method: Network Definition, we have constructed the DP2 and DP3 systems as shown in Figure 4. Based on a visual inspection of the networks, the DP3 system clearly has three main components in its main switchboard, whereas the DP2 system has two components. However, the connections between the transformers in DP2 seem to add to the overall reliability. Lastly, the double connection to one of the computer system components in DP3 creates an additional loop. This is expected to add to the distribution redundancy estimation.

Table 3 shows the different calculated network metrics (of subsystems) of the DP2 and DP3 systems. The first two networks show the metrics of the complete DP systems as shown in Figures 2 and 3. The last two columns contain the metrics of the simplified DP systems as shown in Figure 4. The bold green values indicate a "higher reliability", which is not for all metrics a positive correlation. First, the table is inconclusive in indicating the most reliable system based on the selected network metrics. The component redundancy, estimated using effective graph resistance and maximum flow, contradicts itself. This is also the case for the distribution redundancy metrics global clustering and circuit rank. However, the independent subsystem defined using network modularity is higher for the two DP3 network representations.

7) Number of Edges	130	126	44	46

## CONCLUSION

The goal of this study was to compare empirical DP regulations and theoretical network metrics. This was approached by 1) providing a clear outline of the assumptions made to enable the comparison, 2) introducing a selection of network metrics and their working principles, and 3) discussing the comparison and future research directions. We have translated two dynamic positioning systems into network representations and analysed these networks using selected network metrics. This selection was based on the assumed working principles behind the regulations in Table 2.

The resulting comparison shows that the selected network metrics do not affirm the working principles. The DP3 systems have a higher modularity and maximum flow indicating higher component redundancy, however, the higher effective graph resistance indicates the opposite conclusion. No conclusions can be drawn about the DP2 and DP3 power and thruster subsystems distribution redundancy since the networks contain no triangles (global clustering coefficient is 0) and the same number of closed loops (3).

## Discussion and Outlook

This study has been an initial attempt to express regulations for dynamic positioning systems as network metrics. Despite the inconclusive results, we believe that a future framework based on network theory can aid ship designers and marine engineers in designing safer onboard systems. However, we like to emphasize that additional research is essential before completing such a framework:

- This case study used two DP systems based on literature. Having actual networks (complete systems or subsystems) to compare would be a major step in making the network metrics more applicable to real-world systems. In future research, we aim to study systems with a higher number of components. This might reduce the arbitrariness in defining the network and could therefore yield more reliable results.
- The research approach of this study contained a series of assumptions: definition of reliability principles → matching these principles with regulations → selecting network metrics as a proxy for the reliability principles. We have been aware of possible bias in these steps, however, a formal framework to make these steps would be recommended for future research. This framework should also contain a very good and very bad example of a DP system to facilitate bench-marking the studied networks and the corresponding metrics.
- The translation of the DP systems to networks included a number of assumptions as well. Whilst most of them have been described in Section "Method: Network Definition", a significant assumption has been disregarded so far: the difference in network size between the DP2 and DP3 systems. The authors are aware that it is no common practice in network science to compare networks with different number of nodes (components). This size difference is, however, a network aspect that is inherent to systems onboard ships. Therefore, a comprehensive approach to this sizing problem and related normalisation concepts is recommended as future research.
- The aspect that makes the analysis of DP system regulations interesting, the fact that it sets requirements on different aspects of the integrated system, also makes it challenging to study. The DP systems often show a variety of components and connections. We consider the different components and connections to be a multilayer network: nodes and edges are part of a certain "layer" based on their respective type of flow. Interdonato et al. (2020) shows a range of possible approaches to simplify a multilayer network, motivated by reducing system "noise", being able to use already existing monoplex analysis methods, improved computational performance. The case study is presented as a multilayer network in Figure 5. The multilayer aspect is further disregarded in line with the motivations provided by Interdonato et al. (2020).

# Integration of the methanol power propulsion and energy systems' temporal uncertainties in a Markov decision process framework

Apostolos S. Souflis - Rigas<sup>1a,\*</sup>, Jeroen F.J. Pruyn<sup>1,2</sup> and Austin A. Kana<sup>1b</sup>

## ABSTRACT

*The ongoing technological development of methanol energy converters (EC) towards decarbonization means that their dimensions and performance characteristics will be continually updated during the lifecycle of vessels currently designed. These advancements influence the ease of EC integration within the general arrangement of the vessel. The decision to switch from an internal combustion engine to a fuel cell or a hybrid configuration depends both (1) the technology adoption costs (i.e. CAPEX, OPEX) of the EC and (2) on the effect of EC on the actual engine room layout. The state-of-the-art literature has typically addressed these two challenges separately. This study proposes a design method to bridge these two fields by combining the use of (1) Markov decision processes to assess uncertain future methanol EC developments during the vessel lifecycle and (2) a generative probabilistic layout algorithm to quantify the risks associated with the EC systems layout integration. The case study identifies the drivers behind the EC technology choice during the lifecycle of a notional yacht vessel.*

## INTRODUCTION

### Background

Greenhouse gas (GHG) emissions produced from the maritime industry have increased by 9,6 % between 2012 and 2018, in spite of operational measures regarding the speed of the vessel being imposed (IMO, 2021). Forecasting studies have shown that emissions may increase between 90 % to 130 % compared to 2008 levels (IMO, 2021). Chen et al. (2019) demonstrated that the targets of International Maritime Organisation (IMO) cannot be met with the current measures in place. In 2023, IMO (2023) introduced the revised target of net zero GHG emissions in 2050 matching the goals of European Commission policy (EU, 2023), which are more strict in comparison to the standards in the study of Chen et al. (2019). Aakko-Saksa et al. (2023) and Lindstad et al. (2021) found that adoption of carbon neutral fuels is key towards reaching the ambitious and challenging emissions mitigation targets. Several energy converter (EC) technologies are available to facilitate the transition towards carbon neutrality. A large proportion of existing fleet are using diesel internal combustion engines (ICE) (2-stroke or 4 -stroke) that when using conventional diesel contribute to emissions generation (Gray et al., 2021).

Retrofitting of these vessels is a necessary measure towards decarbonization (Gray et al., 2021) and the dual fuel engines have proven popular option (Tadros et al., 2023). Methanol has emerged as one of the prime candidates, being the 4th most widespread fuel (IMO, 2021), because it is in a liquid state and has properties resembling more closely to diesel in comparison to other alternative fuels (Zincir and Deniz, 2021; Harmsen, 2021). Methanol is thought to require minor modifications to be integrated within a vessel (Korberg et al., 2021; Zincir and Deniz, 2021). However, when considering the technologies available to be integrated within the power, propulsion and energy systems (PPE) (i.e. fuel cells (FC), batteries) as well as safety requirements for the fuel Zincir et al. (2023) and redundancy for vessel operation, the modifications will likely prove to be more than minor and thus more investigation is necessary. Souflis Rigas et al. (2023) showed that a large estimation discrepancy exists when attempting to compute the effect on the overall size of the vessel, pointing out the need for further research.

This study aims to compare different methanol energy converters on a lifecycle scope, while factoring in the challenge of layout modifications required for methanol EC technology adoption. A common trend in recent studies so far is to compare the alternative technologies and fuels based on financial and emission objectives (Zwaginga and Pruyn, 2022; Lindstad et al., 2022; Lagemann et al., 2022, 2023). However, these evaluation approaches have traditionally overlooked the challenges of the energy converters integration. Korberg et al. (2021) studied the feasibility of alternative fuels and propulsion configuration based on the total cost of ownership (TCO) and found methanol an advantageous choice, pointing out that FCs would need efficiency enhancement and capital cost reduction to become competitive. Similarly Lagemann et al. (2023) considered the most appropriate propulsion configurations based on uncertain emission regulations and pricing of fuel and carbon emissions and found methanol and LNG as strong candidates, but did not have a clear conclusion on which energy converter (FC or ICE) to use. Assessing the ease of implementing the proposed configuration is crucial before reaching a conclusion about the optimal choice. Lagemann et al. (2022) pointed out that technical and safety challenges may influence the solution outcome. This study aims to consider at a conceptual level the factors affecting the integration of the systems by integrating a probabilistic layout generation tool developed by Souflis Rigas et al. (2023) and Poullis (2022) to compute the probability of shifting to another energy converter during the lifecycle of a vessel, within a Markov decision process (MDP) employed for lifecycle modelling.

### Energy converter uncertainties

ICEs, FCs, or a hybrid configuration can be selected for the methanol adoption. FCs are still under development, meaning their specific power density (volumetric and gravimetric) and efficiency rate remain uncertain van Biert et al. (2016); Van Veldhuizen et al. (2023). Elkafas et al. (2022); van Biert et al. (2016); Van Veldhuizen et al. (2023) highlighted that the efficiency rates and the power densities (volumetric and gravimetric) remain highly uncertain, as shown in Table 1. FCs are still a technology under development (EMSA and DNV, 2021), and it is fair to assume that their volumetric power density is far from becoming a deterministic value. Even, methanol internal combustion engines are still under development with their volumetric power density and efficiency rate improvements being part of ongoing research (Juho Repo et al., 2023). Additionally, Table 1 presents the uncertainty in estimating the cost of acquiring the main energy converter. This study focuses on interpreting the uncertainty in volumetric power density via Equation 1 (Torabi and Ahmadi (2020)) into physical dimensions uncertainty that is an input parameter for the probabilistic layout tool.

**Table 1: Energy converters uncertainties considered (data derived from Elkafas et al. (2022); Zwaginga and Pruyn (2022); MARIN (2024); Wartsila (2024); MAN (2024))**

Energy Converter	Volumetric Power Density (kW/m <sup>3</sup> )	Capex (€/kW)	Efficiency Rate
PEM - Fuel Cell (PEM-FC)	45-500	500-1680	47%-65%
ICE 4-Stroke	120-290	451-677	30% - 45%

$$P_{volumetric} = \frac{Power_{installed}}{L \cdot B \cdot H} \quad (1)$$

in which:

- $Power_{installed}$ : installed power of the component
- L: length of the component
- B: width of the component
- H: height of the component

### Review of studies on alternative fuels adoption -shaping of the research gap

Besides the studies focused on EC technology development, there are comparative studies for alternative fuels that consider the challenge of adopting alternative fuels in the form of additional space, volume, or weight objectives within an optimization framework. Ritari et al. (2023) investigated several ways to configure the PPE systems within the lifecycle period of a vessel using a total cost of ownership (TCO) minimization framework, but did not consider uncertainties in the dimensions or the performance of the components described. The properties of the potential PPE components were deterministic. Similarly, Zhang et al. (2023) evaluated different PPE configurations for a cruise vessel based on emissions and costs. Zhang et al. (2023) estimated the additional space demand in proportion to the size of the prime energy converters (EC): meaning that the engine room is assumed 5 times larger than the size of an internal combustion engine (ICE) and fuel cells are set to 2.5 times bigger than the fuel cell (FC) volume. Additionally, the conclusions of this study, through time, proved highly sensitive to the carbon pricing variation. Rivarolo et al. (2021) implemented a tool that evaluated various energy converters for a cruise ship based on volume, weight, costs and emissions and calculated volume and weight based on empirical equations derived from market data. The computed volume remains mostly focused on the additional fuel storage, disregarding possible alterations because of the PPEs uncertainties. These studies highlight that the space requirement is a decision influencing factor when comparing alternative fuels and energy converters. Additionally, the development of the EC technologies and their related sizing uncertainties have been totally overlooked. Higher fidelity in the layout modelling can generate more insightful information regarding the actual integratability of the EC within the engine room space.

Table 2 presents the elements that constitute relevant studies on lifecycle analysis and evaluation of suitable main EC (energy converter) technologies. Two elements are not sufficiently addressed:

- Space requirement for alternatively fuelled components integration: has been calculated based on volume requirement for additional fuel storage based on empirical equations or data trendlines and overlooks PPE configuration complexity Rivarolo et al. (2021); Lagemann et al. (2023); Ritari et al. (2023)
- The performance of the components under development (FCs, batteries, ICEs) and their *uncertainty* in terms of *volume, gravimetric power density and efficiency rates* as presented on Table 1

**Table 2: Overview of objectives of studies focused on alternative fuels**

Table 2 in combination with the overlooked discrepancy estimations in the size effect of the alternative fuelled PPE components integration Souflis Rigas et al. (2023) and the uncertainties in the performance evolution of energy converters - see Table 1, shapes the need to integrate the 4 objectives considered within Table 2. This paper developed a method that combines elements of the studies of Kana et al. (2015) and Souflis Rigas et al. (2023) to take a step further in the accuracy of the lifecycle evaluation and integrate the uncertainty aspects described.

## State of the Art of Markov decision process in ship design

Markov decision process has been selected to quantifiably propagate the technical uncertainties of the ECs through time. Kana et al. (2015) highlighted that MDPs are beneficial because they integrate quantified uncertainties related to policy application, reflect the net present value per epoch via the rewards and provide the optimal decision per epoch (*epoch: refers to the executed time steps*). Kana and Harrison (2017) pointed out that MDPs generate an understanding of the decisions made within a time dynamic framework rather than provide one optimized solution on a specific time static case.

Kana et al. (2015); Kana and Harrison (2017) demonstrated through a case study regarding the conversion of a container ship vessel to LNG fuel, that the emission regulation advancement uncertainties and supply chain risk uncertainties can be captured within an MDP to generate insight on the conversion choices through time. Niese (2012) developed an MDP framework that accounts for policy to generate a strategic maintenance plan for a ballast water treatment system and showcased the effect of uncertain regulation requirements on the maintenance decisions of deteriorating components. Niese et al. (2015) applied ship centric Markov decision process (SC - MDP) to evaluate the effect of alternative technologies, alternative fuels and operational measures adoption (e.g. engine derating) to the design choices (e.g. principal ship dimensions) being made as well as the rewards generated throughout lifecycle. The design space of the alternative vessels' was produced via low-fidelity modeling. However, this study outlined the potential of MDPs to compare and evaluate the influence of various technologies on the design and the economic viability of a vessel. Overall MDP, provide a reliable method to capture stochastic temporal uncertainties caused by regulation, policy, costs, and technology alterations.

## Research contribution

As shown in Table 1 and using equation 1, the uncertainty of volumetric power density can be matched to the uncertainty of the physical dimensions of the component. The focus remains on propagating the uncertainty of the physical systems dimensions throughout the vessel's lifecycle and thus accounting for uncertainties overlooked by previous research. The main goal of this work is to compare the potential ECs through the vessel lifecycle while using the probabilistic layout tool output to define the transition probabilities and see which are the influential factors to the outcome.

## METHOD

MDPs are designed to capture and solve a sequential decision-making problem that deals with time dynamic uncertainties in the state space (Kana et al., 2015; Russell et al., 2010).

The key components to define an MDP are:

- states ( $s$ ): representing a set of states that the agent may be in through time
- actions ( $a$ ): a finite set of actions that can be selected
- Transition Probabilities ( $T(s'|s, a)$ ): expresses the probability upon choosing action  $a$ , the agent in state  $s$  will move to state  $s'$  in the upcoming epoch.

- Rewards (R): is the reward given after moving to a new state  $s'$  by selecting action  $a$

*Note: agent represents the entity that selects the action to be implemented based on the solution followed for the MDP.*

Solving MDPs produces a sequence of states through time that are selected based on the optimal value per epoch. The algorithm selected to solve the MDP is the value iteration algorithm using the Bellman equation (see Equation 2), which is typical for solving a stochastic dynamic programming problem Bethke and How (2009). Equation 2 is used to compute the utility for each state per epoch. The sequence of actions selected using Equation 3 compiles the policy of actions to be made per state throughout the defined time horizon. The optimal policy in this case is considered the one that yields the highest expected value.

$$U(s) = R(s, a) + \gamma \max_a \sum_{s'} T(s, a, s') U(s') \quad (2)$$

$$\pi(s) = \arg \max_a \sum_{s'} T(s, a, s') U(s') \quad (3)$$

Russell et al. (2010) described the value iteration algorithm as: *a way to propagate the information through the state space by means of local updates, which provides a way for uncertainty percolation through time*. The selected MDP has a finite time horizon and features non-stationary dynamics, where both the probability and reward vectors evolve over time. Kana et al. (2015) pointed out that the changes in the probability and reward vectors can be caused by degradation, regulatory shifts and logistics risks. In this case study the non-stationary property is derived from the changeable performance properties and technology acquisition/ adoption costs of the ECs.

## Novel Transition probabilities definition

The transition probability in a MDP represents the probability of moving from state B at epoch  $n$  ( $B_n$ ) to state A at epoch  $n+1$  ( $A_{n+1}$ ) (see Equation 4), depending on the decision-action that is selected per time step Sheskin (2010). However, if the states are considered independent, the probability is equal to the probability of event A, according to Equation 4. For this study, the states are considered independent and probabilities are defined applying Equation 5.

$$P(A_{n+1}|B_n) = \frac{P(A_{n+1} \cap B_n)}{P(B_n)} = \frac{P(A_{n+1}) \cdot P(B_n)}{P(B_n)} = P(A_{n+1}) \quad (4)$$

Probability can be defined by using the relative frequency approach Gebali (2015), as shown in Equation 5. This means that an experiment is conducted  $N$  times and based on the  $N_a$  times that the selected outcome occurs, a probability is defined.

$$P(A) = \lim_{N \rightarrow \infty} \frac{N_a}{N} \quad (5)$$

Connecting this approach to the framing of this study's problem, the probabilistic layout tool by Souflis Rigas et al. (2023) conducts a Monte Carlo simulation (MCS) on the dimensions of components to be fitted in a simplified engine room layout based on various system architectures and generates distributions of engine room length (see Fig. 1). Souflis Rigas et al. (2023) showed there is inconsistency between the input dimensions and the output of the overall engine room size, which is the foundation for using a layout modeling tool to incorporate the dimension uncertainties rather than empirical trendlines. Using the distribution of the engine room length against a specified requirement for the length, Equation 5 can provide the probability of a PPE configuration with uncertain dimensions to fit within the required length. The uncertain dimensions can be derived from the volumetric power density uncertainty underlined in Table 1. Souflis Rigas et al. (2023) therefore

highlighted that there is a struggle with available space when existing vessels convert to methanol. A threshold of a required length reflects the requirement of fitting the equipment for the retrofit of an existing vessel from ICEs to using FCs as prime energy converter. The requirement and testing of specific  $Length_{engine\ room}$  reflects on a potential length threshold that leads to moving a bulkhead and triggering extra conversion costs.

**Figure 1: Representative engine room length distribution per epoch per energy converter**

## Framework for Energy Converters case study

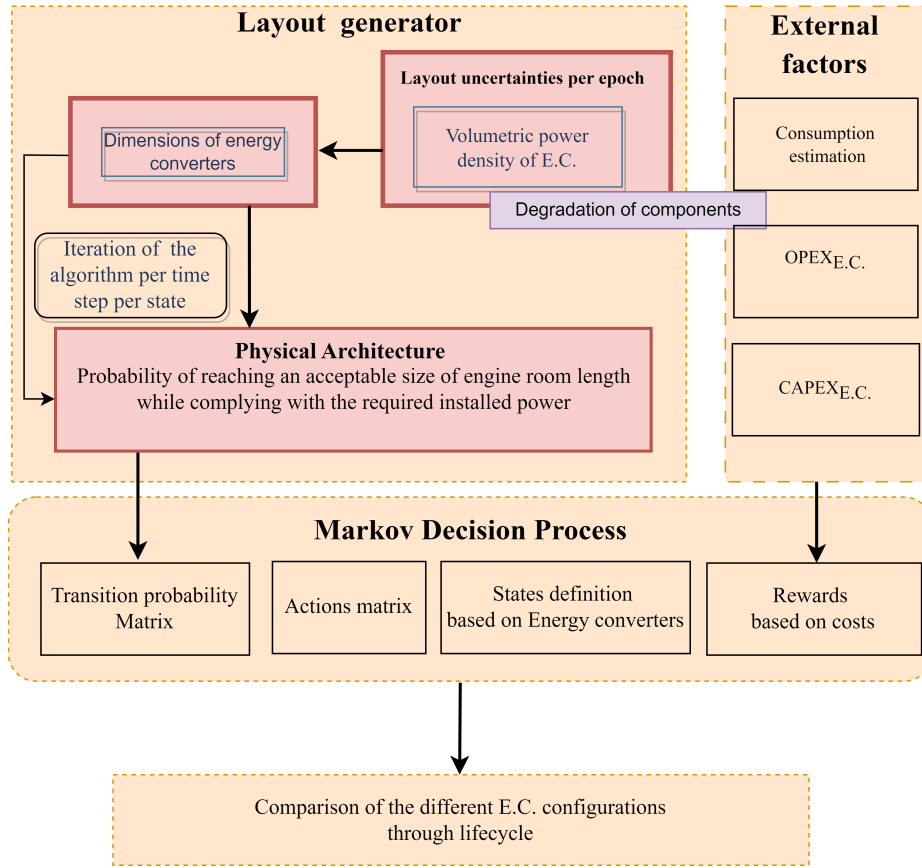

The current model framework is based off of a modified ship centric markov decision process (SC - MDP). Figure 2 shows that the model starts by generating the necessary inputs for the MDP - transition probabilities and rewards matrices. Firstly, it uses the uncertainty analysis in the physical space of an engine room that is conducted with the probabilistic layout tool Souflis Rigas et al. (2023) for transition probabilities definition. By computing the fuel consumption for every EC on a yearly basis, the OPEX is calculated. Using the CAPEX values on Table 1, CAPEX is calculated, and based on the action, the reward over time is computed. Rewards are considered to be changing every 4 years until the 12th year. In this case study 1 year equals 1 epoch. The MDP in this case study consists of:

- **states:**

- Energy converters that can be selected during the lifecycle of the vessel: ICE, FC, Hybrid.
- Substates have been defined to be able to apply extra maintenance costs after 4 years for Hybrid and FC states. Dall'Armi et al. (2022) showed that the performance of PEMFCs deteriorates after 2 years. Additionally, the lifetime of FCs shows a variation between 5000 and 10000 hours Elkafas et al. (2022). Considering the estimation variation, an extra operational is incurred every 4 years. Substates that would lead to extra maintenance were defined for the FC and the hybrid state. When entering the state of a brand new EC, it is considered that the model will transition until the year the extra maintenance cost is applied.
- Combination of states and substates generates 9 states in total that can be accessed from the agent, 1 for ICE and 4 for FC and hybrid respectively.

- **actions:**

- Switch Energy Converter: is the action of switching to an energy converter (e.g. ICE).
- Use Energy Converter: keep using the same energy converter for the next epoch.
- There are 6 actions in total, 2 for each energy converter.

**Figure 2: Architecture of modelling framework**

• **Transition probabilities**

$$\mathbf{T} = \begin{matrix} & \begin{matrix} \text{ICE}' & \text{FC}' & \text{Hybrid}' \end{matrix} \\ \begin{matrix} \text{ICE} \\ \text{FC} \\ \text{Hybrid} \end{matrix} & \left\| \begin{array}{ccc} p_{\text{ICE}} & 1 - p_{\text{ICE}} & 0 \\ 0 & 1 & 0 \\ 0 & 1 - p_{\text{Hyb}} & p_{\text{Hyb}} \end{array} \right\| \end{matrix} \quad (6)$$

$$p_{\text{ICE}} = \frac{\sum_{n=1}^{N_{\text{eff}}} \text{ICE layouts reaching the required length}}{\sum_{n=1}^N \text{ICE layouts}} \quad (7)$$

$$p_{\text{Hyb}} = \frac{\sum_{n=1}^{N_{\text{eff}}} \text{Hyb layouts reaching the required length}}{\sum_{n=1}^N \text{Hyb layouts}} \quad (8)$$

$N_{\text{eff}}$ : defines the amount of produced layouts that reach the engine room length requirement.

- Probabilities: are dependent on the action selected. Using Equation 5, the probability of an EC configuration attaining the required  $Length_{\text{engine room}}$  is computed. These probabilities change per 4 years (see Figure: 5a), as volumetric power density improvement for each EC is considered (see Figure 4). An example of the transition probability matrix definition for the action *Use FC* is given in Equation 6. For the FC state, it is set to stay in

the same state and thus a probability value of 1. For ICE, the probability of switching to FC is the remainder of the stochastic row of the  $p_{ICE}$ . Similarly, probabilities for the hybrid state are defined. To make the definition of  $p_{ICE}$  and  $p_{Hyb}$  more elaborate, Equations 7 and 8 are provided respectively.  $p_{ICE}$  and  $p_{Hyb}$  represent the amount of generated layouts per EC that reached the set Length threshold. The transition probabilities matrices are parametric and dependent on the probability distributions generated by the layout algorithm (see Eq. 4). The transition probability matrices have been kept the same both for the *Use actions* and *Switch actions* per EC.

- Probabilities for EC degradation: the probability is assumed 1 that the agent will switch to the degrading sub-states, until the extra maintenance cost (for replacing stacks of the FC) occurs.

- **Rewards:** are dependent on the action selected and the initial state, see Table 3 and the calculation of CAPEX, OPEX is done based on Table 4. For FC and hybrid, an additional maintenance cost was calculated based on CAPEX. This is set 4% of the CAPEX according to Elkafas et al. (2022) and trial and error. The  $OPEX_{maintenance}$  is applied only to FC, hybrid states when it is selected to keep using the same EC.

**Table 3: Reward definition per action**

Use Energy Converter	Switch to Energy Converter
$OPEX_{EC}$	$CAPEX_{EC} + OPEX_{EC}$

- **discount factor( $\gamma$ ):** is calculated with Equation 9 (Sheskin, 2010), and in this case study interest rate is assumed:  $i = 7\%$

$$\gamma = \frac{1}{1 + i} \quad (9)$$

**Table 4: Parameters of each computed cost**

$OPEX_{EC}$	$f(\text{fuel consumption}_{EC} [\text{tons/year}], \text{fuel cost} [€/\text{ton}], EC)$
$OPEX_{maintenance FC}$	$4\% CAPEX_{FC}$
$CAPEX_{EC}$	$f(CAPEX_{EC} [€/kW], P_{installed}[kW], EC)$

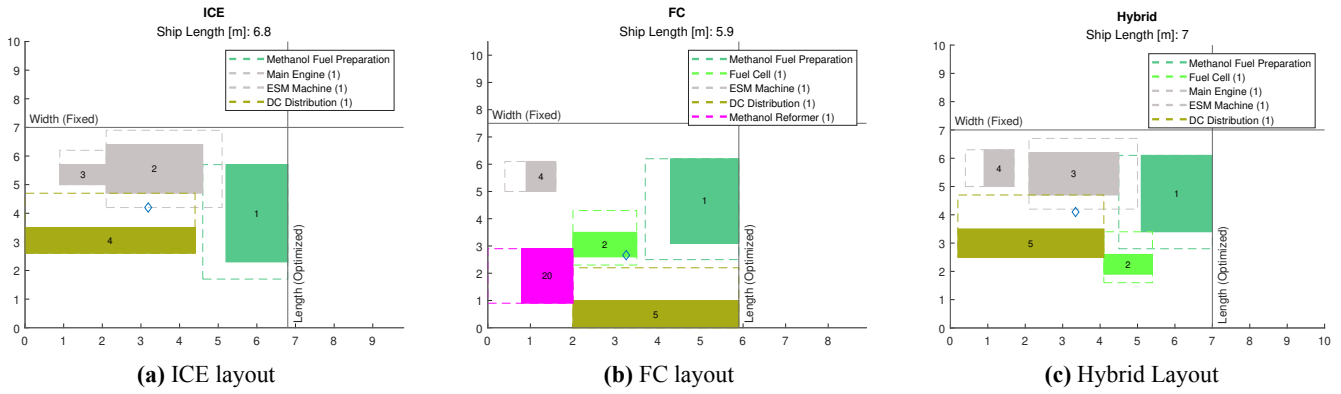

It is worth noting that MDP is memoryless, meaning that the optimal action per time step is selected regardless of the path that the agent followed to reach that state. Based on the solution of the EC decision-making problem, an analysis is conducted of the financial risks of each main Energy converter configuration choice to determine methodological insights and influential parameters to the solution trends.

## CASE STUDY

A simplified yacht engine room was selected based on the studies of Poullis (2022), and Souflis Rigas et al. (2023). Table 5 presents the components configurations that were selected to be tested per case and Figure 3 presents indicative layouts for each state, that are generated per scenario in the layout simulation. The operational profile of the vessel was set up based on a master thesis studying a yacht similar to our conceptual vessel (L. Menano de Figueiredo, 2018).

**Table 5: Engine room configurations represented per state**

ICE	FC	Hybrid(ICE + FC)
Methanol supply	Methanol supply	Methanol supply
ICE	Generator	ICE
Generator	Switchboard	Generator
Switchboard	FCs	Switchboard
	Reformer	FCs

**Figure 3:** Indicative layouts per Energy converter

## Operational Profile and EC sizing

Based on the maximum required power found in Table 6 the installed power of the ECs was determined. Table 7 presents the installed power selected for each EC state. In hybrid state, FC was sized to be able to meet the power demand during maneuvering and anchor loads (see Table 6).

The consumption was calculated using Equation 10 and the values referred in Table 8. In the hybrid state, the loads below 250 kW are assumed to be satisfied by the FC and the loads above 250 kW by the ICE.

$$\text{fuel consumption} = \begin{cases} \eta_{FC} \cdot \eta_{Reformer} \cdot Energy_{demand} & , FC \\ SFC \cdot Energy_{demand} \cdot \frac{LHV_{diesel}}{LHV_{methanol}} & , ICE \end{cases} \quad (10)$$

where:

- SFC [g/kWh]: specific fuel consumption
- LHV [MJ/Kg]: Lower heating value
- $Energy_{demand}$  [kWh]
- $\eta$ : efficiency rate of a component

**Table 6: Operational profile and yearly consumption per configuration**

**Table 8: Values assumed for consumption calculation**

Unit	Value]	Reference
sfc [g/kWh]	205	(Warsila, 2024)
$\eta_{FC}$	0.58	(Elkafas et al., 2022)
$\eta_{Reformer}$	0.82	(RIX, 2024)
$LHV_{methanol}$ [MJ/kg]	19.9	(Harmsen, 2021)
$LHV_{diesel}$ [MJ/kg]	42.7	(Trancossi, 2015)
$sailing_{time,year}$ [h]	2600	(L. Menano de Figueiredo, 2018)

Considering the uncertainties in volumetric power density of the main ECs (see Table 1), the length and width of the ECs were sampled in the probabilistic layout tool with steadily reducing uncertainty margins changing every 4 years as shown in Table 9. The uncertainty margin is reduced to account for the potential technology development during the lifecycle of the vessel. Figure 4 illustrates the actual distribution of volumetric power densities ranging from 5% to 40% depending on the epoch and the technology. 40 % FC means that there was a 40 % uncertainty range for the width and length of the FC system.

**Table 9: Dimension uncertainty margins per epoch per EC**

Year	ICE [%]	FC [%]
0	30	40
4	20	30
8	10	20
12	5	10

To derive the dimensions of the ECs, a PEMFC model of Ballard (2024) was selected as a reference case, and a 4 stroke high-speed engine by Warsila (2024) for the ICE. Their dimensions are shown in Table 10. ICE is assumed to be a methanol-only ICE, and the FC a PEMFC. Dimensions for the additional layout components are shown in Table 11. By fixing the EC height and installed power, the volumetric power density uncertainty is matched to uncertainty margins in the EC's width and length. Using the probabilistic layout tool developed to better understand its effect on the overall size of a simplified engine room, this uncertainty can be integrated within the MDP as a factor reflecting on technical uncertainty and systems integration challenges.

**Table 10: Reference dimensions for energy converters**

Energy Converter	L [m]	W [m]	H [m]	Power [kW]	Power Density [ $W m^{-3}$ ]	Reference
FC	1.20	0.87	0.51	100	189.52	Ballard (2024)
ICE	2.3	1.4	1.8	865	149.24	Warsila (2024)

**Table 11: Auxiliary systems dimensions ranges**

Building Block	Length [m]	Width [m]
Methanol Fuel Preparation	2.6 - 3.5	1.6 - 2.1
ESM Machine	1.1 - 1.4	0.6 - 0.9
DC Distribution	3.8 - 5.1	0.8 - 1.1
Reformer	2-2.4	1-1.2

## MDP implementation

The MDP time horizon is set to 20 years to observe how the actions are converging. From year 0 until year 12, there is an update of the probabilities per state, the CAPEX and the OPEX, as shown in Figure 5. The inputs are kept constant to evaluate the convergence of the MDP solution.

**Figure 4: Comparative plot of EC volumetric power densities distribution per epoch**

Figure 4 illustrates that ICE has a smaller power density variation than the FCs, which is in accordance with the uncertainty margins found on Table 1. The required engine room length is set to 6.52 m based on the mean engine room length of the 30 % ICE case. The computed probabilities for each EC are shown in Table 12 and Figure 5a. Similar volumetric power densities were used for the Hybrid state calculations. It is clear that the FC state displays the highest probabilities and these probabilities depict a similar trend to the trends of volumetric power densities in Figure 4.

**Table 12: Probabilities per state per epoch**

Energy converter	Yeat 0	Year 4	Year 8	Year 12
ICE	0.382	0.389	0.458	0.534
FC	0.756	0.779	0.699	0.751
Hybrid	0.023	0.037	0.080	0.080

**Figure 5: Inputs for finite horizon Markov decision process**

Figure 4 illustrates the evolution assumed in the volumetric power density of the ECs according to the tightening dimension uncertainty margins selected per time step (Table 9). Volumetric power density is calculated with Equation 1, by fixing the height of the EC and using the installed Power per state (Table 7) and using the variable length and width of the ECs per scenario (see Table 9). To make the layout solution comparable, it was assumed that FCs can be stacked on top of each other, meaning an overall height  $H = 3$  m. Similarly, the reformer in the hybrid configuration is considered packed within the FC unit. ICE height was set to  $H = 1.8$  m according to the reference engine (Table 10).

Table 12 and sub-Figure 5a illustrate that FC has the relatively highest probability of integration in accordance with the higher volumetric power density displayed in Figure 4. From a methodological point of view, the interest lies on observing which kind of actions are selected depending on the newly proposed way of defining the transition probabilities according to Equation 5. The state FC that had more increased power densities presented the highest probabilities of layout integration through time, and the switch to that state was selected on several consecutive steps from the hybrid state, in spite of the extra maintenance cost per 4 years. Additionally, state ICE displays a period of 4 years potentially switching to FC, but selects again *Action: Use ICE because of the extra maintenance cost*.

CAPEX and OPEX for each technology were calculated using Equations 11 and 12. Methanol cost is assumed to be constantly decreasing from 525 [€/ton] in year 0 to 300 [€/ton] by year 12 (MARIN, 2024). The specific CAPEX is set according to the values on Table 1. The trend of the CAPEX and OPEX cost are presented on Figures 5b and 5c.

$$CAPEX_{year,EC} = CAPEX_{EC} \cdot P_{installed} \quad (11)$$

$$OPEX_{year,EC} = fuelconsumption_{year,EC} \cdot fuelcost \quad (12)$$

Figure 6 provides an action pathway for each state of the MDP. In this case, 2 extra states (FC0.25 and hybrid0.25) are plotted to reflect the degradation of *FC* and *Hybrid* states. In these states, the extra maintenance cost is applied, and because of that, a switch to another EC may occur. Figure 6 shows that the switch to FC is the optimal decision for the *Hybrid* state in several years, which is explained both by the lower OPEX costs that FC offers in comparison to hybrid as well as the much lower probabilities of hybrid layout fitting - see Figure 5. Additionally, the action switch to FC becomes optimal after year 12 for state ICE, which is explained by the convergence of the CAPEX costs for the technology adoption (see Figure 5b). Lastly, a switch action is not selected at all for *FC* state, which is justified by the highest probability of reaching the required engine room length and the relatively low OPEX.

**Figure 6: Policy map indicating optimal action per state and per year**

Complementary to Figure 6 that prescribes an action path for each state per year, Figures 7, 8, 9 represent the optimal state accessed based on following the actions derived from the MDP policy pathway. This metric was developed based on Kana et al. (2015) and provides the optimal state to select, given a starting state. The colorscale on the side indicates the probability of being in that state, with red meaning 100 % chance and blue meaning 0 % chance. In Figure 7, ICE was selected as the starting state and shows that FC starts being the optimal state after year 12, which is in agreement with the policy of Figure 6. When selecting FC as the initial state, Figure 8 illustrates that FC is the optimal state to be selected. Lastly, Figure 9 demonstrates that for hybrid as the initial state, the switch to FC becomes the optimal after year 4 after completing the degradation phase that is modeled with substates hybrid0.75 to hybrid0.25. This result is in accordance with the policy map produced by the MDP in Figure 6. Figures 6, 7, 8 and 9 prove that both the high layout fitting probabilities, as well as competitive actions rewards, are necessary for a *switch action* to take place. For the ICE initial scenario, the FC state becomes optimal after the interval between the states' CAPEX cost has been zeroed.

**Figure 7: Optimal state accessed per action using ICE as initial state**

**Figure 8: Optimal state accessed per action using FC as initial state**

**Figure 9: Optimal state accessed per action using hybrid as initial state**

Figure 10 is used to plot the cumulative expenses that arise per state if the agent follows the policy proposed per epoch in accordance with Figure 6. To make a reasonable comparison, the most degraded substates of hybrid (Hybrid0.25) and FC (FC0.25) were plotted, in which the  $OPEX_{maintenance}$  was applied. Figure 10 shows that FC has the lowest cost, in spite of the extra maintenance cost introduced every 4 years. Also, the cumulative cost deviation between the different states remains around 100.000 €, which is relatively small for a 20-year period. The relative cost convergence can be explained by the selection of *actions*: Use EC and not having to switch to other ECs. To have more robust outputs, the need for more detailed rewards calculation arises.

**Figure 10: Cumulative cost for each EC option, when adopting the policy of the MDP decision matrix**

## DISCUSSION

The method presented is an attempt to integrate within a MDP framework, the technical uncertainties that are overlooked in lifecycle studies evaluating alternative configurations for a decarbonized vessel. The probabilities that reflected the integration challenges proved influential as the energy converter (FC) with the highest probability was the only one that the other two states may switch to in the future. Decisions are highly impacted by the reward vectors set for each action, meaning that the bigger differences in Capex costs for technology adoption during the first years of the case study prevented the switch action from being selected for ICE. The extra maintenance cost accounting for FC degradation did not prove triggering enough to cause a switch action and should be modeled in more detail. For more insightful results, a model of higher accuracy for the consumption costs should be applied that can integrate variable EC efficiency rate parameters and compute costs based on produced emissions per EC. Additionally, the selected type of vessels and its power profile influence the OPEX per technology and thus it is valuable to investigate the policy that would come out for alternative operational

profiles. Complementary to that, the probabilistic layout tool can be further advanced to handle scenarios with more components and possible system architectures, to increase the reliability of the predicted probabilities. Keeping in mind that this paper focused on applying a novel methodology to combine two normally disassociated tools - a lifecycle model and a probabilistic layout modeling tool, the core idea has proved to function successfully when applied to a proof of concept.

## CONCLUSIONS

This paper outlined a way to further advance the lifecycle evaluation of the alternative fuelled PPEs by accounting for ECs' technical uncertainties that have traditionally been disregarded by the state-of-the-art research. The uncertainty quantification of systems layout integration challenges combined with the constant evolution of ECs technologies, led to the proposed method which has advantages worth highlighting. Markov Decision processes offer a very clear structure in which inputs from other models can be integrated and generate insights into decision pathways of PPE configurations towards a decarbonized ship design. The transition probability matrix, relating to selected actions, offers a clear structure to model the stochastic probability of the decision to switch or use a PPE technology based on its fitting to the layout. The reward vector can reflect on costs arising for the adoption of each technology. The MDP produces insight to the evolution of decisions within the lifecycle of the vessel. The coupling of MDPs with the probabilistic layout tool is a method that can account for technical, environmental, and financial uncertainties. The EC case study demonstrated that the probabilities defined for each EC based on their layout, paired with the computed EC costs, strongly influence the optimal decision pathway. The presented method sets the base for further development of both the probabilistic layout tool and the MDP, as well as their coupling, to produce insights for design pathways to be selected towards decarbonization with alternative fuels.

# **An Evaluation of System Modularity and Interface Standards as a Means for Continued Platform Level Relevance**

**Jason D Strickland, PhD, PE, FSNAME<sup>1,\*</sup>**

## **ABSTRACT**

This paper will develop a descriptive working definition of modularity regarding ship systems. An effort will be made to expose the underlying motivation and attractiveness of modularity in naval vessels utilizing economic salvage value and continued operational relevancy. A survey of 50 years of modern system development in support of modularity will be supported by a historical case study. The historical analogy will focus on the concurrent development of platforms and weapon systems during the age of sail. Specific focus will be given to platform developments and the advent of marine artillery and their associated technological development. The insight developed will then be applied to two modern naval corollaries.

## **KEY WORDS**

Modularity, Naval Design, Weapons Systems, System Design, Decoupled Architecture

## **MOTIVATION**

The first section of this paper will develop a descriptive definition of modularity along six continuums: 1) Componentization, 2) Architecture, 3) Configurability, 4) Flexibility, 5) Interface Points, and 6) Allocation. An effort will be made to expose the underlying motivation and attractiveness of modularity in naval vessels utilizing economic salvage value and a less tangible ship effectiveness. Finally, the first section concludes with a look at investment duration by project for the last five decades relating to the development of architectural standards and why many modern modularity efforts have failed to produce the envisioned results.

The second and third section of this paper develop a historical analogy and review modern corollaries, respectively. The historical analogy will focus on the concurrent development of platforms and weapon systems during the age of sail. Specific focus will be given to platform developments and the advent of marine artillery and their associated technological development. The final section presents two modern modularized naval vessels and will assess their success of integrating modularization, considering these historical lessons learned.

It is the goal of this paper to illuminate several critical factors in determining the success or failure of a modularization effort on the scale of a modern naval vessel. To this end, this discourse is driven by four motivational questions:

1. What is the allure of system level modularity for ships?
2. How does an architectural standard develop to support sustained modularity?
3. Why have modularity efforts failed to date?
4. What can we learn from historical implementations of modular system architectures in the marine environment?

## MODULARITY DEFINITION

Let's begin our analysis of system level modularity and impact that it potentially may have on a modern naval vessel with a standardized definition set. What exactly is modularity? We will double back to the guiding questions outlined in the motivation once we establish a baseline vernacular. To begin with modularity is an imprecise term. As such it has a multitude of meanings dependent upon the context of the discussion. (Kubota et al., 2017; Schank et al., 2016) For the purposes of this discussion, I would like to define modularity along six continuums: 1) Componentization, 2) Architecture, 3) Configurability, 4) Flexibility, 5) Interface Points, and 6) Allocation. While several of these concepts are potentially understood I will expand upon each to maintain clarity.

1. Componentization is the degree to which the end unit system is comprised of segregable subunits. This concept is the underpinning of modern software development approaches, define a self-contained reusable block of code that is insulated from changes in the rest of the stack. (Baresi & Miraz, 2011) For this discussion which is focused upon hardware systems componentization will range from *sparse* to *prevalent*.
2. Architecture is the degree to which new components can be integrated into the overall system. (Elmenreich, 2007) An architecture can assume values between *closed* to *open*. Theoretically in a completely open architecture any new component could be easily incorporated into the existing system. This does have some limitation in application.
3. Configurability is the degree to which subsystems and components can be dynamically arranged. (Balka & Wagner, 2006) Configurability can be scored on the continuum from *unconfigurable* to *adaptive*. It is important to note that each new configuration needs to function for an intended purpose.
4. Flexibility can be considered the number of functional uses for a single component or subsystem. (Lafou et al., 2016) Flexibility is scored between *limited* to *versatile*. While higher levels of flexibility are typically a good thing, the versatility of an object typically comes at the expense of another system attribute.
5. Interface points are either *customized* or *standardized*. One might be wondering what the gradation between these end points. An example of an interface point that is partial standardized and partially customized would cell phone chargers or USB 2/3 A-plugs. While the form factor is the same the power and data rates vary greatly depending on the standard that is being employed.
6. The final continuum definition has to do with the system level allocation or more specifically the requirement that is being addressed with this subsystem, this value can be assessed between *single use* to *multipurpose*.

While this six-vector scoring system is not likely to incorporate all the features that a designer would be concerned about during the integration of a complex system, it does begin to outline some of the major factors for the consideration of modularity and the influence of that modularity upon the rest of the ultimate system. Some notable exceptions would be system level mission effectiveness, space and weight considerations, and ultimately total system level cost. Now that a vernacular has been developed let's revisit the motivation and explore some recent efforts in sustaining system level modularity.

## WHAT IS THE ALLURE OF SYSTEM LEVEL MODULARITY FOR SHIPS?

As highlighted in the prior example the cost versus capability of an upgrade in context with the service life of the total system creates the trade space for a modularity reasonableness assessment. If you consider the traditional economic concept of salvage value in conjunction with the fact that a ship is not a singular end system but truly a system-of-systems, the modularity of the subsystems becomes an imperative for continued operation.

First let's address the concept of asset depreciation and salvage value. The basic formula for calculating salvage value of an asset can be found in any engineering economics textbook or various other sources. (Eschenbach, 2011) Equation 1, below represents a simple declining balance depreciation approach.

$$S = P(1 - i)^y \quad [1]$$

The salvage value,  $S$ , is the product of the present value of the asset,  $P$ , and value retention rate,  $(1 - i)$ , raised to the number of years,  $y$ . If one begins with a present value of \$1B and applies a constant depreciation schedule (DBD) of 10% annually (TR 2021/3, 2021) the salvage value is approximately \$42M at the end of 30 years or 4.2% of the initial value. However, if one applies a compounding custom schedule depreciation (CSD) behaving similar to Moore's Law that doubles every decade, the salvage value is nearly \$200K or 0.02% of the initial value.

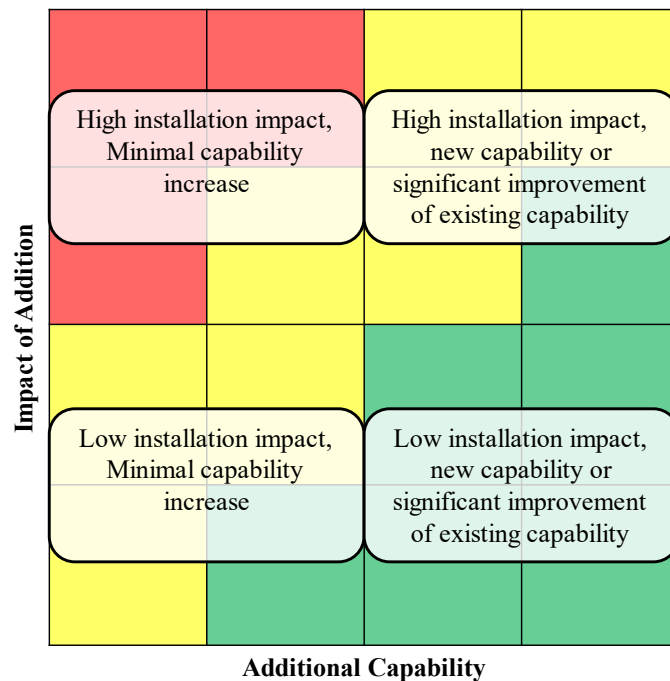

The custom schedule depicted in CSD data presented in Figure 1, applies a 10% depreciation for the first decade, a 20% depreciation for the second decade, and a 40% depreciation for the third decade. This acceleration in depreciation can be largely attributed to vessel wear and tear and system level obsolescence. The accelerated rate of obsolescence and depreciation is particularly applicable to military vessels, a bulk carrier would not be as dramatically affected by technology modernization.

**Figure 1 - Salvage Value with Respect to Time**

While this is only part of the picture it does start to bring into the focus the financial side of the discussion. In short how much will the proposed upgrade cost versus the cost of the vessel. This starts to drive at a fundamental question that should be asked before a system upgrade commences. Is it worth the expense given the current value of the asset? It is acknowledged that salvage value is an artifice of economics, just because an asset has zero value on the books doesn't mean that it has no capability. Specifically in the context of working ships and military vessels capability is often the point. So, if the upgrade passes the initial cost-based litmus test, then the conversation returns to cost versus capability. While this gets more subjective there are some basic ground rules that should be employed. Consider a 4x4 grid with Additional Capability on the horizontal axis and Impact of Addition on the vertical axis. Then each block would roughly represent quartiles. The low end of the Additional Capability scale would be replacement in kind systems or software upgrades. The high end of this scale would be wholly new capabilities such as new weapons systems, launch and recovery systems, or automation approaches. The low end of the Impact of Addition could be bolt on systems that do not require an availability in a shipyard. The high end of this scale is a multi-year yard period with a complex or total overhaul. With these end posts, Quadrant 1 would represent high installation impact for a minimal capability increase. This is largely an area to be avoided for maximizing end product capability. Quadrant 2 would represent high installation impact but the addition of a potentially game-changing new capability. Quadrant 3 has low installation impact with a minimal capability increase. This leaves Quadrant 4; low installation impact and significant capability increase. Quadrant 4 is the optimist's corner, high payoff with low cost. Upgrades that fall into this area should be executed once they pass the previous financial screening. Figure 2 below summarizes this construct.

**Figure 2 - Capability - Impact Scoring**

“Note that while there has been considerable progress in maturing technology, no single technology has successfully met all the criteria for being institutionalized.” (Doerry, 2014) In Figure 3 it can be seen how the total ship effectiveness is maintained and augmented by individual system additions across a span of 25 years. In this case since the design interface standard was locked to a MK41 Vertical Launch System incremental improvement was possible as technology matured across the complete system. However, if there was not a definitive standard such as the MK41 this story may have been much less compelling, this is also supported by historical development.

**Figure 3 - Ship Effectiveness: SEAMOD vs Conventional (Abbott, 2006)**

A. MODERNIZATION VIA SYSTEM REPLACEMENT

B. INCREMENTAL MODERNIZATION AT THE COMPONENT LEVEL

Figure 4 - Incremental Modernization Prior to Systems Obsolescence (DREWRY, 1975)

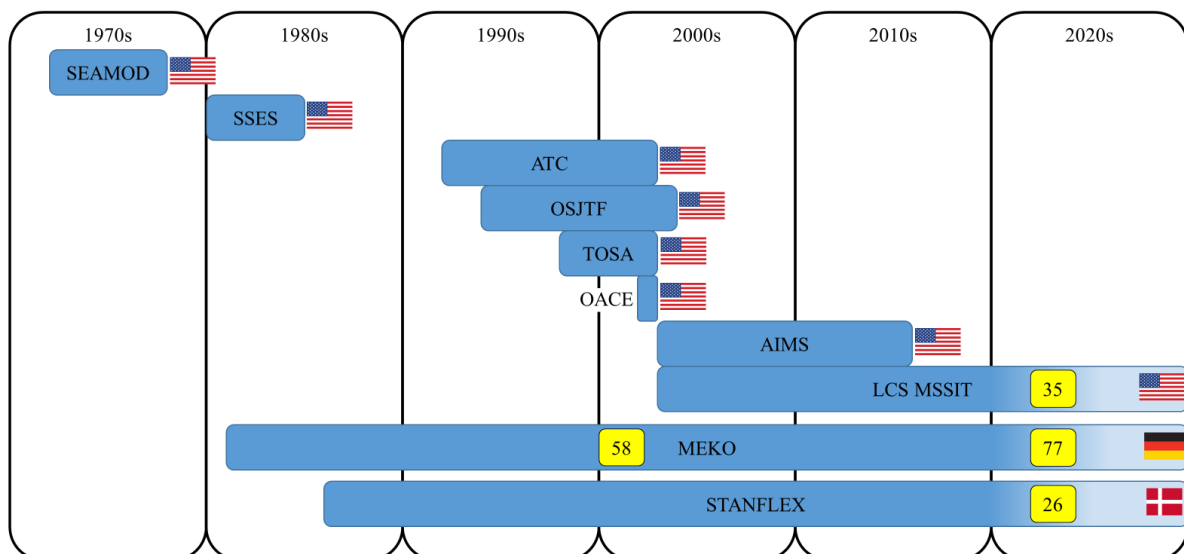

Figure 4 - Incremental Modernization Prior to Systems Obsolescence (DREWRY, 1975) illustrates an idealized scenario in which “incremental modernization at the component level” are made on a consistent basis to maintain the overall “military worth” of the vessel across the service life of the ship. This is proposed in contrast to the “modernization via system replacement” approach. The challenge with this approach is it requires an immense amount of consistency across the life of the class, and it assumes a linear technology growth path. Both are potentially flawed assumptions.

This section has looked at what system modifications should be entertained based upon the capability enhancement and the impact of installation, what are the alternative fielding strategies for modifications, and an example of incremental upgrades in a fielded system. This sets up the next discussion point.

## HOW DOES AN ARCHITECTURAL STANDARD DEVELOP TO SUPPORT SUSTAINED MODULARITY?

The US Navy has had sporadic efforts related system level modularity in naval vessels since 1972. (Schank et al., 2016) The following bullets provide a synopsis of US Navy efforts in the establishment of a modular architectural standard.

- 1972 – 1978: Sea Systems Modification and Modernization by Modularity (SEAMOD)
  - Focused on modularized combat systems
  - Results were encouraging but required an overhaul of business and design practices
  - DD963 (com. 1975) and FFG7 (com. 1977) baseline ships under evaluation
- 1980 – 1985: Ship Systems Engineering Standards (SSES)
  - Focused on interface standards and variable payload systems
  - DDG51 (com. 1991) was the baseline for this effort
- 1992 – 2003: Affordability Through Commonality (ATC)
  - Focused on the reduction of acquisition and life cycle cost
  - Fleetwide implementation vice specific baseline
- 1994 – 2004: Open Systems Joint Task force (OSJTF)
- 1998 – 2003: Total Ship Open systems Architecture (TOSA)
- 2003: Open Architecture Computing Environment (OACE)
- 2003 – 2015: Architectures, Interfaces, and Modular Systems (AIMS)
  - Focused on a future implementation of modularity vice a backfit scenario

**Figure 5 - Global Modular System Efforts (Strickland, 2023)**

“The DDG 51 Class, which was supposed to be limited to 8,300 tons full load to show it was smaller than the preceding CG 47 cruiser class, was not fitted with extensive modularity for that reason. Only the 2 VLS weapons were built to Ship Systems Engineering Standards (SSES) Interfaces.” (Garver et al., 2011)

Figure 5 illustrates to scale, the time span of efforts of the US Navy, Thyssen Krupp Marine Systems (TKMS) Mehrzweck-Kombination (MEKO) (Thyssen Krupp Marine Systems, n.d.), and Royal Danish Navy (RDN) Standard Flex (STANFLEX) (Harboc-Hansen, 1992), while this does not represent the total volume of funding expended it does begin to illustrate two key points. The first is that a steady state development absent of temporal breaks produces better results in terms of number of full systems delivered. The second is that there is not a single approach. Both the US Navy and the RDN have subscribed to an encapsulated subsystem that can be removed and replaced depending on the platform mission set and the need at present. This contrasts with the TKMS MEKO system that has less overall flexibility but creates standardized “sections” to produce vessels in support of customer requirements. This approach of modularized sections has been well received on the global market with 2-3 times the number of ships produced above encapsulated subsystems. The numbers in the yellow boxes on Figure 5, represent the total number of vessels delivered with these inherit features. This is somewhat misleading because the MEKO vessels are full systems complete with associated combat systems, and in some cases for the US Navy and RDN vessels the combat systems is dependent upon the installation of a mission module governed

by a separate procurement. (Piñeros Bello & Segovia Forero, 2020) This construct of decoupled weapon systems and vessel design is not novel. The basic premise of allowing each to progress along a desired development path and then integrate them also brings a series of opportunities and challenges.

## **WHY HAVE MODULARITY EFFORTS FAILED TO DATE?**

It is hard to discuss system level modularity without being drawn to the IT sector. In order to illuminate this critical question, I will begin this section with a personal anecdote. When I first started buying my own computers in the late 1990s, I realized that the rate of development and change was hard to keep pace with and there was the balancing act of being a cash strapped college student. As such I chose a tower chassis that had several expansion slots for additional RAM and PCI cards. In turn I continued to upgrade that machine utilizing the system level “modularity” of the PC market. After a RAM upgrade, a HDD, a sound card, a video card, and a modem, I reached the functional limit of the machine. While the process of upgrading a machine was gratifying, after the fact I still needed to replace it. While I continued to increase the relevance of the machine over time the cost of the upgrades was clearly in excess of the total cost of a machine that had these upgrades at the beginning. Further once you factor in the personal time in trouble shooting software compatibility issues it was far cheaper to purchase the end product at the beginning. This is the first axiom of modular systems. The cost over time of the end item is greater utilizing modular upgrades than the initial purchase cost of an upgraded system.

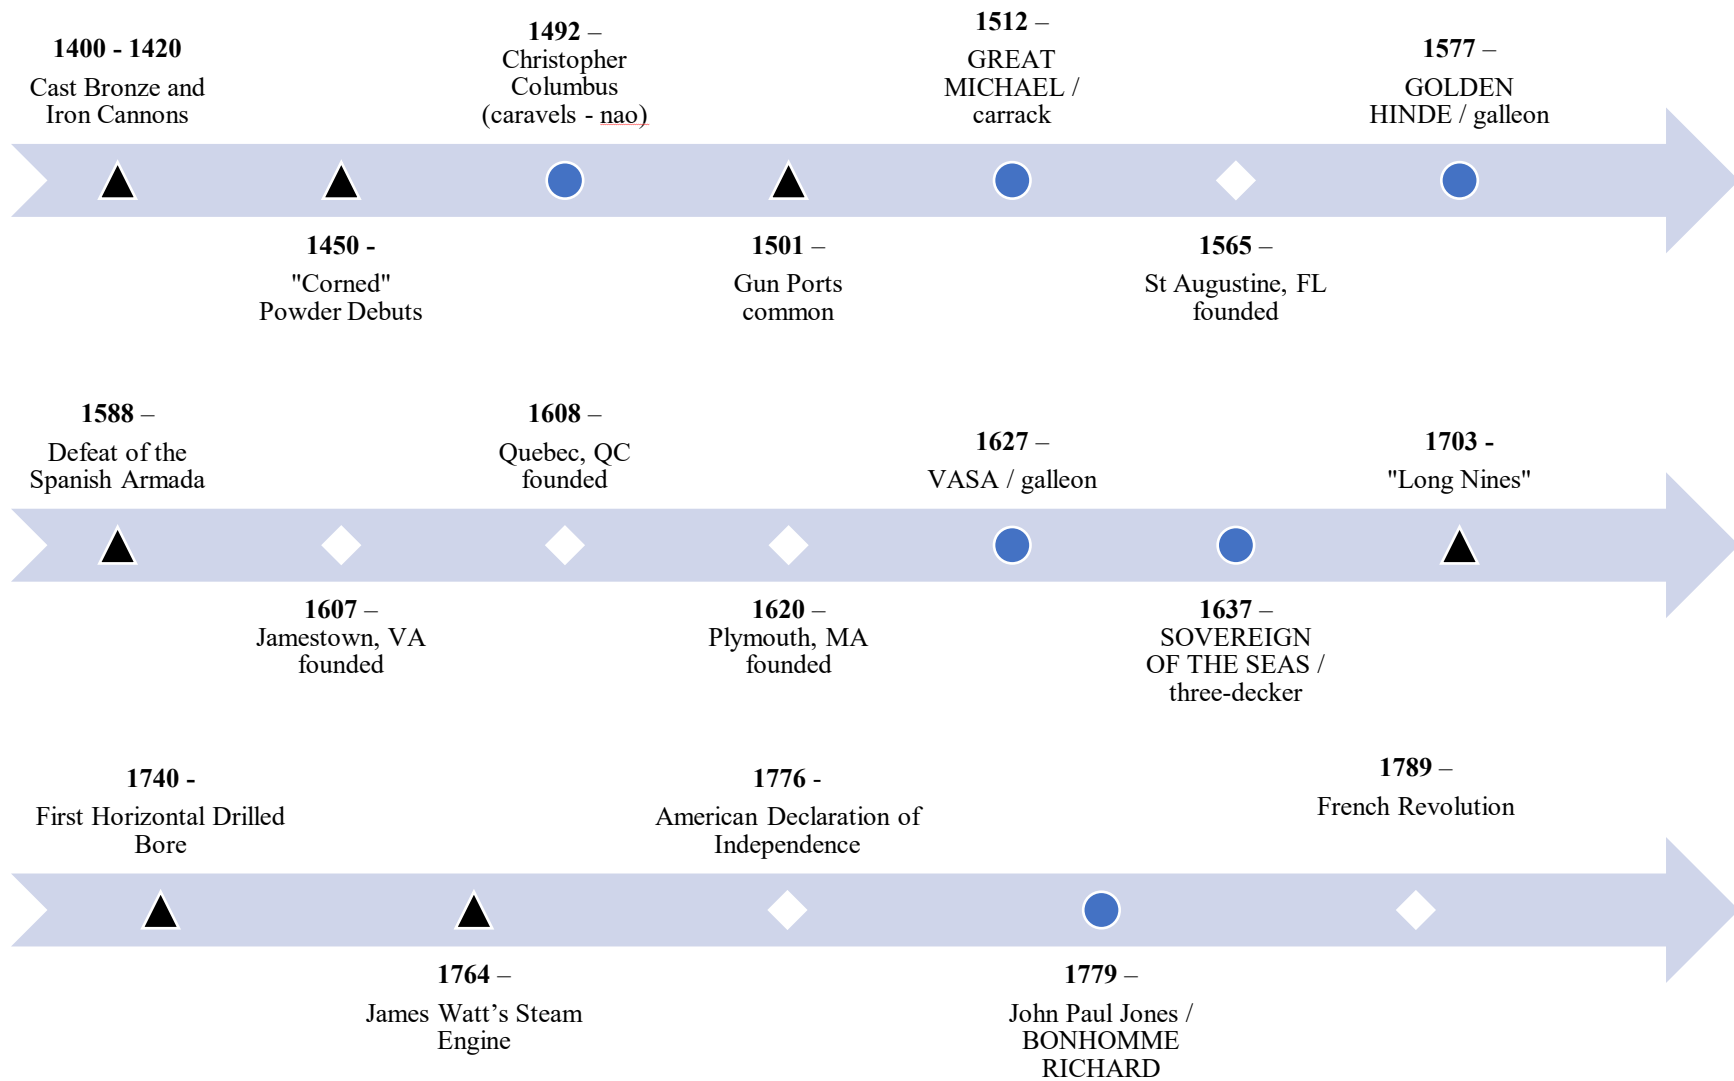

But there was a larger failed premise underlying this learning exercise. The machine was going to continue to be relevant even after all possible upgrades had been made. While the interface standards remained consistent during the personal example above, and many of those standards are still in use almost 30 years later the incremental upgrades could not keep pace with the component rate of change. I believe that this is one of the fundamental sources of failure in total system level modularity.

While interface standardization and commitment are necessary conditions, they are not fully sufficient for successful implementation on modularized systems. Even with the necessary conditions met one needs to balance the cost vs the capability of the system upgrade. Back to the PC example, if it is determined that the service life of the machine is five years, this adds a context to support the tradeoff of cost versus capability. With the addition of Moore’s Law, it can be shown that within the five-year service life of the machine, the industry standard computing power quadrupled. So, the question becomes is the cost of the upgrade going to increase the relevance of the total system to a point that is on par with the current industrial standard. The answer is unfortunately no. While the modular upgrade may add a new capability or even improve an existing capability it will not be competitive with the current market standard.

This brings us to the second axiom of modular system failure; piece meal system acquisition will never keep pace with the developmental capability of new production. The computer growth issue highlighted by Moore’s Law is just one component of total system level capability maturation scheme. This axiom has transcended computer systems into mechanical systems at this point. The automobile industry is a great example of the last point. New vehicles have hundreds of processors and are incapable of operation if the Electronic Control Unit is offline. (Charette, 2021)

## **HISTORICAL ANALOGY: AGE OF SAIL AND MARINE ARTILLERY**

During this 400-year period of history it is the height of European colonialism, a great power competition, and a technological development race. The renewed focus on scientific pursuits from the Renaissance and the Great Enlightenment ultimately culminated in the Industrial Revolution. This is the backdrop for the historical analogy. See Figure 6 - Timeline of key developmental events.

**Figure 6 - Timeline of key developmental events; In the above figure entry symbols represent the following: ▲ technological advancements that influenced maritime system development; ● significant vessels discussed within the context of this paper; ◇ major geopolitical events that impacted naval systems and maritime system development**

## European Colonialism

For this discussion the colonialization of North America is representative of the broader world stage. On Figure 6 there are six events represented by a diamond. The first four of these events represents the establishment of permanent settlements in North America by the Spanish, English, and French. St Augustine (Spanish) (*Our History | St. Augustine, FL*, 2023), Jamestown (English) (US National Park Service, 2022), and Quebec (French) (Mendel, 2022) were the new focal points in a struggle between these three countries that dated back hundreds of years at this point. The founding of Plymouth, MA is interesting for several reasons. First the MAYFLOWER was a hired transit, while they did need permission to build a colony it was not strengthen the position of the European Monarchs via trade routes and raw materials. The final two diamonds are the American and French Revolutions. These resulted in massive changes to the geo-political fabric of the time and helped to fuel the great power competition underway by destabilizing the established order.

## Technological Development Race

To continue to support the competitive nature and massive expansionism, new technologies were being developed and fielded almost constantly. Any advantage or technological edge could make an enduring difference in the power race. From a naval perspective two technology trends need to be discussed, the advancement of sailing ships and marine artillery. These technology milestones are marked by circles or triangles respectively, see Figure 6.

“During the Hundred Years' War (1339-1453) cannons came into general use. Those early pieces were very small, made of iron or cast bronze, and fired lead or iron balls. They were laid directly on the ground, with muzzles elevated by mounding up the earth. Being cumbersome and inefficient, they played little part in battle, but were quite useful in a siege.” (Manucy, 1949) In the early part of the 15<sup>th</sup> century artillery manufacturing obtained a critical breakthrough, casting of iron and bronze of ever increasing size. (Dana, 1911) In this same timeframe the transition from a ground-based siege weapon to a naval weapon was well underway. (Devries, 1990) In fact by the turn of the 15th century, most English ships of any size were equipped with powder fired weapons. (Devries, 1990) It should be noted that these weapons were mounted on the topsides of the vessels and cannon/gun ports do not become prevalent until vessel construction moves away from clinker type hulls. The technological advance of casting muzzle loading cannons is met with the development of corned powder, “corned powder develops its propulsive force far more quickly than a tightly packed charge of dry-mixed, or serpentine, powder” (Guilmartin, 2007) This massive increase in the effectiveness and consistency of gunpowder allowed for greater range and control of the combustion in support of artillery operations.

On the timeline this brings us to Columbus' voyage to North America, possibly one of the most fortuitous mistakes of history. But the focus for this discussion is on the three vessels utilized in the 1492 crossing. The Nina, Pinta, and Santa Maria were two caravels and a carrack / nao, respectively. The caravel class of vessel began to use carvel construction approach vice the previous clinker type hulls. These smoother hulls proved durable, agile, and faster than their rougher predecessors. This is largely why the caravel became a popular platform for exploration and trade. Figure 7 illustrates a model of a caravel likely in a typical rigging pattern. The caravel's prominence was supplanted by the larger carrack. Larger in every dimension the carrack was like a caravel in construction with the addition of a focsle. Figure 8 illustrates the squared rigged sails forward with the prominent focsle. These vessels maintained the aft lateen sail.

**Figure 7 - Three masted caravel with lateen rigged sails (Deutsches Historisches Museum, n.d.-a)**

**Figure 8 - Three masted carrack / nao with square rigged sails forward and lateen sail aft**

With carvel construction as the dominating European approach, smooth hulls with carefully carved butt joints between planks affixed over a series of deep frames, the stage was set for the next advancement in naval artillery. The relocation of guns from the topside is largely due to the advent of gun ports. By the early 1500's gun ports were a predominant feature in naval designs. (Skaarup, 2021) The GREAT MICHAEL (Newhaven Heritage Centre, n.d.) and the MARY ROSE (Mary Rose Trust, 2023), both launched 1511, featured extensive armament via gunports below the weather deck.

As the GREAT MICHAEL and the MARY ROSE began to maximize the capacity of the carrack, the next evolutionary step was devised in the platform. The galleon's length was increased to support an additional mast and provide better seakeeping and resistance characteristics without a reduction in cargo fraction. (Deutsches Historisches Museum, n.d.-b; Mariners' Museum and Park, 2023). These vessels were specifically designed to support military operations and open ocean transits. "The Golden Hind, an English galleon launched in 1577 and best known for her privateering circumnavigation of the globe between 1577 and 1580, captained by Sir Francis Drake" (National Historic Ships UK, 2023) is a great example of this design marriage. The purpose of Golden Hind was to sail the oceans and raid Spanish settlements further supporting the building international competition to colonize the globe. Upon Drake's return tensions between the English and Spanish were at an all-time high. These tensions culminated with the English defeat of the Spanish Armada. This historical milestone was not solely predicated on technological advancements but on the employment of innovative new tactics. "In 1588, Spain's King Philip II ordered a naval invasion of England. Philip's Spanish Armada of 124 ships, 27,000 men, and 1,100 guns departed from Lisbon on May 30, 1588. England meanwhile, led by Queen Elizabeth I, readied a counterforce of 197 vessels, 16,000 men, and 2,000 guns." (Adams, n.d.) The English had the advantage of numbers in ships, but they were smaller and more agile than the landing force galleons employed by Spain. A fundamental shift in tactics made all the difference in the outcome. "To the Spanish, ships were floating fortresses to be grappled and taken at sword's point, but to the English, they were fast and maneuverable gun platforms." (Niderost, 2007) This new style of naval combat, maintaining a standoff and pummeling your opponent with gun fire, remains a prevalent tactic. We have however just increased the standoff distance and engagement speed with missiles. This decisive victory cemented the cannon's place in naval artillery as a ship-to-ship weapon not just a tool for shore bombardment.

The first half of the 17<sup>th</sup> century is marked by another expansion of platforms to support naval artillery and longer sailing distances at speed. The ship of the line had become the preferred battle tactic and quite often the vessel with the most guns won. Most vessels in this role during this time were galleons with one or more full gun decks. Let's look quickly at two such ships in the pivotal time. The VASA was a galleon, with a traditional design and a single gun deck. The original design was to carry thirty-two 24-pound guns. (Fairley, n.d.) During the construction revisions to the design added a second deck and another thirty-two 24-pounders (5,600 lb. / cannon). (Kessler et al., 2001) This

raised her effective center of gravity. Further ships were a symbol of national pride and as such they were extremely ornate. This also created an increase in the center of gravity. The vessel's maiden voyage lasted 1,300 meters, before capsizing in 1628. The SOVEREIGN OF THE SEAS was a three-decker, meaning she carried three full gun decks. She had very similar ornate decorations and an increased capacity from her predecessors. The SOVEREIGN OF THE SEAS served in multiple campaigns from 1637-1696. (Holmes, 2010) Table 1 allows one to compare the principal characteristics of the VASA to the SOVEREIGN OF THE SEAS. One should note that there is only a decade between the launch dates of these vessels. Further the VASA would have been one of the most aggressively armed vessels of the time, although the SOVEREIGN OF THE SEAS had a 55% increase in the total number of cannons with a modest increase in total displacement. Finally, if the cannon designations seem confusing, it is because they are nonstandard. Every country at this time forged their own barrels and mass standardization of barrel length, bore diameter, shot weight, and other key attributes of marine artillery were not standardized until the middle of the 18<sup>th</sup> century. (Berkowitz & Dumez, 2016; Henry, 2009; Manucy, 1949) The end of the 18<sup>th</sup> century effectively marks the end of the golden age of sail. With the advent of the steam engine, and the further geopolitical unrest the stage was set for the next major development modification of platforms. This conjoined development process of weapon systems and platforms continues to this day. While there are almost endless volumes of historical examples that could be evaluated. Let's use the balance of the discussion to examine a few select modern corollaries considering this context.

**Table 1 - Comparison of VASA to SOVEREIGN OF THE SEAS (Holmes, 2010; The Vasa Museum, 2015)**

	Vasa	Sovereign of the Seas
LOA	155.8 ft	167 ft
Beam	38.4 ft	48.3 ft
Depth	63.3 ft	76 ft
Displacement	1210 tons	1683 tons
Armament	Lower Deck 28 x cannons (24 pdrs) Upper Deck 22 x cannons (24 pdrs) Weather Deck 2 x cannons (1 pdrs) 8 x cannons (3 pdrs) 6 x cannons (6 pdrs)  Total 66	Lower deck 20 × cannon drakes (42-pdrs) 4 × demi-cannon drakes (32-pdrs) 2 × demi-cannon drakes (32-pdrs) 2 × demi-cannon drakes (32-pdrs) Middle deck 22 × culverin drakes (18-pdrs) 2 × demi-culverin drakes (9-pdrs) 4 × culverins (18-pdrs) 2 × culverins (18-pdrs) Upper deck 22 × demi-culverin drakes (9-pdrs) 2 × demi-culverins (9-pdrs) 2 × demi-culverins (9-pdrs) Quarter deck 6 × demi-culverin drakes (9-pdrs) Poop deck 2 × demi-culverin drakes (9-pdrs) Forecastle 8 × demi-culverin drakes (9-pdrs) 2 × culverin drakes (18-pdrs)  Total 102

## MODERN COROLLARIES

This section will discuss the development of two of the three modern modularity exercise highlighted in Figure 5. Specifically, the Littoral Combat Ship (LCS) and the Standard Flex (STANFLEX) efforts will be analysis for similarities and difference. The previous historical case study will be utilized for contextualization. The MEKO approach has been omitted from this conversation since the approach is dramatically different than that employed by

the US and Danish Navies. Global componentization in construction should be further evaluated and the MEKO would be a beneficial case study in that endeavor.

## **Littoral Combat Ship**

The Littoral Combat Ship was envisioned to be a high speed, inexpensive platform with a modular mission system that could be dynamically assigned in theater. “Rather than being a fully multimission ship like the Navy’s larger surface combatants, the LCS is to be a focused mission ship, meaning a ship equipped to perform one primary mission at any given time. The ship’s primary mission orientation can be changed by changing out its mission package, although under the Navy’s latest plans for operating LCSs, that might not happen very frequently, or at all, for a given LCS.” (O’Rourke, 2019) One potential performance issue with the disaggregated development and acquisition of the LCS Mission Packages was the fact that each Mission Package consisted of multiple Mission Modules. (Asst Secretary of Navy, Research, Development, and Acquisition, 2018) These Mission Modules had different developers and integrators. This is further confounded by the development and testing timeline associated with each Module at the sub-Package level. The result was “the total initial mission package operational capability has been delayed by about 9 years (from 2011 to 2020) and the Navy has lowered the level of performance needed to achieve the initial capability for two packages”. (Francis, 2016) Further, “Changes in the LCS concept of operations are largely the consequence of less than expected lethality and survivability, which remain mostly unproven 7 years after delivery of the lead ships”. (Francis, 2016) this brings us to the current scenario with 35 hulls being awarded in various stages of construction with two distinct variants. Despite the lapse of 21 years since program initiation, and almost 3 dozen ships, the reality of a hot swappable flexible combat system has fallen dramatically short of the initial vision.

Why did this effort fall so short of initial expectations? It is my feeling that there are two fundamental underlying contributors to these results. First, a lack of established standards. This total system acquisition effort undertook the development effort of two distinct sea frames, three mission packages, and the development of modular interfaces. This effort would have been challenging enough with a single sea frame, mission package, and associated interface standards. This challenge coupled with aggressive requirements created a scenario for the much-publicized difficulties of the LCS Program. Unlike the historical scenario above there was not a clear shipboard interface for independent development of modularized systems. The gun port, albeit simplistic, allowed for independent development of platforms and weapons and further facilitated the integration of these systems without major retrofits. The complexity of integrating a modern cannon or missile system is not lost here, however the point is that the interface standards did not exist prior to program initiation and these newly developed standards created in stride with the program development needed to accommodate a range of modules further increasing the total system complexity. Regarding system complexity this brings us to the second contributor, the hierarchical mission package – mission module – mission system construct adds a tremendous amount of requirement interdependency and thus increases the overall risk to execution. With three distinct Mission Packages each comprised of multiple modules and sub systems all being coincidentally independently developed by a variety of vendors the opportunity to encapsulated schedule risk and hedge performance characteristics is virtually nonexistent. A performance or developmental failure in a lower tier system would lead to cascading failures. This was realized with Surface-to-Surface Missile Module (SSMM), Remote Multi-Mission Vehicle (RMMV), and Dual-mode Array Transmitter (DART).

The SSMM was designed and tested with the AGM-114L Longbow Hellfire missile. This missile variant was actively produced until 2005 and is scheduled to be replaced with the AGM-179 Joint Air-to-Ground Missile (JAGM). Meanwhile the first successful land attack exercise was conducted with the Longbow Hellfire on 12MAY2022. (Hardgrove, 2022) While this is not a failure in the development of the SSMM it will mean the need to retest and potentially delay operational use of the module as it is being certified for the launch of another missile platform. The RMMV was somewhat operationally successful but unreliable. (Remote Minehunting System (RMS), 2016) After ship integration issues due to launch and recovery (FY15 Navy Programs - Remote Minehunting System (RMS), n.d.), two Nunn-McCurdy programmatic breaches (2009, 2015) (Eckstein, 2015), and failure to progress after a dedicated reliability improvement effort (FY15 Navy Programs - Remote Minehunting System (RMS), n.d.) the RMMV was officially canceled in 2016 (Remote Minehunting System (RMS), 2016). This realized failure in a critical system within the Mine Countermeasures (MCM) Mission Package required that the entire package be refactored and rearchitected. As such years of delay were experienced, in fact the MCM Mission Package just obtained its Initial Operational Capability in early 2023. (Shelbourne, 2023) The DART was optimized for weight considerations and

modular employment within the LCS waterborne systems area of the mission bay. The prototypes were initially accepted in 2018 and then development was subsequently canceled in 2022. This cancellation was due to SONAR performance and reliability. (Abott, 2022; *Navy Canceled Raytheon's DART Sonar Due to High Risk | InsideDefense.Com*, n.d.) Given the above one can begin to see how the inability to encapsulate schedule and performance risks during the development created a realized risk in each of the Mission Packages for the 35 LCS sea frames.

## STANFLEX

“The driver for StanFlex was money—the Royal Danish Navy needed to replace 22 warships of three classes, but it could not afford to do so on a one-for-one basis, so it came up with the idea of building 16 multirole modular vessels (later cut to 14).” (*Beware the Allure of Mission Modularity*, 2023) The basic assumption behind the STANFLEX concept was that “logistic standardization and operational flexibility can be achieved by use of rapidly exchangeable, modular systems matching a variety of roles” (Harboc-Hansen, 1992) Does this sound familiar? It should, it is the exact same justification that was utilized for the LCS program. So, the ultimate question becomes why the STANFLEX experience is considered successful and the LCS experience is considered painful. Maybe it is the scale of the effort, the complexity of the end system, or acquisition approach.

The first vessels to be outfitted with the STANFLEX modules were the Surface Auxiliary Vessel (Harboc-Hansen, 1992) later designated as the Flyvefisken Class (SF 300) (“Flyvefisken Class (SF 300),” n.d.). These composite vessels were of a size and complexity that supported a multitude of roles from MCM to environmental support and provided a perfect opportunity to work out the bugs associated with fielding a modular combat system. The length of the Flyvefisken is 54m, with four STANFLEX slots accounting for 12m of the vessels weather deck. In this initial case of modularization, the RDN allocated a smaller vessel than the LCS with a much higher percentage of modularization. The total scale of the initial effort is drastically different, but it allows for the required learning by the government and industry. The complexity of the ultimate end system and desired mission effectiveness could be the next key to success. Again, like the LCS the RDN had originally envisioned surveillance, combat, offensive mining, anti-pollution, anti-submarine warfare, and MCM mission packages composed of distinct modules. The biggest difference is that each of the modules all conformed to the same structural envelope and utilized standardized connections. This self-encapsulated module approach helps to mitigate performance and schedule risk associated with the concurrent development of the mission packages. Finally this brings us to an acquisition approach, Naval Team Denmark (*Https*, n.d.) is an industry and regulatory consortium that develops, and delivers the STANFLEX modules. It does make one wonder if the top 20 naval defense agencies in the US was to form a design and fabrication consortium that would have sufficiently altered the LCS experience. In this case the parallels to the historical case are enlightening. The RDN had a definitive fixed standard for modularized systems that was trialed on a small case and then eventually expanded to all following classes. This allows for consistent spiral development and compatibility. The ultimate complexity was managed starting with the least taxing cases and eventually evolving and increasing capability to account for more challenging configurations. And finally, this became a point of national pride. Much like the capital sailing vessels the defense conglomerate that was empowered around the STANFLEX project pulled the best from the industrial base to develop a successful program and new naval standard.

## SUMMING UP

During the first section of this paper a more descriptive definition of modularity has been developed. This definition describes modularity along six continuums: 1) Componentization, 2) Architecture, 3) Configurability, 4) Flexibility, 5) Interface Points, and 6) Allocation. While the treatment of this definition is subjective in this document a more objective mechanism has been developed and is under evaluation at this time. An effort has been made to expose the underlying motivation and attractiveness of modularity in naval vessels utilizing economic salvage value and a less tangible ship effectiveness. Finally, the first section concludes with a look at investment duration by project for the last five decades relating to the development of architectural standards and why many modern modularity efforts have failed to produce the envisioned results. Culminating in two axioms of modular system failure: 1) the cost over time of the end item is greater utilizing modular upgrades than the initial purchase cost of an upgraded system, and 2) piece meal system acquisition will never keep pace with the developmental capability of new production.

The second and third section of this paper develop a historical analogy and review modern corollaries, respectively. Specifically with respect to the historical section the decoupling of platform and weapons system development allowed for gains in both systems since the interface point was a loose constraint. This concept of independent development allowed for each system to evolve based on technological limits and the application of new techniques. The maintenance of a loose interface standard allowed for frequent upgrades and modifications to occur on a timeline that made the most sense for system fielding. Additionally, developmental and schedule risk was encapsulated thus minimizing the total acquisition impact. The final section presented two modern modularized naval vessels considering these historical lessons learned. One program fell far short of its envisioned capability due to the lack of established standards, and a tremendous amount of requirements interdependency. While the second controlled the scale of the effort, the complexity of the end system, and applied a community-style acquisition approach. Even though the initial case of modularization was assigned to a much smaller vessel than the previous example, there was a much higher percentage of modularization.

While this is a quick survey of 50 years of modern system development spanning countless millions of dollars, supported by a case study that spans almost 300 years, the principal key to success in modular systems is the adoption and commitment to an interface standard that is not overly constrained. Historically the gun port allowed for the development of platform and weapon technology to be decoupled and developed independently. Similarly, the STANFEX fixed a geometric interface and has allowed for the iterative development of new combat and support systems to be developed and successively deployed across new classes. Modularity will continue to be attractive to naval vessels but to realize the potential of this modularity, a definitive standard must be adopted and employed uniformly across multiple classes.

# Statistical Reliability Analysis of Marine Systems with varied Levels of Redundancy

Andrey Ware<sup>1,\*</sup> and Matthew Collette<sup>2</sup>

## ABSTRACT

*In designing autonomous vessels for long-duration independent operation, maintaining the performance of machinery systems without human intervention is a key challenge. Designers are faced with a range of potential system architecture choices but have little guidance on which will be optimal. Working only with high-reliability components can increase the probability of completing a voyage successfully, though the availability of such components may be limited. Alternatively, designers can select a redundant architecture to provide options for reconfiguration if a component fails during a voyage, such architectures typically have weight, space, and cost implications. This work presents a parametric exploration of the probability of system failures over time under different architectures. The reliability of individual components is expressed through exponential probability distributions and the weight of each component is approximated. Two systems are presented and the effectiveness of various architectures for both systems is compared. A simple design penalty function is also tracked to capture the different architectures' weight and implication number of components. From this study optimal architectures for long-term autonomous missions are proposed.*

## KEY WORDS

Reliability; Redundancy; Series-Parallel Configuration; Marine Systems; Fuel Oil System; Cooling System.

## INTRODUCTION

Ship systems are highly sophisticated systems, being comprised of many subsystems and numerous components. Components in these systems are often placed in parallel configuration on-board ships as a safeguard against catastrophic system failures. Ensuring spare parts are on-board and readily available during emergency is vital to performance of the ship and the ensured safety of the crew. This point is reinforced by classification societies, such as American Bureau of Shipping (ABS, 2018), Lloyds Register of Shipping (Lloyds Registrar of Shipping, 2013) and also International Marine Organization (IMO, 2002), which all have established guidelines for redundancy levels in critical systems, such as main propulsion. Guidelines on system redundancy exist for both main engine systems and their supporting systems, such as engine cooling water, fuel oil, and lube oil systems (Liberacki, 2007). Generally, societies require systems to have secondary pumps and valves in major systems because these parts are known to have high rates of failure. While parallel configuration of components may mitigate system failures, the precise balance required for optimal operation and reliability over a desired period remains ambiguous, prompting the need for a more data driven approach. This approach toward including reliability in systems has not proven to prevent critical failures of systems or unexpected maintenance being necessary. The existing redundancy rules also assume humans are on-board the vessel, which means the systems must be reliable and safe enough to mitigate risk to human life. Assuming a crewed vessel also implies that there will be human intervention if a system malfunction or failure is found by the crew, happening in the form of maintenance, reduction in the operating state of the vessel, or a return to port. For a crewless vessel however, their may be a higher risk profile that is acceptable since there are no human lives at stake.

As the maritime industry progresses toward autonomous operations, reliance on human intervention for system monitoring diminishes, deepening the importance of accurate predictive maintenance strategies. Traditional methods such as scheduled inspection and condition-based monitoring will become more heavily influenced by the predictive models that leverage component reliability data for failure predictions. Accuracy of such predictions requires historical data, which is scarce in the maritime sector due to limited sharing of failure statistics. Data sharing in this industry is driven by mutual benefit, often

resulting in retention of vessel and component data deeming it to be confidential (Teijl, 2014). Despite this, recent reports can be found which utilize confidential data and present their limited findings (Knežević et al., 2022). Additional information may be gathered from reports which interview crew members and vessel maintenance workers, many of which mention that preventative maintenance and avoiding machinery failures are a major concern in mission planning (Sulkowski et al., 2022). Reports such as these can be leveraged in statistical investigations and predictive modelling approaches such as the one presented here.

Current redundancy standards lack statistical foundation proving the level of redundancy can lead to overall improvements in system reliability. Predictive modelling approaches also lack consideration concerning factors such as component weight and cost. Addressing this gap, this work aims to quantify the trade-offs between high-reliability components and redundancy through simulations, assessing various configurations for their redundancy levels, reliability, and weight. The systems that have been analyzed include the engine cooling water and fuel oil systems. Results from the study conducted here may offer insights into optimal system configurations and informing future standards in naval system design practices.

First, the metrics defining system reliability are presented. Next, assumptions made to estimate weights of components are detailed. An overview of the initial models for both systems is given and the results of testing various configurations of these systems with differing levels of redundancy are presented. Finally, conclusions are drawn from observed trends.

## MODELLING ASSUMPTIONS

### Reliability Metrics

Reliability of a component has long been defined as “the probability that a component will be able to perform a required function for a given operational period and stated conditions” (MIL-STD-721C, 1981). Various metrics have been used to quantify a components reliability. The chosen metrics for analysis in this paper are average failure rate and mean time between failures for each component tested. A component or systems rate of failure (Equation [1]) and mean time between failures (Equation [2]) are defined as:

$$\text{Failure Rate } (\lambda) = \frac{\text{total number of failures}}{\text{operational time}} \quad [1]$$

$$\text{Mean Time Between Failure (MTBF)} = \frac{\text{operational time}}{\lambda} = t_f - t_0 \quad [2]$$

These definitions assume a fixed operational time. Failure rate is given in units of failures per million operating hours, so a operational time of 1 million hours has been assumed. Mean time between failures may also be defined in terms of a difference between the time related to a component’s maximum reliability, the initial operation start time,  $t_0$ , and the components time of failure,  $t_f$ . This modelling approach will assume no maintenance interventions or environmental affects. All components are modelled individually with distinct average lifetimes and average rates of failure. The python *SciPy* package was utilized for creating exponential random variate distributions of failure times for each component. From each distribution 1000 random failure times were selected.

Reliability metrics for this study were taken from multiple sources with all components designated supporting an approximately 17,000kW 6-cylinder Diesel Engine (MAN, 2009). For the high-pressure pumps, metrics come from a study investigating the optimal maintenance plan for high pressure fuel systems (Knežević et al., 2022). Metrics for the low-pressure pumps, heat exchanger, and cross tie valves are sourced from a study optimizing maintenance of heat exchange systems for submersibles (Zhang, 2021). SciPy random exponential function is defined by a variance of failure and not a failure rate, therefore the variance of failure is set so that each parts exhibits the failure pattern described by the failure rates gathered.

**Table 1: Reliability Metrics for Components Considered**

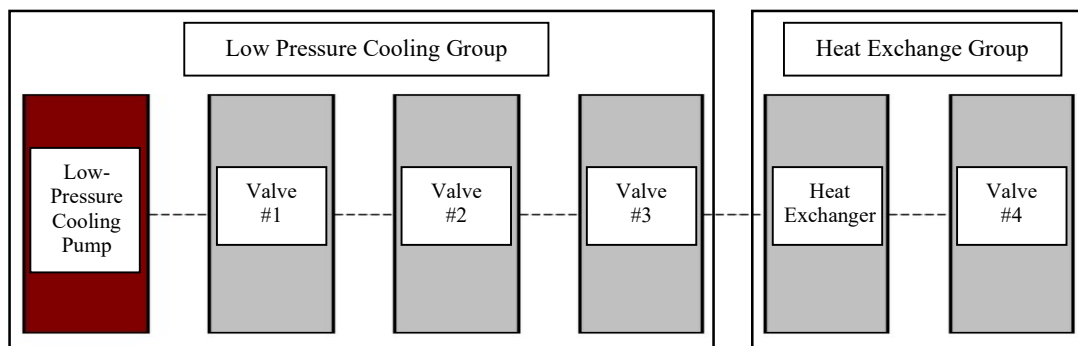

Component	Mean Time Between Failure (MTBF) (Years)	Variance of Failure Used in Simulation (Years)	Failure Rate ( $\lambda$ ) (fails/ $10^6$ Hrs.)
Low-Pressure Pumps	1.97	0.30	56.88
High-Pressure Pumps	0.54	0.08	208.69
Heat Exchangers	6.85	1.65	16.36
Valves	27.52	4.48	4.07

## SYSTEM MODELS

Two marine propulsion support systems are included in this paper: the fuel oil system and the cooling water system. A failure of either system can lead to malfunction or failure of propulsion systems which would be a critical failure. Both system configurations are based initially on the schematics of the Marine Design Laboratory, a propulsion simulator at the University of Michigan which emulates shipboard machinery systems using six coupled systems (Marine Engineering Laboratory, 2022). Of the existing ship systems in the simulator, the cooling and fuel oil systems feature redundancy of cooling lines and fuel injection lines, as well as simulation valves for clogs and leaks. In this paper, the initial system configurations only included in-series layout of components with high rates of failure, such as pumps, valves, and heat exchangers will be considered. Clogs and leak simulator valves were removed and other components of the systems with lower rates of failure were also ignored. Additionally excluded components include oil service tanks and cooling water tanks as they are not prone to failure and are low risks components of these systems.

### Engine Cooling System

The cooling water system consists of 6 total components, which were divided into two groups. The first group consisted of a single cooling pump and three valves, valve #1, #2, and valve #3 respectively. The cooling pump was considered as a centrifugal pump, assuming the reliability and weight of a low-pressure pump. The second group consisted of a heat exchanger and a final valve, valve #4. Components were considered in two groups so that parallel lines for cooling pumps or parallel heat exchangers could be implemented in testing various configurations. The initial layout of the cooling system is seen below with the component of highest failure rate highlighted in red in Figure 1. In this initial configuration, it was determined that the low-pressure cooling water pump causes cooling system failure most often.

**Figure 1: Initial Engine Cooling System Model**

For this initial system layout, a reliability over time curve was generated as seen below, over a period of 100,000 operating hours. The system reliability followed the lowest reliability of all parts in the system at each time step, which happened to be the low-pressure cooling pump at all times tested. The four valves have similar reliability curves to each other as expected and showed slightly higher reliability at each time step compared to the cooling pump. The reliability of the heat exchanger far exceeds the reliability of the low-pressure cooling pump and valves. Due to this observation, most tested configurations of this system will investigate adding cooling pump groups in parallel, rather than parallel heat exchange groups in order to improve overall system reliability.

**Figure 2: Initial Engine Cooling  $R(t)$ , Reliability over 100,000 operating Hours**

## Fuel System

The fuel oil system consisted of 7 components total. These components were again split into two distinct groups. Starting with the cooling pump, valve #1 and valve #2 they were referred to as the fuel cooling group. The fuel injection group was comprised of a high-pressure fuel injection pump and valves #3, #4, and #5. This grouping allows for investigation of parallel lines of fuel cooling or fuel injection during testing. For this system, the fuel injection pump was the component with the highest failure rate, highlighted in red in Figure 3, and caused most of simulated fuel oil system failures.

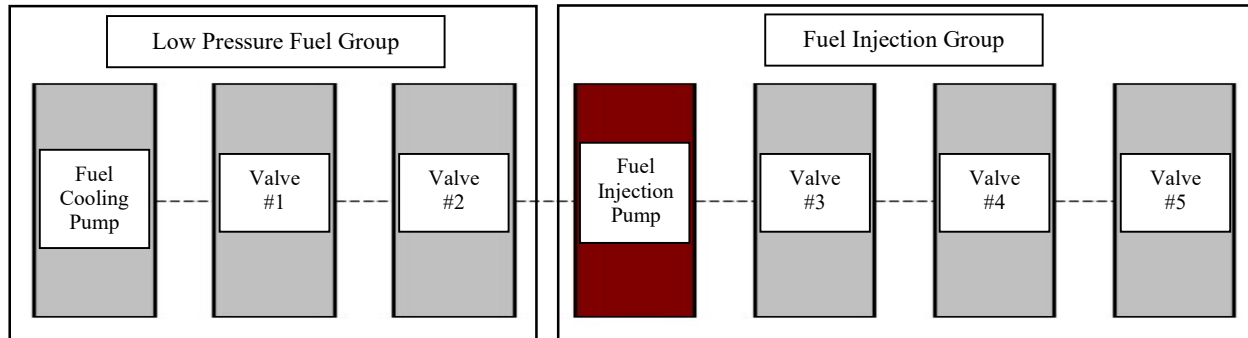

Figure 3: Initial Fuel Oil System Model

The reliability curve for the system was generated using the metrics for low pressure cooling pumps, high pressure fuel injection pumps and valves presented in the previous section. For this system the high-pressure cooling pump was the lowest reliability component in the system at each time step and was therefore equal to the system reliability over time. In testing, many configurations adding parallel redundancy of the cooling pump group for improving system reliability were tested.

Figure 4: Initial Fuel Oil System  $R(t)$ , Reliability over 100,000 operating Hours

## System Weight Estimation

The components selected for the fuel oil and cooling systems were intended to support a 6-cylinder slow-speed diesel engine, MAN 6S70MC-C, with a maximum continuous rating of 16,780 kW operating at 91 RPM (MAN, 2009). This engine is a frequent choice for tankers and bulk carriers (Žan, 2009). The total weight of both two auxiliary systems combined was assumed to be 5% of the main engine weight. For the 550-ton engine this yields a total weight of 27.5 tons split between the total components in each system. To distribute this weight amongst the individual component's, catalogues were reviewed to determine a weight ratio between parts. The resultant total weight was then distributed amongst the individual components as seen in Table 2. The weight presented assuming inclusion of all necessary piping and fittings for each component, for example, high pressure fuel injection pumps may be double walled, so the casing and pipes and other subcomponents of the assembly were included in the estimated weight.

**Table 2: Distribution of Total Auxiliary System Weight Between Components**

Component	Quantity in Initial Systems	Individual Component Weight (tons)	Fraction of Total Initial Systems Weight (%)
Cooling Pump	2	5.64	41.07
Injection Pump	1	13.30	47.41
Heat Exchanger	1	2.70	9.82
Valves	8	0.05	1.70
Total Auxiliary Systems	12	27.50	100

From the calculated individual weights of components, the total weight of each proposed system was found. The total weight of the initial engine cooling system and fuel systems are presented in Tables 4 and 5 below.

**Table 4: Distribution of Total Cooling System Weight**

Component	Quantity in Cooling System	Individual Component Weight (tons)
Cooling Pump	1	5.64
Heat Exchanger	1	2.70
Valves	4	0.05
Cooling System	6	8.44

**Table 5: Distribution of Total Fuel Oil System Weight**

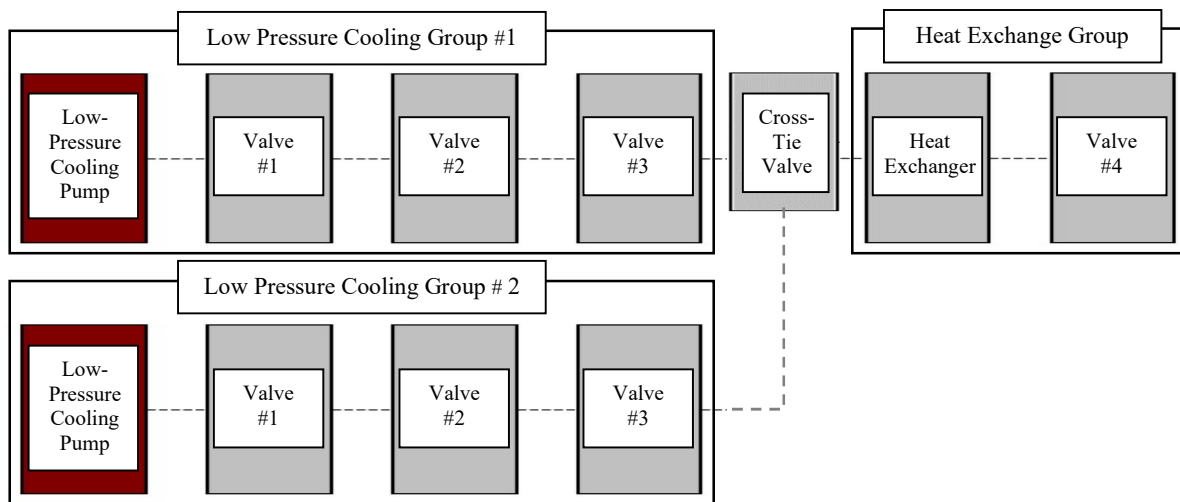

Component	Quantity in Fuel System	Individual Component Weight (tons)
Cooling Pump	1	5.64
Injection Pump	1	13.30
Valves	5	0.05
Fuel System	7	19.19

The next section explains parallel configurations required a component for switching between parallel lines. A cross-tie valve was placed between groups for this purpose. The fixed weight of this valve was 0.07 tons and was found using factors determined from marine valve manufacturer catalogues. This additional weight was factored into tested configurations having increased levels of redundancy. The reliability of the cross-tie valve is assumed to be the same as that utilized for all other valves.

## TESTING PARALLEL CONFIGURATIONS

### Redundancy in Testing

For testing the reliability of increased levels of redundancy, the groups were configured in different ways to determine the improvements to system reliability that could be gained from parallel component groups. For Tables 6 and 7, Test #0 outlines a system with no redundancy which was presented in section 2 of this report as the initial systems. For comparison, these systems are included as in tables and graphs in this section. Test #0 was the only configuration with no cross-tie valves. In the event of parallel groups, a cross tie valve is also added to the system between groups to allow for switching between lines. For all tested parallel configurations, the weight of the cross tie was also be added to the total system weight. An example configuration of the engine cooling system with parallel cooling groups, a singular heat exchange group, and a single cross tie is seen in Figure 5. This example is the same as Test #1, conducted for the fuel cooling system.

**Figure 5: Test #1 of Engine Cooling System with Parallel Redundancy, 2 Cooling Groups, 1 Cross Tie Valve and 1 Heat Exchange Group**

### Cooling System Tests

For the engine cooling system, a total of 30 tests were conducted, with 12 presented in Table 6 below. Many of the test focus on increasing the number of cooling groups since the cooling pump is the most frequent cause of failure within the system. The tests presented within Table 6 highlight the general trends observed from simulations. Test #0-3 shows a single heat exchange group, Test #4-8 shows two heat exchange groups in parallel and Tests #9-12 shows 3 heat exchange groups in parallel. The number of parallel cooling groups is increased until the system failure is no longer completely determined by the cooling group. System weight was also limited to be less than 50 metric tons.

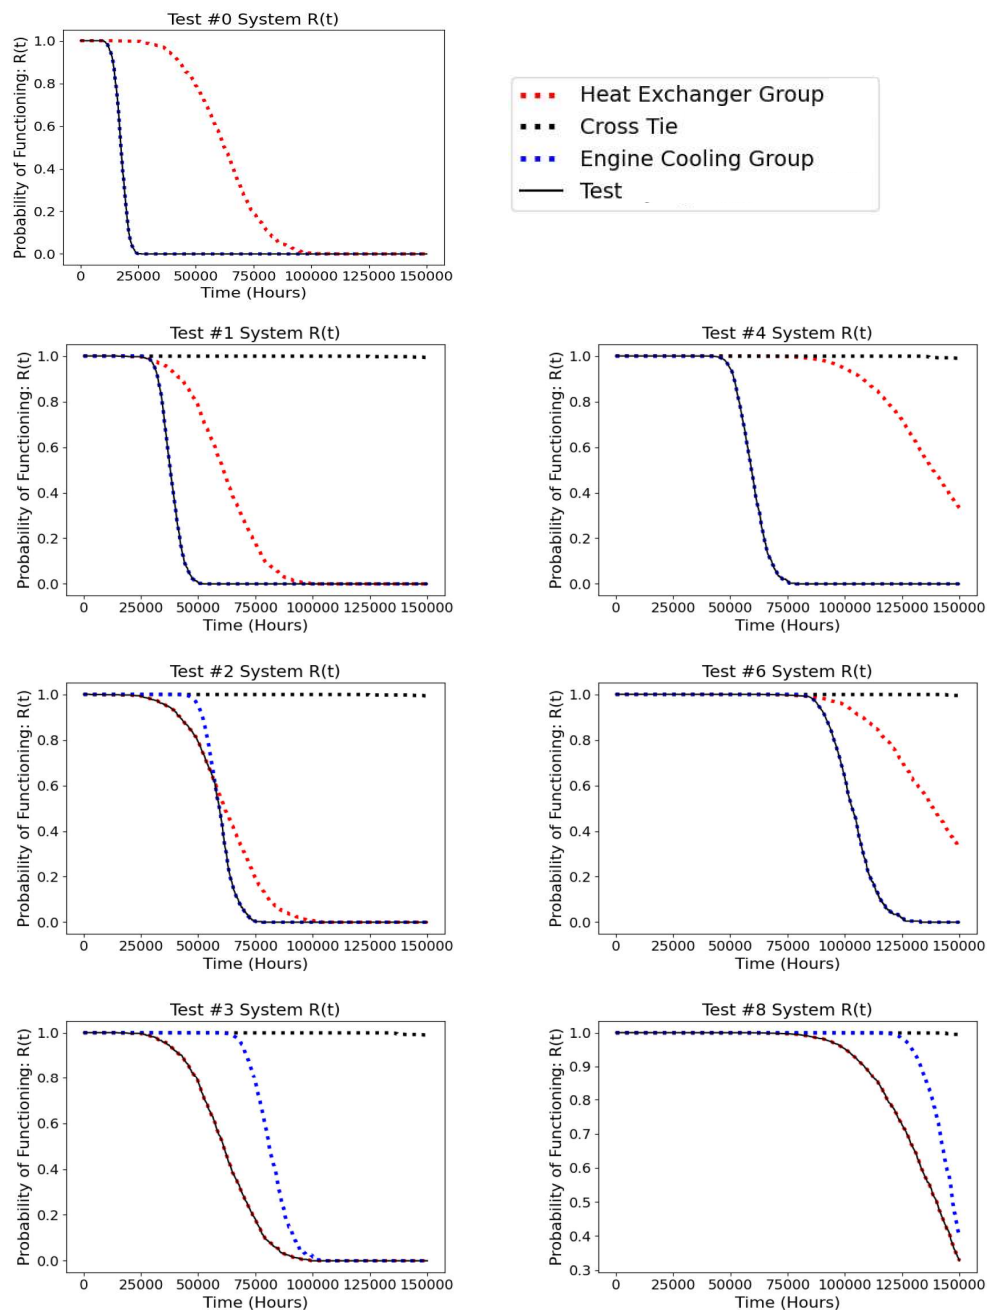

**Table 6: Results from Cooling System Configurations Tested**

Test #	# of Cooling Groups	# of Cross Ties	# of Heat Exchange Groups	Total Count of Components	System Weight (metric tons)	MTTF (Years)	Failure Rate (fails/MH)
0	1	0	1	6	8.54	3.02	11.94
1	1	1	2	11	14.40	6.04	10.14
2	1	1	3	15	20.19	9.05	7.95
3	1	1	4	19	25.98	11.81	6.64
4	2	1	3	17	22.94	8.95	7.07
5	2	1	4	21	28.73	12.07	5.99
6	2	1	5	25	34.52	15.09	5.20
7	2	1	6	29	40.31	17.91	4.86
8	2	1	7	33	46.10	21.03	4.68
9	3	1	4	23	31.48	11.97	5.43
10	3	1	5	27	37.27	14.89	4.73
11	3	1	6	31	43.06	18.01	4.41
12	3	1	7	35	48.85	21.03	4.11

As more cooling groups were added, the mean time between failure of each system increased, allowing for more operational time before the system would need maintenance services. The overall failure rate of the various configurations also decreased with the inclusion of multiple cooling groups. This which reflects higher reliability of the system caused by higher levels of redundancy, with mean time between failures increased by about 3 years per cooling group added in parallel. The tradeoff of this improved reliability is a much heavier system with a system weight increase of 60 % of the initial weight per cooling group in parallel.

For single heat exchange system configurations, Tests #0 – 4, the reliability of system was improved each time a cooling group was added to the parallel configuration. The reliability plot for Test #0, seen in the top left of Figure 6, shows the cooling group (blue curve) has a lower reliability at every time step then the heat exchanger group (red curve) and is the first group in the system to fail. In tests 1 to 4, the number of cooling groups in parallel increased by one each test. This additional redundancy moves the reliability curve the cooling groups to the right, indicating a longer time of high reliability and an extended mean time to failure of the grouping. Test 2 shows the system reliability is only partially determined by the 3 cooling groups in parallel, whilst in test #4 the system is no longer dependent on the failures of the cooling pumps at all, but instead on the heat exchanger group.

Investigating a system with two heat exchanger groups a similar trend persisted. The system reliability over time curve,  $R(t)$ , was completely dependent on the cooling group reliability curve in Test #4, with only four cooling groups in parallel, whilst in Test #8, the addition of seven cooling groups in parallel pushed the reliability of the cooling group to be greater than that of two heat exchange groups.

**Figure 6: Engine Cooling System Single Heat Exchanger Tests #0, 1, 2, 3 (left), and Double Heat Exchanger Tests #4, 6, 8 (right)**

## Fuel System Tests

For the fuel system similar simulations were conducted. Fuel injection groups were added in parallel until the system reliability was no longer entirely dependent on failure of the fuel injection group. Test #0-7 considered single cooling group with varied numbers of redundant injection groups. Test #8-10 investigated system configurations with 2 cooling groups, and tests #11 was the only simulated test configuration including triple cooling groups. The fuel injection pump was the heaviest part considered in this report, so the system weight was found to be increasing even more rapidly than the previously tested cooling system, when adding more fuel injection groups. A total of 30 systems were investigated in simulation but only the systems weighing less than 100 metric tons in total are presented in Table 7.

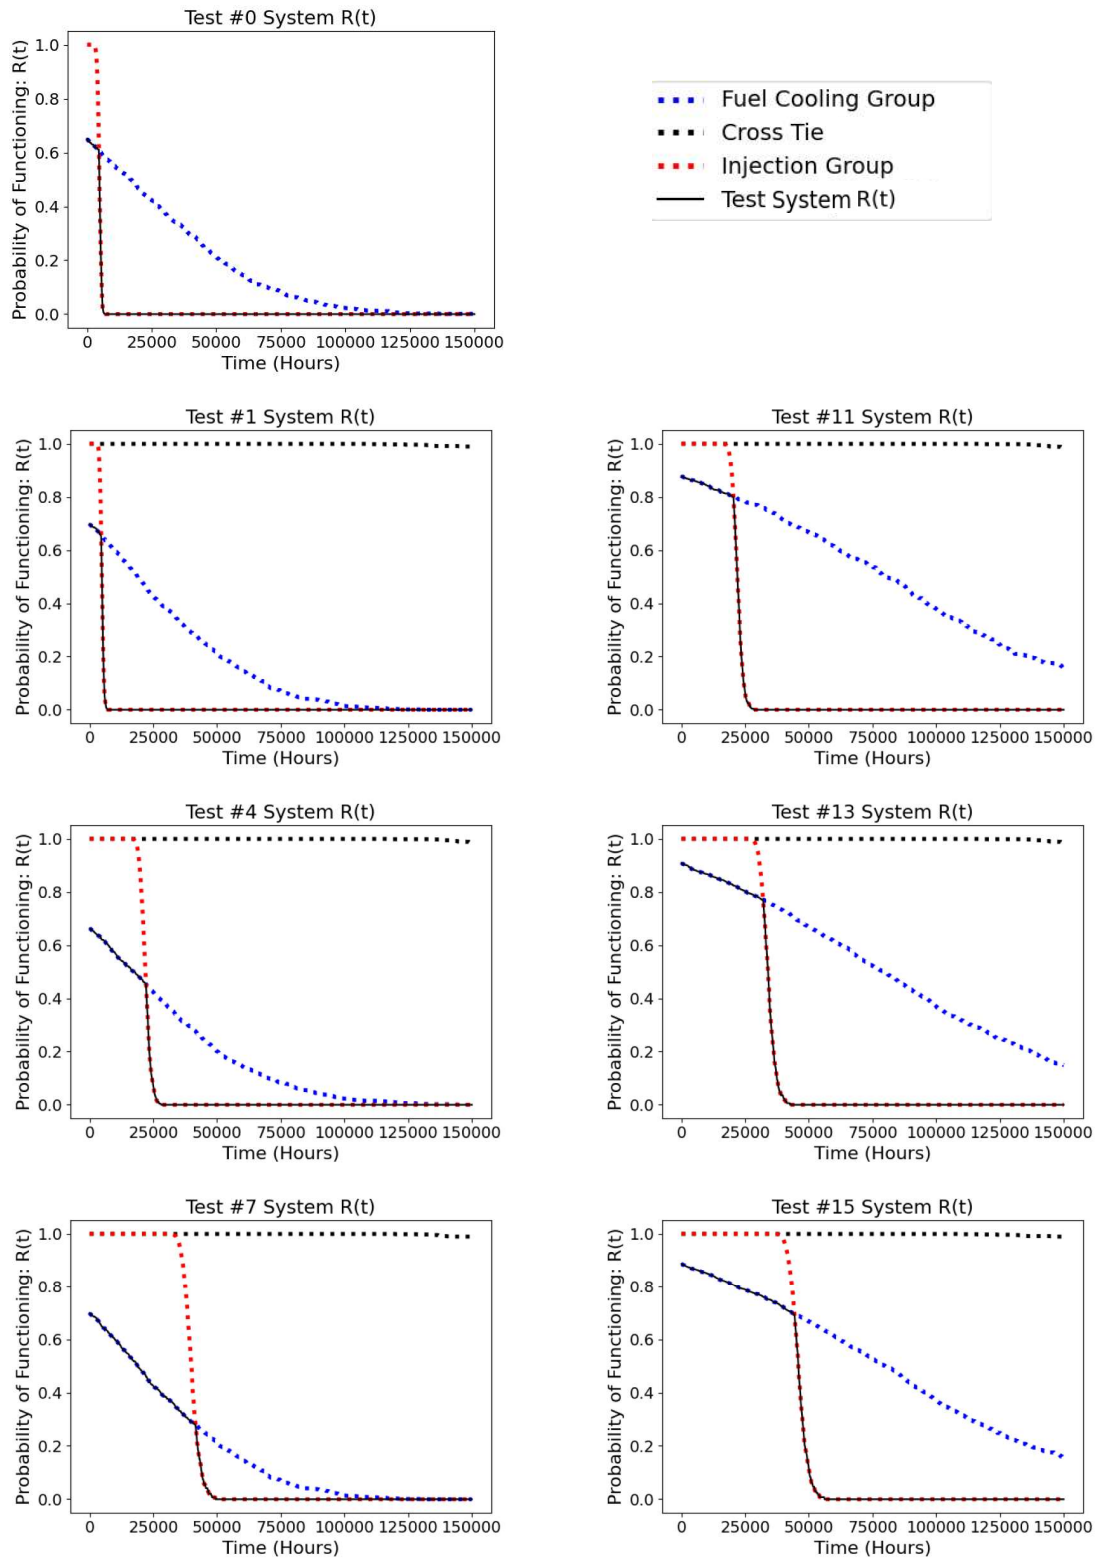

**Table 7: Results from Fuel System Configurations Tested**

Test #	# of Cooling Groups	# of Cross Ties	# of Injection Groups	Total Count of Components	System Weight (tons)	MTTF (Years)	Failure Rate (fails/MH)
0	1	0	1	7.00	19.19	0.79	30.29
1	1	1	1	8.00	19.26	0.77	22.19
2	1	1	2	12.00	32.71	1.53	27.32
3	1	1	3	16.00	46.16	2.34	18.66
4	1	1	4	20.00	59.61	3.12	14.83
5	1	1	5	24.00	73.06	3.86	12.54
6	1	1	6	28.00	86.51	4.64	10.92
7	1	1	7	32.00	99.96	5.46	9.55
8	2	1	4	23.00	65.35	3.11	14.47
9	2	1	5	27.00	78.80	3.94	11.78
10	2	1	6	31.00	92.25	4.70	10.57
11	3	1	6	34.00	97.99	4.65	10.01

As of the fuel injection groups, the group with the lowest reliability components, were added in parallel the mean time between failure of the system increased while failure rate reduced. This is desirable as the system will be more likely function over extended periods of time. The weight increase cost for this increased system reliability was approximately 70 % the original system weight per injection group added in parallel. This weight cost in many cases might not be justified by the minimal increases in mean time between failures and reductions in failure rate for some applications, so an optimum configuration would be based on a desired the operational time. Applicability of these results is discussed more in the next section.

Observing the reliability over time plots of the tests presented these trends can be better understood visually. The low variance of the fuel injection failures results in an almost vertical reliability curve, this corresponds to components whose failures occurred at approximately the same time every time it fails. The high variance of failures of the cooling groups leads to a much more spread reliability curve. Presented in Figure 7, the right side shows reliability curves for a singular cooling group and two, four and seven parallel injection groups considered in Test #0, #1, #4 and #7. The right side of Figure 7 shows reliability over time for Tests #8, #9, and #10, which considered two cooling groups and four, five, and six parallel injection groups.

For both sets of tests, the addition of parallel injection groups shifts the reliability curve for these groups minimally and corresponded to a small increase in mean time between system failures. Looking specifically at the right column of figure 7 we see per injection groups added, the reliability curve moved right about 12,000 hrs., this corresponded to an increase mean time to failure of less than 1.5 years. The weight of three injection groups however is more than 30 tons. Addition of such a heavy group, for a low tradeoff in increased reliability over time is not justifiable in for any design where being lightweight is desired. This is more important for vessel which operate at high speeds or in shallow waters and seems to be less relevant for heavy vessels such as bulk carriers and tankers.

**Figure 7: Fuel System with Single Cooling Group, Tests #0, 1, 4, and 7 (left), and Double Cooling Groups Tests #11, 13, 15 (right),**

## APPLICATION OF TEST RESULTS

From the resulting reliability metrics of various system architectures tested, a level of redundancy needed for desired performance can be quickly decided for a specified mission lengths. The few crewless vessels existing today have a maximum operational range is 2000Nm at 16 Knots (Ziajka-Poznańska & Montewka, 2021). This application of autonomous vessels corresponds to only 125 hours of autonomous operations. A long-term goal could be to have the vessel operate autonomously for months to years at a time with no on-board human interference. This goal will only be achieved if a highly reliable machinery system is implemented. Using the results from the test cases, an optimal configuration for the cooling and fuel oil systems can be selected for an autonomous vessel operating for 1, 2, 3, 4, and 5 years at a time. The optimal system was selected with emphasis on reliability of at least 30% probability of functioning until the end of each desired mission length, as well as minimizing the weight of the system.

**Table 8: Cooling System Performance of Optional Configurations over Various Mission Lengths**

Mission Length (years)	# of Cooling Groups	# of Cross Ties	# of Heat Exchange Groups	Total Count of Components	System Weight (tons)	System Reliability at the end of the Mission Length
1	1	0	1	6	8.54	99.9 %
2	1	0	1	6	8.54	53.8 %
3	1	1	3	15	20.19	99.5 %
4	1	1	3	15	20.19	96.5 %
5	1	1	3	15	20.19	88.6 %

The cooling system, at the beginning of its operation would highly reliable because of its higher reliability components compared to the fuel oil system. As seen in the curves present previously, most components in this system do not fail until about 25,000 Hrs. which is after approximately 3 years. This being known, the initial configuration is optimal for mission lengths on 1 or 2 years but for 3-5 years of operation, a more redundant configuration would be the more optimal choice for reliable system performance. The fuel system on the other hand was shown to fail much earlier than the cooling system in its initial configuration and this leads to a much more diverse selection of optimal architecture dependent on increasing mission lengths as seen below.

**Table 9: Fuel System Performance of Optional Configurations over Various Mission Lengths**

Mission Length (years)	# of Cooling Groups	# of Cross Ties	# of Heat Exchange Groups	Total Count of Components	System Weight (tons)	System Reliability at the end of the Mission Length
1	1	1	2	12	32.71	62.9 %
2	1	1	4	20	59.61	49.3 %
3	1	1	5	24	73.06	40.8 %
4	1	1	6	28	86.51	34.8 %
5	2	1	8	39	119.15	70.5 %

The goals presented here are assuming complete autonomy of the vessel and continuous operation, but in practice would require a consideration of scheduled inspections for maintaining the vessel, as well as stops to prevent overloading or over heating of equipment. These considerations are not made in this paper but would be needed for a real-life implementation.

## CONCLUSIONS

This paper has presented the tradeoffs between increased reliability through parallel configurations at the expense of increase system total weight. Investigations showed that low reliability components should be the focus of parallel options if reductions in system failure rate and increases to mean time between failures are desired. Simulated results for multiple configurations of cooling and fuel oil system have been presented. Pumps proved to be the most common failing components investigated in both systems, cooling water pumps in the cooling system and fuel injection pumps in the fuel oil system.

Testing of parallel configurations revealed a considerable increase in system weight for improvements in system reliability. The necessity of these improvements in reliability should be determined by the application specific needs, whether that be a desire to remain highly reliable or lightweight. These results were tested and normalized over various mission lengths to find optimal configurations for 1, 2, 4, and 10 years of system operation. The results from this investigation reaffirm that the selected level of redundancy should be based on specific mission criteria required rather than classification society rules to

result in highly reliable autonomous operations. Future studies may investigate lighter weight or higher reliability components for increases to system reliability over time for a lower increase in system weight. Additional parameters such as cost of components should be considered in future work if they are available.

The majority of this work was completed using estimated values but for companies and organizations that have similar data available to them, this statistical analysis approach could be utilized. Methods for estimating reliability metrics and system weights presented here are repeatable and using this information, various configurations could be simulated and compared. Following such simulations, a predetermined mission length can be used to decide and the most reliable configuration for this requirement.

# Application of Sampling Methods for Constrained Space in Hull Form Optimization

HOU Wen-long<sup>1,2</sup>, CHANG Hai-chao<sup>1,2,\*</sup>, FENG Bai-wei<sup>1,2</sup>, LIU Zu-yuan<sup>1,2</sup>, ZHAN Cheng-sheng<sup>1,2</sup>, CHENG Xi-de<sup>1,2</sup>

## ABSTRACT

*Use of approximation models instead of direct application of CFD tools plays a crucial role in hull form optimization to enhance efficiency. The selection of sample points directly impacts the accuracy and cost of approximation models, and the effectiveness of hull form optimization. This paper presents a sampling method based on constrained space. The distribution pattern of the constrained space is initially analyzed, and its boundary is subsequently extracted by the Support Vector Machine (SVM), providing guidance for the subsequent sample selection. To ensure effective sampling within the constrained space, the maximum minimum distance criterion is employed. The proposed methodology is validated via a case study involving a 13,000DWT inland twin-screw bulk carrier. The Kriging approximation model is constructed to optimize the hull form while adhering to specific constraint conditions, thereby demonstrating the feasibility and efficacy of the proposed approach.*

## KEY WORDS

Hull Form Optimization; Constrained Space; Support Vector Machine; Maximum Minimum Distance Criterion.

## INTRODUCTION

At present, ship shape optimization based on approximate model has garnered significant attention. Utilizing an approximation model, instead of a higher-accuracy simulation model, during the ship optimization process serves to reduce computational complexity and enhance optimization efficiency. Wang et al. (2018) introduced the Kriging approximation model in the multi-objective fast optimization process of container ship (KCS) and combined it with the non-dominated genetic algorithm (NSGA-II) to complete the resistance optimization objective for KCS ship under design draft and service speed, and at the same time, improve the ship's wave resistance and optimization efficiency. Liu et al. (2022) constructed a multi-fidelity Co-Kriging agent model, and illustrated the advantages of multi-fidelity Co-Kriging agent model compared with single-fidelity Kriging agent model in terms of fidelity and efficiency through a series of numerical examples. Finally, the ship shape optimization design for the total hull drag of DTMB-5415 at the design speed is given. Chen et al. (2015) optimized the hull shape of a high-speed Delft catamaran to reduce the drag based on the idea of dimensionality reduction in the design space and geometrical variability assessment by means of the Karhunen-Loève unfolding, approximate modeling, and deterministic Particle Swarm Optimization (PSO), compared with the previous optimization process. Compared with the previous optimization process, the computational cost is reduced by 90% and the drag is further reduced by 6.6%. Bonfiglio et al. (2018) used multi-fidelity gaussian process regression (MF-GPR) to build a probabilistic approximation model and explored the 35-dimensional SWATH hull-shape optimization and 17-dimensional underwater wing-shape optimization, respectively, which greatly reduced the optimization and computational workload. In order to further improve the accuracy of the approximation model, Hochkirch et al. (2013) studied the Hybrid Model (HM).

Before constructing the approximation model, a certain number of sample points need to be selected in the design space for CFD calculation, and subsequently they will be used as the training set for constructing the approximation model. Currently, the common sampling methods used in ship optimization are as follows: orthogonal design, Latin square design, uniform design, sobol random sampling and so on. On the basis of these commonly used methods, many scholars have conducted a large number of detailed studies. Ouyang et al. (2022) proposed a maximum entropy adaptive sampling method based on uniform experimental design. By comparing with the incremental Latin hypercube-based method, the adaptive sample distribution obtained by the proposed method is more uniform and the global approximation model is more accurate. Chang et al. (2021) proposed a dynamic sampling method (DSM) to improve the accuracy and efficiency of the approximation model by taking into account the effect of sample quality measurements in the input and output parameter spaces. The proposed method is compared with the conventional sampling method, and it is proved that the DSM outperforms the static sampling method. Wang et al. (2021) comparatively analyzed the hydrodynamic performance of a smooth boat in the mono-hull state (MFS) and the three-hull state (TFS), and the optimal range of the sideboard arrangement is given by using the full factorial design space sampling method, which is verified on the scale of a real boat. Based on the LHD sampling method, Wang et al. (2021) analyzed the prediction accuracy of the SVR model with different sample set sizes, and completed the multi-objective optimization of drag and companion flow of offshore aquaculture vessels. Feng et al. (2018) also optimized the hull profile and jet conduit shape of a water-jet propelled trimaran based on the LHD sampling method.

The above studies on approximate modeling and sampling methods seek to make the samples fill the entire design space uniformly, while the limitations of the constraints are not considered. This means that the sample set we obtain through the above sampling methods will contain both sample ship types that satisfy the constraints and sample ship types that do not satisfy the constraints, leading to a decrease in the accuracy of the model forecasts. Therefore, if the constraints can be considered at the sampling stage, and the sample point sets satisfying the constraints can be obtained directly through the sampling method, avoiding the mixing of sample ship types satisfying the constraints and those not satisfying the constraints to the maximum extent, it will be conducive to the construction of the subsequent approximate model and optimization algorithms, which will improve the forecast accuracy of the approximate model and at the same time, save the time cost of optimization.

This paper focuses on a 13,000DWT inland twin-screw bulk carrier, considering the total ship resistance as the optimization objective. The paper employs the constraint-space oriented sampling method proposed herein to construct a Kriging approximation model. A comparative study is conducted on the optimization of the ship type under specified constraint conditions.

## **SAMPLE POINT SELECTION METHOD FOR CONSTRAINT SPACE**

To incorporate constraints into the sampling stage and achieve the goal of directly obtaining a set of sample points that satisfy the constraints through sampling, this paper introduces a sample point selection method based on the support vector machine in the constraint space. The workflow is illustrated in Figure 1. The specific process is as follows:

- (1) The range of variation of the variables is first determined to form the initial design space;
- (2) Sampling in Design Space;
- (3) The constraints on the sample points are calculated to complete the data preparation for partitioning the initial design space;
- (4) The initial design space is partitioned using the support vector machine method to obtain the space we need to satisfy the constraints;
- (5) If the number of sample points in the feasible space that satisfies the constraints is sufficient, these sample points can be used for the construction of the approximation model, otherwise, new sample points have to be co-opted in the feasible space that satisfies the constraints until the requirement of the number of sample points for the construction of the approximation model is met.

**Figure 1: Constraint space oriented approximation model construction process.**

As can be seen, the core of the method is the delineation of the design space and the selection of subsequent sample points, which are described below respectively.

## Support Vector Machine Algorithm Principles

The SVM algorithm is a machine learning method based on statistical learning theory, which aims to find the "optimal hyperplane" that can effectively classify the training samples. In most cases, this "optimal hyperplane" should have the best robustness to local perturbations in the training samples, while having the smallest classification error and the strongest ability to generalize to unseen examples.

Suppose that for a given training set is as follows:

$$\{(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)\}, \quad x \in R^n, y \in \{1, -1\} \quad [1]$$

The hyperplane can be expressed as  $\omega^T x + b = 0$ , where  $\omega = (\omega_1; \omega_2; \dots; \omega_d)$  is the normal vector and  $b$  is the displacement term. It can be found that the normal vector  $\omega$  and the displacement  $b$  determine a hyperplane, so we can denote a definite hyperplane as  $(\omega, b)$ . In order for a hyperplane to classify all training samples correctly and have a classification interval, it is required to satisfy the following constraints:

$$y_i[(\omega^T \cdot x_i) + b] \geq 1 \quad i = 1, 2, \dots, n \quad [2]$$

As shown in the Figure 2., the closest sample points to the hyperplane such that the equality sign of the constraints holds are the "support vectors", and the sum of the distances of the two dissimilar support vectors to the hyperplane is

$$\gamma = \frac{2}{\|\omega\|} \quad [3]$$

$\gamma$  is also referred to as the classification interval. In order to maximize the classification interval, the problem of constructing an optimal hyperplane can be transformed into solving the following equation under constraints:

$$\begin{cases} \min_{\omega, b} \frac{1}{2} \|\omega\| \\ s.t. y_i [(\omega^T \cdot x_i) + b] \geq 1 \end{cases} \quad [4]$$

Using the Lagrange factorization method and the dyadic principle, the above equation can again be transformed into the following optimal classification function problem:

$$f(x) = \text{sign}[\sum_{i=1}^n \alpha_i y_i \langle x_i, x \rangle + b] \quad [5]$$

**Figure 2: Optimally separating hyperplane and support vectors.**

If the data are nonlinearly differentiable, SVM first maps the input space to a high-dimensional linearly differentiable space through the kernel function, and then classifies in the new space. In addition, the outliers in the data will seriously affect the classification performance of SVM, in order to make the model more robust, the soft interval and penalty term are introduced, and the improved SVM objective function is as follows:

$$\begin{cases} \frac{2}{\|\omega\|} \min_{\omega, b} \frac{1}{2} \|\omega\| + C \sum_{i=1}^n \xi_i \\ s.t. y_i (\omega^T x_i + b) \geq 1 - \xi_i, \quad \xi_i \geq 0, \quad C \geq 0 \quad i = 1, 2, \dots, n \end{cases} \quad [6]$$

In the above equation,  $C$  is the penalty coefficient to control the misclassification of outliers, the larger  $C$  means the stricter, the lower tolerance for outliers; on the contrary, it means the more lenient, the higher tolerance for outliers. The classification function of SVM in the case of kernel mapping is:

$$f(x) = \text{sign}[\sum_{i=0}^n a_i y_i K \langle x_i, x \rangle + b] \quad [7]$$

In the above equation,  $K \langle x_i, x \rangle$  is the kernel function. The commonly used kernel functions are polynomial kernel function, Gaussian radial basis kernel function and Sigmoid kernel function.

## Dividing the Design Space

In this paper, SVM method is utilized to divide the design space to get the corresponding form of constraint space, the basic division process is shown in Figure 3., and the specific division process is as follows:

Step 1: The sample point set that completes the calculation of constraints is filtered and divided into samples that satisfy the constraints and samples that violate the constraints, forming the sample point set respectively. And then the whole sample set is divided into training set and testing set according to a certain proportion.

Step 2: Preliminarily, the penalty coefficient  $C$  and other related parameters of the SVM model are selected, the Gaussian kernel function is selected as the kernel function of the SVM, and the kernel function parameters, which will affect the number of support vectors and the dispersion of the sample features.

Step 3: The training samples are classified and the relevant parameters of the SVM are adjusted appropriately according to the accuracy of the classification.

Step 4: Finish training the SVM model and save the model output.

With the SVM algorithm, it is possible to divide the region occupied by feasible and infeasible sample points to obtain a new feasible space that satisfies the constraints, providing a guide for subsequent sampling in the feasible space.

Figure 3: Process of dividing the design space.

## Sample Points Selection Method

After dividing the design space by SVM method, we get the feasible space and infeasible space. If the number of sample points in the feasible space is not enough for constructing the approximate model, then we need to select new sample points in the feasible space. The following briefly describes the sample point selection strategy in the feasible space:

First, the existing sample points in the feasible space are formed into a sample point set, and then, starting from the selection of the first point, it is necessary to satisfy the maximization of the minimum distance from each newly selected sample point to the existing sample points. According to the following rule, the sample points are selected sequentially until the number of sample points in the point set meets the required number of inputs (Teng et al., 2018). Denote the minimum distance between any two points as the Euclidean distance:

$$d(x, y) = \|x - y\|_2 \quad [8]$$

The first  $n$  sample points that have been selected are  $s_1, s_2, \dots, s_n$ , then the set of points is

$$S_n = \{s_1, s_2, \dots, s_n\} \quad [9]$$

The distance from any sample point  $x$  to the set of points  $S_n$  is

$$d(x, S_n) = \min \{d(x, s_i)\} \quad [10]$$

The next sample point to be selected is

$$s_{n+1} = \arg \max \{d(x, S_n)\} \quad [11]$$

All sample points in the final point set are widely and uniformly distributed in the feasible space.

Taking the two-dimensional constraint space constituted by inequality [12] as an example, the effect of sample point selection is shown in Figure 4. Where the region constituted by the blue points is the constraint space region, and the red points are the sample points obtained by sampling.

$$\begin{cases} 0 \leq x \leq 10 \\ 0 \leq y \leq 10 \\ x + y \leq 10 \end{cases} \quad [12]$$

Figure 4: Sample point selection oriented to the constraint space

## EXAMPLE

### The Optimization Model

Taking the 13,000DWT inland bulk carrier as an example, a three-dimensional parametric model of the ship was constructed in the fully parametric modeling software CAESSES, with a scaling ratio of 1:25 (e.g. Figure 5), and its main parameters are shown in Table 1. Three variables to be optimized for the design were selected as  $b_B$ ,  $y_b$ , and  $area\_ratio$ , and their specific meanings and ranges of variations are shown in Table 2.

Figure 5: 13,000DWT inland waterway twin-screw bulk carrier

Table 1: Main parameters of model ship

$L_{pp}$	$L_{cb}$	$B$	$T$	$C_b$	$\nabla$	$S_{wet}$
5.08 m	2.564 m	0.872 m	0.22 m	0.86	0.836 m <sup>3</sup>	6.018 m <sup>2</sup>

Table 2: Design parameters

Design Variables	Design Variable Meaning	Initial Value	Lower Bound	Upper Bound
$b_B$	Stern Axis Distance Breadth Ratio	0.5287	0.5	0.55
$y_b$	Bobtail Medial Fullness	0.4162	0.1	0.6
$area\_ratio$	Design Below-Waterline Fullness	0.8356	0.75	0.9

Minimizing the total resistance  $R$  of the model ship at the draft of  $T=0.22m$  and  $F_r=0.1457$  is taken as the optimization objective.

$$\min f_{obj} = R \quad T=0.22m \quad F_r = 0.1457 \quad [13]$$

The constraints are listed below:

(1) The optimized displacement must not be less than that of the mother ship, and this constraint is shown in Equation [14]:

$$\frac{\nabla_{opt} - \nabla}{\nabla} \geq 0 \quad [14]$$

(2) The optimized longitudinal position of the buoyant center of gravity of the corresponding structure must not exceed the midship position at 0.55% towards the bow, and this constraint is shown in Equation [15]:

$$\frac{L_{cb} - L_{pp} / 2}{L_{pp}} \leq 0.55\% \quad [15]$$

## Analysis of the Design Space

According to the upper and lower limits of the three design parameters, 500 sample points are sampled in the design space using the uniform design sampling method, and these 500 sample points correspond to 500 different sample ship types. The hydrostatic calculation module of CAESSES is used to calculate the hydrostatic data for these 500 sample points, and the calculated results are compared with the optimized performance constraints of the ship types. The 500 sample points are classified into two categories based on the comparison results: 1. feasible sample points that satisfy the constraints; 2. infeasible sample points that do not satisfy the constraints. Visualize this 3D design space as shown in Figure 6.

**Figure 6: Three-dimensional design space**

The red points in Figure 5 indicate infeasible sample points that do not satisfy the constraints, and the green points indicate feasible sample points that satisfy the constraints. From the figure, it can be seen that most of the sample points obtained after sampling according to the original design parameter variation range do not satisfy the performance constraints, and only a small number of feasible sample points satisfy the performance constraints and are distributed in the corner of the design space, so constructing an approximation model based on the whole set of sample points will cause a big trouble to the optimization work.

## Optimization Strategies

### Optimization Processes

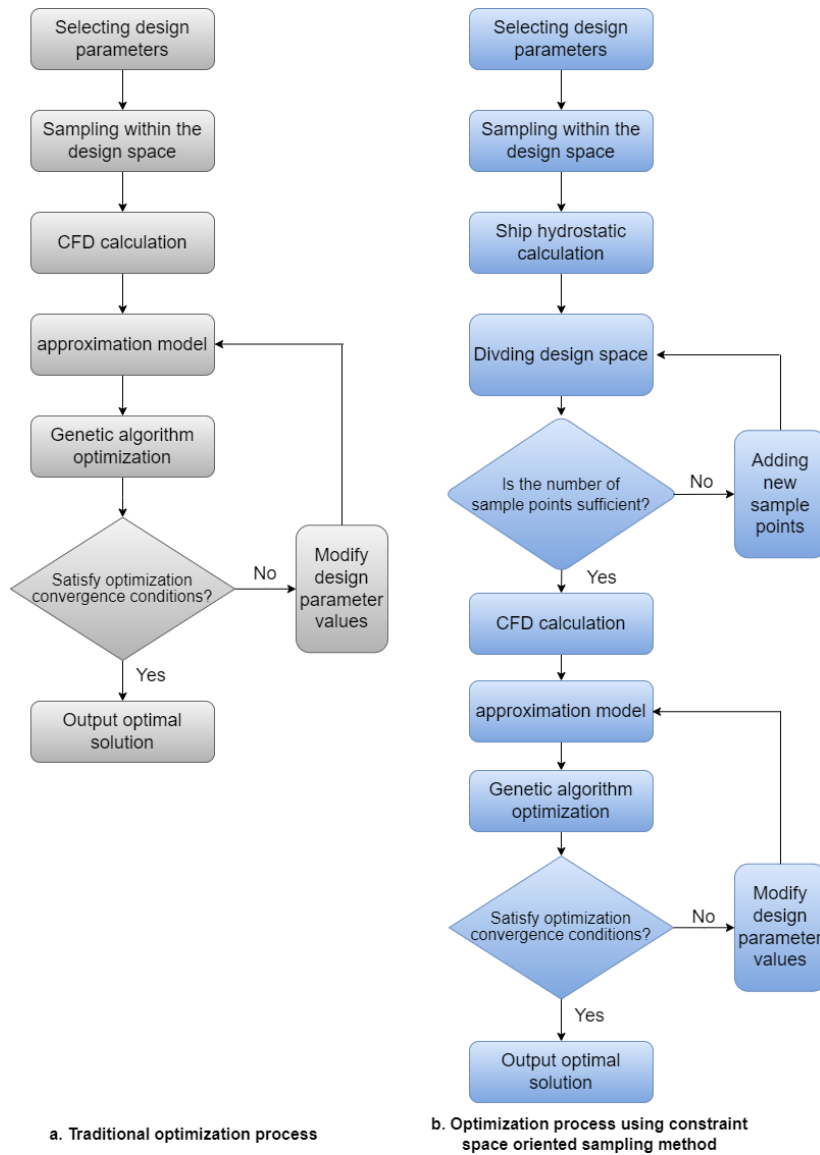

After obtaining the feasible space, the number of sample points distributed within it is 71 in total, which does not meet the demand for the number of samples for constructing the approximation model, and it is necessary to increase the number of sample points in the feasible space to 80, and use the sample point selection method based on the maximum-minimum distance to increase the sample points by 9 sample points in the feasible space. Some of the selected sample points are shown in Table 3 below:

**Table 3: Selected sample points co-opted in the feasible space**

Number	b_B	y_b	area_ratio
1	0.5500	0.1256	0.8154
2	0.5423	0.1641	0.7500
3	0.5500	0.3051	0.7731
4	0.5436	0.1128	0.7615
5	0.5498	0.2154	0.8000
6	0.5449	0.1641	0.7962
7	0.5487	0.2026	0.7615
8	0.5346	0.2795	0.7500
9	0.5415	0.1256	0.7885

And then the total resistance of these 80 sample ship types is calculated by STAR-CCM+ software to get the sample set for training the approximation model. Then the Kriging approximation model is constructed and the optimization solver is set up, and the genetic algorithm is chosen for optimization. Finally, the study on the hydrodynamic performance line optimization of this ship is completed.

The constraint space-oriented sampling method proposed in this paper and the traditional method based on uniform test design are simultaneously applied to optimize the hull profile, and the optimization effects of the two methods are compared, and the basic flow of the two methods is shown in Figure 7.

**Figure 7: Optimization process**

In order to compare the accuracy of the approximate models constructed by the two methods, five sample points are re-selected in the feasible space using the Latin hypercubic sampling method, and the total resistance value is calculated for each sample ship type using the STAR-CCM+ software as the corresponding prediction sample set, and these samples are shown in Table 4. The prediction sample set was forecasted using the Kriging approximation model constructed through two different methods. Finally, the forecasting results of the approximate models constructed by the two methods are evaluated using the root mean square error (RMSE), and the evaluation results are shown in Table 5.

**Table 4: Sample points used for assessment**

b_B	y_b	area_ratio	Traditional optimization method	Constraint space-oriented optimization method	CFD calculation results
0.5465	0.215	0.7875	14.003 N	13.964 N	13.974 N

### Optimization Results Analysis

Taking the CFD calculation result as the real drag value of the ship model, the prediction error of the drag and the computational cost of the approximate models constructed by the two methods are compared as shown in Table 5. From the table, it can be seen that the prediction error of the constructed Kriging approximation model is smaller and the prediction accuracy is higher compared with the traditional optimization process after using the method proposed in this paper. This is because the optimization process based on the constraint-space oriented sampling method excludes the sample points that do not satisfy the constraints in the process of constructing the approximation model, which improves the forecast accuracy; On the other hand, using the method proposed in this paper has a lower CFD computational cost, i.e., the number of training samples required to achieve the same accuracy of the approximation model as the traditional method is lower, which is also due to the fact that we only select the sample points that satisfy the constraints to perform the CFD computation and construct the approximation model.

**Table 5: Comparison of the accuracy and computational cost**

	RMSE	RMSE Comparison	The number of samples for modeling that need to be calculated by CFD
Uniform Design	0.0414	——	500
Constrained Space Sampling Optimization	0.0193	-53.4%	80

Comparison of the bow and stern profiles of the optimized ship and the initial ship obtained after optimization using the two methods can be seen in Figure 8, and it can be seen that some of the ship's profiles have changed to different degrees before and after optimization. As can be seen from the waveforms in Figure 9, the amplitude of the rising wave of both optimized ships is reduced to some extent after optimization compared with the initial ship.

**Figure 8: Comparison diagram of the hull lines**

**Figure 9: Comparison of waveforms**

Comparison of the hydrostatic data of the ship model optimized by the two methods is shown in Table 6. From the hydrostatic data, the displacement volume of the ship model optimized for constraint-oriented spatial sampling increases by 0.23% compared to the initial ship. The longitudinal position of the center of gravity is shifted to the stern direction by 0.001 m compared with the initial ship, and its wet surface area is reduced by 0.75% compared with the initial ship. The drainage volume of the optimized ship model sampled by the traditional uniform design method increased by 0.39% compared to the initial ship, the longitudinal position of the center of buoyancy shifted by 0.003m in the aft direction compared to the initial ship, and the wet surface area decreased by 0.50% compared to the initial ship. It indicates that the frictional resistance of the ship models optimized using both methods has been reduced to different degrees.

The comparison of the drag optimization results of the two methods is shown in Table 7. The total drag of the ship model optimized by the constraint-oriented spatial sampling method is 13.778 N, which is a decrease of 3.35% in the total drag compared with the initial ship, and the error of the approximate model forecast is 0.36%; the total drag of the ship model optimized by the traditional uniform design method is 13.876 N, which is a decrease of 2.66% in the total drag compared with the initial ship, and the error of the approximate model forecast is 0.36%. The approximate model prediction error is 0.36%. Through comparison, it can be found that the approximate model constructed by the constraint space-oriented sampling method proposed in this paper has higher optimization accuracy and better optimization effect.

**Table 6: Hydrostatic data**

	Drainage volume $\nabla$ (Percentage change)	Longitudinal position of the floating center $L_{cb}$ (Magnitude of change)	Wetted surface area $S_{wet}$ (Percentage change)
Mother ship	0.836 m <sup>3</sup>	2.564 m	6.018 m <sup>2</sup>
Uniform Design	0.8393 m <sup>3</sup> (+0.39%)	2.561 m (-0.003m)	5.988 m <sup>2</sup> (-0.50%)
Constrained Space Sampling Optimization	0.838 m <sup>3</sup> (+0.23%)	2.563 m (-0.001 m)	5.973 m <sup>2</sup> (-0.75%)

**Table 7: Ship model drag optimization results**

	Approximate model forecast values	CFD calculated values	Resistance reduction ratio
Mother ship		14.225 N	
Uniform Design Optimization	13.613 N	13.876 N	-2.66%
Error	1.90%		
Constrained Space Sampling Optimization	13.728 N	13.778 N	-3.35%
Error	0.36%		

## CONCLUSIONS

This paper proposes a constraint space oriented sampling method in ship shape optimization, taking an inland river 13,000-ton double-tailed bulk carrier as the optimization object, using the method to select the sample points meeting the constraints to construct the approximation model, and using the optimization algorithm to search for the optimal in the feasible space, and finally completing the research on the application of the constraint space oriented sample point selection method in the line shape optimization of this ship. The conclusions are as follows:

(1) The constraint space-oriented sampling method proposed in this paper can improve the forecasting accuracy of the constructed approximate model and save the time cost of calculation.

(2) The application of the constraint space-oriented sampling method to the hydrodynamic performance line shape optimization study of an inland double-tailed bulk carrier, and the comparison with the optimized ship obtained by using the uniform experimental design optimization, shows that the application of this method to the ship shape optimization is feasible.

## ABSTRACT

*Flipflop is an East African organisation with a mission to end single use plastic, driving this agenda using circular economy principles applied to the design and build of fully recycled plastic sailing dhows from their boatyard in Lamu Kenya. Flipflop has achieved measurable global impact by showcasing the world's first ocean going recycled sailing boat, Ndogo, a 9 metre long, lateen rigged dhow which has sailed the East African coastline and across Lake Victoria. Flipflop is now aiming to build a much larger ocean-going dhow, named Kubwa, which presents further technical challenges from a marine design perspective. To meet these challenges. Flipflop are utilising a combination of generational heritage boatbuilding expertise in Lamu; specific design experience from building and sailing Ndogo; technological progress driven by other recycled plastic projects; and more formalised naval architecture and engineering design approaches. This paper introduces the context within which Flipflop is centred, the links to circular economy design principles and the specific design challenges from working with recycled plastic as a boatbuilding material.*

## KEY WORDS

Plastic; Recycling; Circular Economy; Boatbuilding; Flipflop.

## INTRODUCTION

In this paper we consider a circular economy approach to the design, construction, and operation of marine craft through a broad overview of current achievements and challenges from Flipflop, an organisation which has launched three sailing dhows made almost completely from recycled plastic waste and now plans to build a larger 24 metre ocean going sailing dhow. We also share some of the practical challenges and continuing design questions from using recycled plastic as a boat building material.

Flipflop is an East African organisation, based in Lamu Kenya, with a stated mission to end single use plastic, ensure all other plastics are part of a circular economy and promote environmental solutions to the plastic waste crisis. The organisation is centred around the construction and operation of fully recycled sailing dhows. Flipflop works with communities to “close the loop” on waste plastics, collecting and recycling waste to produce boats and products rooted in indigenous heritage. They also harness appropriate high technology techniques to meet the unique design demands from using recycled plastic as a construction material.

Flipflop has demonstrated global impact from their campaigning work, perhaps most significantly by showcasing the world's first ocean going recycled sailing boat, Ndogo (small in Swahili), a 9 metre long, lateen rigged dhow with lines typical of Lamu heritage designs (Figure 1). Ndogo has completed several voyages around the East African coast and on Lake Victoria, which stretches across the borders of Kenya, Uganda, and Tanzania. These voyages aimed to promote messages to end plastic

pollution, bring awareness to the issue, engage East Africans in alternative ways to use existing waste plastic and demand legislative action to ban single-use plastics. The impact is evidenced in several end of year organisation reports (Flipflopi 2021; 2022; 2023).

Since building Ndogo, Flipflopi have designed and built several smaller boats, including a canoe and a 7-metre taxi dhow that will carry passengers and light cargo within the Lamu archipelago. A training centre has been established at the Flipflopi boatyard, which has so far taught 30 people from the Kenyan Coast traditional boat building techniques in combination with circular economy practices.

A central ambition for Flipflopi is to launch a substantially bigger dhow, Kubwa (large, in Swahili), which will be about 24 metres long. The design of Kubwa aims to integrate the knowledge generated from Ndogo. There are also new challenges inherent in a larger and more complex boat.

This paper first introduces the context within which Flipflopi is centred – the plastic waste crisis that is especially problematic in LMIC settings such as East Africa. The principles of circular economy design are then introduced, starting from a broad overview and then focusing in on the open-loop recycling system followed by Flipflopi. The application of circular economy principles in other areas of marine design are briefly considered. The paper then focuses on the specific design principles and challenges from working with recycled plastic as a boatbuilding material: developing hull lines, structural design, material properties and joining techniques. The linked challenge of sustainable propulsion is also summarised.

## PLASTIC WASTE AND POLLUTION

Over 8 billion tonnes of virgin plastics have been produced up to 2021 (Geyer et al. 2017). Around 80% of this total has been discarded, demonstrating a loss of valuable resources and the origin of an environmental disaster (Bucknall 2020). The most visible consequence of this is the huge volume of plastic that ends up in the ocean, which has become a maritime crisis. Lau et al. (2020) shows that 78% of the plastic pollution problem could be solved by 2040 but only if all the possible reduction pathways are followed: that means reducing consumption, increasing reuse, improving waste collection and recycling, and accelerating innovation in the plastic value chain.

Plastic pollution strongly affects coastal communities and their natural environment. These communities, particularly in rural and lower economy regions, face sometimes overwhelming quantities of plastics on beaches and in fishing waters (Phelan et al. 2020). Negative consequences to the coastal environment include entanglement in plastic by megafauna, ingestion of plastic by fish, microplastic ingestion by invertebrates, ghost fishing by abandoned nets, algae growth in plastic debris, contaminated fisheries and reduced natural health of beaches littered with plastic (Thushari & Senevirathna 2020).

The focus of this paper is Amu Island, which is part of the Lamu Archipelago on the Kenyan coast with a population of around 30,000. The community generates about 14 tonnes of waste daily, of which about 2.5 tonnes is plastic waste (Moejes 2023a). The quantity of washed-up ocean plastic is not quantified, but by illustration a single community beach clean-up on a 10-km stretch of beach (see Figure 2) typically collects 35 to 40 tonnes of plastic waste (Scott Harden et al. 2020; Moejes 2023b). To exacerbate the problem, there is only one waste disposal site on Amu Island. This area has no separation facilities and waste is left to pile up, blow across the island into the ocean and in many instances is burnt openly.

A community survey in Lamu, completed as part of a plastic waste mapping study by Flipflop in 2022, found that 98% of respondents viewed plastic waste as a problem. They also found significant interest in not only learning about the environment and pollution, but also taking part in innovative solutions, such as boat building with recycled plastic, as a practical way of tackling the growing plastic waste problem (Flipflop 2022).

## CIRCULAR ECONOMY DESIGN PRINCIPLES

### Definition

Circular economy is a model of production and consumption which centres on the reuse and recycling of materials. There are many definitions of circular economy and an extensive body of literature that discusses, applies and critiques the concept. We only provide a summary of some well-established circular economy definitions, for the purpose of contextualising the Flipflop approach. We use circular economy from a practitioner-led perspective, and do not take a detailed theoretical position or critique of the concept in this paper.

Velenturf and Purnell (2021) summarise the circular economy as “a technology-focused concept that can generate economic gains while alleviating pressure on the environment”. It involves “circularity of resource flow by preventing loss of material out of the system” (Bucknall 2020). It aims to make “better” use of resources, although “better” is sometimes difficult to define. For plastics this goes well beyond recycling, incorporating the pillars of sustainability – economic, social and environmental. In this way a product design incorporates life cycle aspects such as durability, reuse, repair, remanufacture alongside beneficial economic activity such as employment and enterprise, environmentally driven considerations of energy consumption and social considerations of ownership costs and community benefits.

The Ellen Macarthur Foundation, inspired by the founder’s solo sailing circumnavigation of the globe, is a leading advocate of circular economy approaches. They base the circular economy on three principles driven by design (Macarthur 2019):

1. Eliminate waste and pollution
2. Circulate products and materials (at their highest value)
3. Regenerate nature

## The Plastic Circular Economy

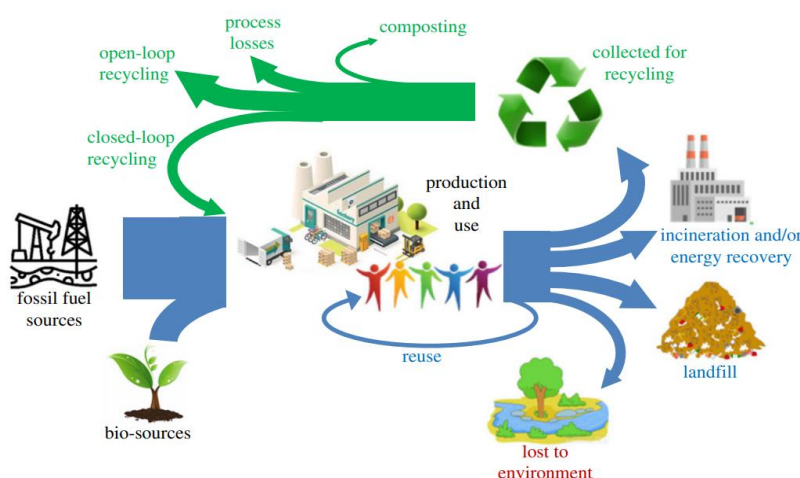

The plastic circular economy, shown in Figure 3, prevents linear economy waste such as landfill, incineration and environmental pollution. Circularity is enabled at several levels, including (Bucknall 2020):

- Reuse of plastic products for their original purpose, such as a reusable water bottle, or for new purposes, such as using a water bottle as a plant pot.
- Open-loop recycling, where the plastic is recycled into a new product or use, such as recycling water bottles into polyester clothing.
- Closed-loop recycling, where the plastic is recycled back to its original purpose, such as recycling used water bottles into new water bottles.

Open and closed loop recycling are typically characterised as remote industrial processes. Waste plastic is collected and removed from a community to a large-scale processing plant. It will then re-enter a different community economy as a raw material or a newly recycled product. Whilst this process may meet the “three principles” definition, there is less community engagement in the complete economic model. This misses opportunities to “better” the sustainability at a local level. For example, despite high awareness of recycling in the UK population, there continues to be pitifully low rates of acceptably separated plastic waste collection from the kerbside (Burgess et al. 2021).

Alternative circular models, such as that advocated by Precious Plastic (Spekkink et al. 2022), promote local engagement throughout the recycling-remanufacture process. This includes developing small scale recycling spaces to process plastic waste and demonstrating innovative manufacturing methods for recycled product designs that benefit the communities that collected the waste. Scott-Harden et al. (2022) discusses the design challenges of locally recycled products. Recycled material can be used to manufacture a diverse range of high precision, durable products where tolerances are high such as sunglass frames, plug sockets and jewellery. However, the processing of larger quantities of locally recycled plastic is often better suited to less refined large-scale structures such as furniture, window frames, bricks and fencing. Traditionally built dhows, and therefore many other wooden boat types, can be included in this category. With proper consideration of the material properties and consistency, boatbuilders can use recycled plastic lumber with established carpentry techniques in very much the same way as wood (Scott-Harden et al. 2022).

As will be shown, Flipflop is an exemplar of a community centred approach to open loop recycling. The flow of plastic from waste to a new product is entirely within the community, and the products themselves contribute to and promote further recycling and awareness of the plastic pollution crisis. The success of Flipflop suggests that alternative circular models hold an important and powerful role for building sustainability into the circular economy.

**Figure 3: The lifecycle of plastics, including linear and circular economy principles (Bucknall 2020)**

## The Flipflop Approach

Flipflop uses an open-loop recycling system coupled to an alternative circular economy model to turn locally generated plastic waste into carpentry products for the community including dhows, furniture and decorative products. The system steps (Figure 4) are:

1. Household, small-scale industrial and washed-up plastic waste from the sea is gathered and macro sorted by people within the Lamu archipelago. At present only some plastic types can be recycled.
2. The waste is collected from various stations or brought to the Flipflop boatyard on special collection days. It is weighed and a collection payment is made.
3. The waste is then further sorted into polymer type and colour. Some polymers, such as PET, are sent away to industrial recycling centres. Polymers that Flipflop can effectively recycle, such as HDPE, continue through the recycling space.
4. The plastic is crushed into shreds, thoroughly washed, and then moulded or extruded into construction materials including planks, beams and special mouldings. New processes such as sheet pressing are being developed.
5. The construction materials are used in several carpentry and boatbuilding spaces within the yard, including a workshop for craft products and furniture, a skills training centre and the boatbuilding sheds.
6. Smaller carpentry products are commissioned and sold, mostly in the local community and often as high value items.
7. The dhows continue to be operated by Flipflop as prototype demonstrators and are the focus of their broader campaign work to end single-use plastic. The smaller boats are also planned to be used for enterprise, such as passenger transport, and for plastic collection.
8. At end of life, the thermoplastics embodied in Flipflop products can be looped back into the recycling process.

**Figure 4: The Flipflop recycling centre process, in this case showing a moulding technique to produce plastic lumber**

Flipflop operates a full systems approach to their organisation strategy, which they define as “the combination of education leading to behavioural change, innovation within the circular economy, and campaigning to influence legislative change to end single-use plastics” (Flipflop 2022). This is applied through a strategy integrating education, innovation and influence. For example:

- Education is directly delivered via a heritage boatbuilding training centre, which piloted a 12-week vocational course in 2022. Broader educational programmes to change behaviour around plastic consumption is delivered via community-based partners and activists across East Africa, with diverse contributions including storytelling, scientific research and projects to advance the role of women in waste management and boatbuilding.
- Innovation is driven broadly to include systems from recovery to upcycling and is applied directly to overcome the practical challenges of building larger boats such as Kubwa from recycled plastic, as outlined in the Design Challenges section of this paper.
- Influence is underpinned by the education and innovation activities, which provide a backdrop for Flipflop to effectively lobby for regional consensus to ban unnecessary single use plastics in East Africa.

The Flipflop approach meets the “three principles” of circular economy. The full systems approach creates added benefit to the design capabilities and philosophy that “better” the overall sustainability of the process:

- Eliminate waste and pollution: Flipflop now collects over 12 tonnes of plastic every month, has become the de-facto recovery and recycling centre for Lamu, and is now extending operations across the entire archipelago. About 30% of the collected plastic cannot be processed on site, and whilst the onward chain to larger recycling centres in Kenya is established it is not yet economical. Whilst this presents space and capacity challenges for the Flipflop boatyard, it

has also driven considerable design innovations to find new ways to use more of the waste plastic. For example, to investigate the use of polypropylene sacks, a common waste product from the food and construction sectors, to provide strength in sheet materials produced in a bespoke press machine. The envisaged outcome is large format sheets suitable for a new range of construction products such as stud walls and doors.

- Circulate products and materials (at their highest value): Flipflopi has proven that circulated plastic waste can be used to produce new products at high value. Apart from the dhows, the most notable high value product is the ‘King’s Throne’ presented to the British monarch on a visit to Kenya in 2023 (Figure 5). However, the range of polymer types, quality, suitability for re-manufacture and subsequent consistency has challenged the design process. Whilst the plastic lumber can be worked in a similar way to wood, it does not have similar material properties. Flipflopi are now quantifying material behaviour by adapting established material testing methods and linking to formalised boat design codes (see Design Challenges section).
- Regenerate nature: Using recycled plastic as a building material potentially places less pressure on wood sourced from local forests. Flipflopi also contribute to regeneration of nature through their influence in better managing the local environment, for example by replanting mangroves, and campaigning for an end to single use plastic. The eco-design philosophy enables further innovation in additional benefits to other environmental issues. For example those hinging around the use of fossil fuels, including reducing carbon emissions from boats, building renewable energy capacity, improving local air quality, and preventing pollution from unburnt and spilled petrol. The potential of electric propulsion, discussed in the Design Challenges section, is an example of this added benefit.

Flipflopi also meets the three pillars of sustainability. An example is the impact on people engaged with the organisation in different ways. Flipflopi employs 30 people directly, 46% of whom are women, and has 9 skilled artisans on contract. The vocational course has trained 30 people in plastic carpentry techniques. The recycling process engages with over 700 local people, 50% of whom are women, from lower income communities. They collect waste and generate income from this, currently representing a cash injection of about \$24,000 in direct payments to date. The employment and education activity therefore has economic benefit by promoting local enterprise. The high percentage employment of women promotes societal benefit, especially within a local maritime economy which is traditionally dominated by men. All the people involved in Flipflopi are engaged and contributing to the environmental benefit from recycling and reusing plastic waste.

## Circular Economy in Marine Design

Flipflopi is centred in heritage boatbuilding and maritime activities. It holds potential for direct application in many other coastal communities, particularly those where more traditional boat use is still prevalent. Whilst this constitutes a majority of the total marine craft across the globe, it is a small fraction of the total tonnage, which is dominated by large cargo vessels. What does the circular economy mean for this wider shipping industry and the marine design that underpins it?

Agarwala (2023) argues that the maritime industry continues to find it difficult to adopt full circular economy approaches to design. Aspects such as shipbreaking-reuse of materials (Rahman 2021) and decarbonization (Gilbert et al. 2014) can fulfil the “three principles” of circular economy, but currently suffer sustainability failings. For example, Dewan and Sibilia (2023) describe those exposed to toxic pollution from shipbreaking as suffering a form of structural violence in the maritime economy. Decarbonization, the most prominent current challenge for the maritime industry, suffers from “woefully insufficient progress in vessel designing with alternative fuels in mind, as well as in securing alternative fuel supply chains” (Tomos et al. 2024).

Despite the tiny-scale of Flipflopi within the global maritime industry, the project provides questions for marine design to more widely integrate full circular economy. For example, we briefly consider the two “grand challenges” for the marine industry summarised above: decarbonization and shipbreaking.

- **Decarbonization:** The media attention for Flipflopi demonstrates the social power of iconic boat design to capture public imagination and more crucially to promote engagement. Coastal communities across the world hold powerful cultural identity to maritime (Alegret & Carbonell 2014), from tangible activities like shipbuilding and fishing through to intangible feelings of ethos and identity. These communities also suffer some of the worst effects of climate change including erosion, extreme weather events and sea level rise. Can marine designers work better with coastal communities - the builders, users and witnesses of maritime activity - to better capture their imagination through iconic, locally centred ship designs, and through this engage community power to drive a more rapid change to decarbonization and zero emissions in the maritime industry?
- **Shipbreaking:** Flipflopi has made a real impact in their local community to reduce plastic pollution, whilst also inspiring action for zero plastic waste policy in Kenya and internationally. For example, Flipflopi and legal partners have drafted a Bill to ban unnecessary single use plastics across all seven countries in the East African Community (EAC). Over 16,000 people have signed a public petition and 22 legislators representing the EAC unanimously agreed to a regional approach to tackle plastic pollution. The Bill is now being considered for tabling at the East African Legislative Assembly. How can this impactful model – where the marine designers are also the campaigners - be transferred to improve the localised human and environmental costs associated with shipbreaking in countries such as Bangladesh, whilst highlighting the responsibility of the entire maritime sector to focus on stopping unsustainable scrapping practices?

## DHOWS IN THE LAMU ARCHIPELAGO

### Dhow Types, Construction Methods and Uses in Lamu

Boats and the maritime economy are woven into the fabric of Lamu's culture and daily life. This means there are many uses of boats including: local passenger transport within the archipelago; cargo transport from the mainland and between island villages; coastal goods transport stretching between Somalia and Tanzania; inshore and offshore fishing; a variety of tourist activities such as cruises, fishing, diving and expeditions; and a dynamic culture of competitive dhow racing.

**Figure 7: Construction Methods. A new wooden build (top left), an older dhow, Utamaduni, prior to renewal (top right), fibreglass taxiboat moulds (bottom left), “Almas” – a fibreglass dhow under construction (bottom right)**

Dhows with traditional aesthetics and construction arrangements are still prevalent, with examples shown in Figure 6. The Jahazi, with a standing bow stem and a flat transom, is the unique Lamu traditional design. The Jahazi is a recognized cultural icon, and is included in international heritage boat collections. The transom is notably different to the stereotypical boom stern of Arabic dhows. The shape is thought to give easier loading and added comfort. Increasingly popular, especially for tourism, are the wider beam Mozambique dhows. These may still be built from hardwood but are now increasingly using fibreglass which needs less skill to produce and reduces the challenges of boat maintenance.

Mashuas, also called taxi dhows, are the most common way of getting around the Lamu archipelago and are also used for fishing and cargo transport. These are slender flat bottom hulls 6-12 metres long and typically powered by a 15hp outboard. In recent years traditional wooden taxi dhows have been increasingly replaced by fibreglass boats.

There is an active boatbuilding, repair and maintenance industry concentrated in Lamu town and several other villages within the archipelago including Matandoni. Construction methods, also shown in Figure 7, include:

- New wooden “artisanal” construction of dhows. These are mostly for tourism;
- Renewal / refurbishment of existing wooden dhows, such as Utamaduni, a 20 metre dhow also pictured in Figure 15;
- Hand layup fibreglass construction of smaller boats using purpose built moulds, with a mashua shown in Figure 7;

- Fibreglass construction of larger boats, also using concrete and aggregates for keels and stems. These may use end of life wooden dhows as plugs, such as mashua Almas, pictured during construction in Figure 7.

## The Flipflop Fleet

Flipflop have designed, constructed and launched three sailing dhows: Dau la Mwao (Canoe), a small mashua (Water Taxi) and the custom designed expedition mashua dhow Ndogo (see Figure 8 and Table 1).

Figure 8: Dau la Mwao / Canoe (left), Taxi (middle) and Ndogo (right) all sailing in the Lamu archipelago

Table 1: Main Particulars

Dhow Ndogo (Figure 9) was conceived in 2016 by Ben Morrison and Dipesh Pabari as a campaigning tool to spread the message about plastic waste. In Lamu they met master dhow fundi (boatbuilder) Ali Skanda who comes from a generational family of expert carpenters and boatbuilders. Ali accepted the challenge and construction started in 2016. Ndogo was conceived as a prototype to learn boat building methods using recycled plastic. The knowledge from this process was captured through different media resources including a boat building “toolkit” that can be downloaded from the Flipflop website. All recycled plastic boat parts were first sourced from external recycling companies in Kenya before the in-house plastic recycling facility took over production later on, enabling a better control over quality. The keel, ribs and structural elements of Ndogo are all made from recycled HDPE (mostly found in jerry cans or other containers for liquids, like shampoo bottles). HDPE has favourable properties (buoyancy and flexibility) and is easily available to be collected in sorted and relatively clean form.

Figure 9: The elements of Ndogo – frames (left), planks (middle) and covering (right)

Dau la Mwao is a small canoe built entirely from HDPE recycled plastic by students on the first Flipflop heritage boatbuilding course. The design follows a traditional fishing canoe (Figure 10) in shape and construction method, enabling the boatbuilders to use their traditional approach and maintain their boatbuilding heritage. The frames were extruded through custom moulds. The build then followed traditional techniques and was completed over a 6 week period. A complete build process is documented by Flipflop in collaboration with Precious Plastic (Flipflop 2023).

**Figure 10: The basis fishing boat (left), placing the mataruma/ribs (centre), the completed canoe (right)**

The Taxi dhow is the latest boat built by Flipflop. It is a bespoke design sized for potential commercial use and to establish a market for recycled boats to compete with equivalent fibreglass designs now dominating in Lamu. The size is suitable for transporting goods and people across the archipelago, and also offering leisure and tourism trips. The build has also enabled Flipflop to stress test new types of plastic lumber from the recycling centre, along with new construction and sealing techniques including plastic welding as shown in Figure 11.

**Figure 11: Mould for a type of rib (left), welding planks (centre), view from transom showing welded transom (right)**

The proposed large Jahazi dhow (Kubwa) will bring together the knowledge, techniques and experience gained from the previous boat builds. The size and subsequent design complexity of Kubwa presents new challenges, which are summarised in later sections of this paper.

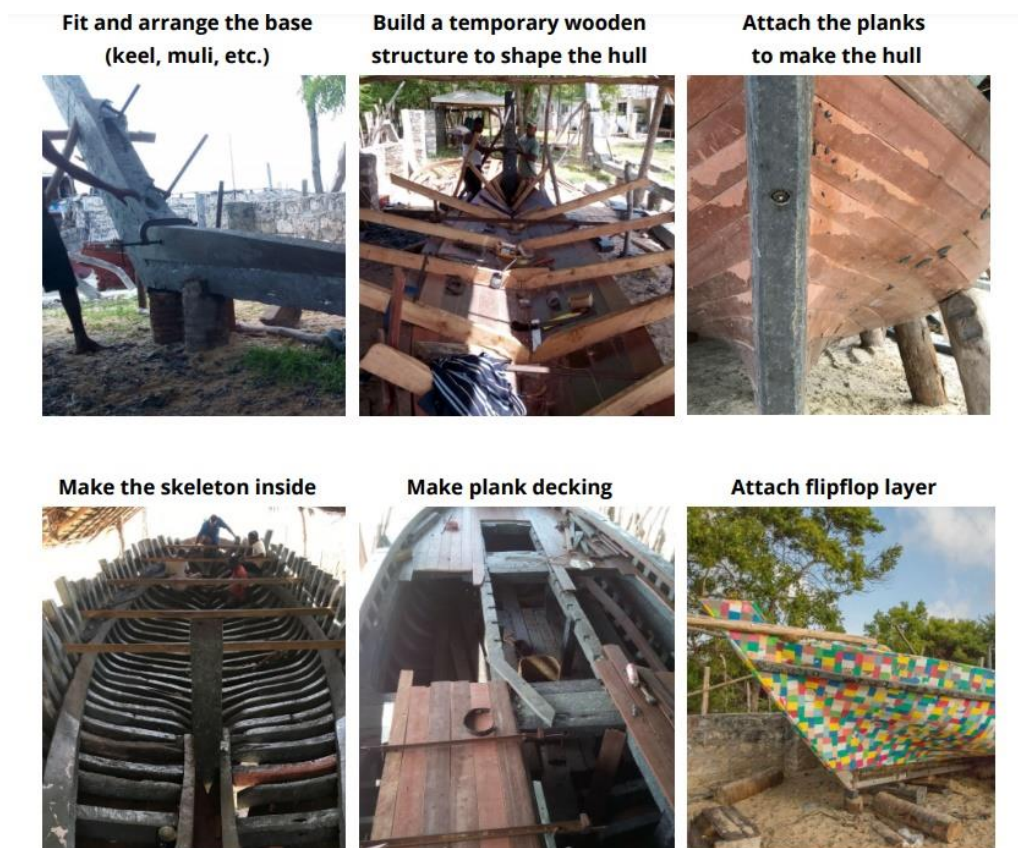

## DESIGN AND BUILD PRINCIPLES

The construction of the traditional dhows of Lamu are easily recognisable as similar to the wooden boat building techniques found in Europe and North America and would be described as carvel planking on sawn frames. However the procedure followed by the dhow builders is not the same as that usually followed elsewhere, being more akin to the method employed in clinker (called lapstrake in North America) boatbuilding. Once the keel, stem and transom have been set up, so defining the overall dimensions, temporary moulds are inserted to guide the shape of the planking. These moulds are continually adjusted by the builder who, using an experienced eye, continually makes minor adjustments to the shape. Once the planking is complete the frames are cut to shape and fastened inside the hull. The timber used has the required curve to the grain, however on larger dhows the entire frame has to be made in two parts (futlocks). These are simply butted together, without doubling pieces for continuity of the structure, however strength is maintained by moving the position of the butt joint in adjacent frames, with the frames themselves being closely spaced. For Ndogo the same traditional procedure was followed, but with plastic timber planks, and the curved plastic frames being made in individual custom steel moulds. This process is illustrated in Figure 12 and documented in the Flipflop boatbuilding toolkit. While the wooden dhows are typically coated with antifouling paint externally, and with linseed oil and turpentine internally, the plastic dhow Ndogo was coated with the instantly recognisable pattern of recycled flip flop sheets.

From the description above the traditional dhows of Lamu are not ‘designed’ in the current sense of the word. The builder is responsible for the shape and scantlings, and this is based on inherited knowledge, experience, and several ‘rules of thumb’ to decide on scantlings. There is also an ongoing element of innovation as the builder responds to personal views of what would be an improvement, feedback from the operators of previous designs, and customer or market requirements. As a result, an evolution in the designs, or styles, can be observed in the multitude of dhows observable in Lamu harbour and the adjoining channels. Abandoned on the beaches can be seen old and decaying wooden vessels, with other similar solid working boats still working, their lateen sails furled while they offload cargos of coral stone bricks, timber, and sack of grain, or land fish at the town jetty. Alongside these are water taxis or small passenger ferries, with slender and sharp overhanging bows, driven by outboard motors. In amongst all these working boats are the latest evolution in the design of the traditional dhow: graceful sailing vessels with high aspect lateen rigs, and a finish that is of a similar standard to that found on many yachts. These are the tourist sailing dhows, taking guests to the reefs for snorkelling, or on sunset cruises in the channels of the estuary. The current peak of the evolution of this traditional craft is manifest in the design of racing dhows, developments in their shape, rig and construction material contributing to the success of this popular and highly competitive sport.

In this context the development of dhows whose shape echoes the traditional vessels in Lamu harbour, and whose construction is based on the heritage skills of the Lamu boatbuilders is in keeping with other influences on the evolution of these vessels. However as more ambitious vessels are planned the need for a more formalised approach to the refinement of the shape, and the scantlings of the structure, becomes increasingly important.

**Figure 12: Design and construction process of Ndogo**

## DESIGN CHALLENGES

Flipflop has encountered and overcome many design challenges since the first preliminary ideas were kindled for a recycled plastic boat building project in 2016. These range from very broad production challenges in the local recycling of plastic into structural materials, through to very specific challenges of a particularly difficult joint in the stern stem of the boat. Therefore, this section is not exhaustive, but instead focuses on five challenges which we have found to be important and specific to the design and construction of the dhow itself.

## Hull Lines

In a new dhow design following traditional methods, the hull lines are developed during planking from the fundi/boatbuilder's knowledge and experience of previous dhows. In other cases, such as Utamaduni pictured in Figures 7 and 13, older dhows are renewed to maintain their shape and characteristics whilst almost the entire structure is replaced.

This process is challenged when replacing wood with plastic, because there needs to be some prior knowledge of shape to efficiently form the frames, rather than selecting and shaping appropriate lumber. In addition, the change in material properties and subsequent scantling weight needs to be more properly considered.

To assist with this, marine design software including Rhino and Maxsurf have been introduced to the Flipflop design process by bringing together a team including the boatbuilding fundis, naval architects and industrial designers. Working together, the team were able to transfer the traditional lines and design philosophy of the fundi into a digital model, with an example shown in Figure 14. This included measuring and digitising an existing dhow (Utamaduni) in Rhino and using this to conceptualise then fair the features for the new design in Maxsurf. The Maxsurf model was then used to give confidence with new features introduced by the fundi into the design, such as the unique rounded stern. This was checked in terms of buoyancy distribution, stability, and the shape of key hull lines known to influence resistance such as at the bilge diagonal. These efforts were effectively communicated back to the Flipflop team through several webinars and online discussions. These were also incorporated into lectures for the heritage boatbuilding course.

The digital model also enabled a scale model of the dhow to be manufactured for towing tank and stability experiments at Newcastle University (Figure 15). A physical model provides a practical and effective way to communicate key naval architectural concepts to the Flipflop team, including the methods to measure stability, the effects of free surface and the hydrodynamic performance.

## Structural Design Principles

Traditional dhows are predominantly built from generational knowledge and expertise, which drives structural design principles including:

- The sizing of scantlings such as the keel, planking, frames, knees and brackets
- The sourcing of appropriate wood, locally and imported. Planks may be imported whilst frames are still sought locally and directly from the forest by the boatbuilder, selecting logs with the right shape for the curved frames.
- Joining methods include nailing, stitching and caulking.
- Dhows need to be heavy, to minimise the need for comparatively expensive ballast. Therefore, the scantlings are likely to be much larger than would be specified in a design driven by lightweighting.

We are unaware of any formal structural design guides, codes or calculations used for dhow construction. Provisions for traditional wood construction in design codes such as ISO12215 and Seafish, or empirical design approaches driven by the scantling number (Sn) such as by Gerr (2000) could probably be applied, but the success across generations of dhows sailing in Lamu probably precludes the need for this in typical wood construction projects.

Changing the material from hardwood to recycled plastic beams and planks must rely on the trusted knowledge of heritage designs. This is also essential for local acceptance of the design with factors including perceived seaworthiness, safety and aesthetics (Birmingham and Wibawa 2018). However, the significant change in material properties must be carefully investigated to ensure the boat remains stiff, strong and robust for a long sailing life.

For the smaller boats, including Ndogo, the Flipflop team made incremental judgements on the structural design principles based on immediate observations of material quality and strength. This iterated with the production processes, with the eventual structure in Ndogo showing improvements during the build process. For example, the first laid planks were bought from external recycling suppliers, and were found to be poor for joining and strength. In response, the Flipflop team developed better production processes and new equipment to produce their own higher quality planks. The relatively small scale of Ndogo also meant the structural spacing and sizing could mostly replicate equivalent wood.

The larger scale of Kubwa, with an envisaged length of 24 metres, further challenges the inherent structural design principles. The photo of the similar length Utamaduni in Figure 7 illustrates the typical magnitudes of wooden beams and planks in a large dhow. It is likely that stiffness, as much as strength, becomes critical for the equivalent recycled plastic structure. The boat will be ocean going, and needs to be prepared for significant wave loads. A judicious use of design codes is therefore being used, accounting for their limitations and boundaries when dealing with a completely different material. This is appropriate for some aspects, for example calculating maximum design hull pressures. But in other cases use of codes can be inappropriate and misleading, especially where they are bounded by material type (such as Seafish rules that are restricted to wooden construction).

This is an ongoing design challenge for Flipflop. For example, ISO12215 can be applied to determine the hull pressure loading, which is independent of material type. ISO12215 provides an appropriate method to calculate bottom, side and deck design pressures (Nabi 2023). Using the provisional dimensions of Kubwa (Table 1), the calculated design pressures are shown in Table 2.

**Table 2: Maximum Design Hull Pressures**

	Value (kPa)
Bottom Pressure	50.3
Side Pressure	17.3
Deck Pressure	17.3

This enables first principles calculations to design and compare plastic scantlings as a replacement for wood. For example, the influence of frame spacing on the bending stress and deflection of different plank thicknesses under a design pressure of 50.3kPa is shown graphically in Figure 16. These provisional results indicate that doubling the plastic plank thickness compared to wood produces similar deflections under the design hull pressure loads whilst also keep bending stresses below typical strength limits for LDPE (note that these limits are literature values, and not necessarily equivalent to the actual strength of the recycled plastic planks).

**Figure 16: Provisional design charts to determine plank thickness as a function of frame spacing**

## Moulding, Welding, Bending and Laminating

The traditional construction of the dhows in Lamu required the need for large timber sections for the internal ribs and structural components. Flipflop have developed low tech closed moulds which uses existing extrusion machinery to produce large complex forms that can then be used in the construction (Figure 17).

**Figure 17: Large mould production using closed mould extrusion techniques**

Traditionally sailing dhows in Lamu and from further afield have been secured together using rope, bolts, screws, and nails. Whilst these fixing methods are superb for use in wood, they present difficulties when applied to equivalent plastic joints. The flexibility and stress concentration around the screw causes them to easily become loosened cause stress concentration points within the plastic that can lead to cracking and failure. This led the team to identify plastic welding as a fabrication process, Figure 18 shows how the welded section removed the stress concentration that led to cracking and failure in the screwed section.

**Figure 18: Testing of (left) screwed versus (right) welded sections of plastic lumber, the welded sections removed the stress concentration that led to cracking and failure.**

Secondary uses (Figure 19) for the welding have yielded other benefits, welding the planks allows the vessels to be watertight, the HDPE planks do not expand when submerged in water so welding is used instead of the traditional methods of caulking. The production facility can also only produce planks successfully up to 4.80m long, to achieve longer profiles the welding can be utilised to join the planks together using the traditional scarf jointing methods already used in traditional timber construction.

**Figure 19: Traditional timber scarf joint (left) and HDPE welding and scarf plank joining system (middle and right)**

Figure 20 illustrates a further application for the welding process in the production of more complex shapes that are produced through post production heat bending and lamination of the planks into larger sections. The planks are re-heated using conventional steam bending used traditionally in timber fabrication, the sections can then be bent into their desired shape and then welded holding them together in their desired final shape.

**Figure 20: Heat bending and welding planks together creating laminated sections**

## Material Properties

Common polymer plastics have material properties less favourable to large boat construction when compared to wood, metals and polymer composites (the “big three” boat building materials). Creating construction materials from recycled plastics present additional challenges in terms of quality and consistency, initial materials produced was of low quality and with significant defects in the material, early testing in 2017 at Northumbria University, UK, yielded poor results. Applying plastic recycling techniques in a relatively low resourced setting furthers this challenge.

**Figure 21: Materials bend testing (left) and materials (middle and right) May 2017.**

Significant innovations in production methods have been developed to improve the material consistency, the principal influences on the material properties and structural behaviour of recycled plastic lumber include sorting appropriate plastics, washing, drying and applying a consistent production processes; appropriate use of moulds or extrusions; monolithic or laminated beam fabrications; the use of complex shapes; methods to bend beams into shapes; the colour; and joining and welding methods.

HDPE is the predominant polymer used in the Flipflop recycling process. Typical material properties for virgin HDPE are 10-30MPa tensile strength and around 1000MPa modulus of elasticity. This means 10% the stiffness and 10-40% the strength of a typical hardwood (depending on the type, treatment and load direction of the wood). Flipflop have completed several efforts to quantify material properties of recycled plastic using established research lab techniques. Figure 22 shows example results from 3-point bend tests on 4" x 1" planking samples conducted in Northumbria University, UK. These tests showed that the recycled HDPE maintained similar properties to equivalent virgin product, but only at this relatively small sample level, which didn't fully account for the manufacturing and environmental variations inherent in the processes used at the Flipflop recycling centre. It has also proven difficult to transfer samples appropriately from Lamu to test facilities within Kenya and internationally.

**Figure 22: Bend test comparison results for Pine (1), Ash (2), White HDPE (3), Black HDPE (4) and Yellow HDPE (5)**

To overcome these challenges an “on the ground” approach was required to test the structural properties of the recycled plastic in-situ and provide further confidence to the boat build. A bespoke 3-point bending test rig was therefore designed and fabricated at the boatyard as shown in Figure 23. This enables beams and planks about 1.45m long to be tested under 3-point bending. The test rig is manually operated and doesn't require an electricity supply. The central load is applied via a hand-turned winch (meaning tests can continue with intermittent power supply) and deflections are measured using a dial indicator.

First results show reasonably linear load-deflection at relatively small loads (Figure 24). The tests are ongoing, so only provisional findings are reported here. These indicate that:

- The recycled plastic has a stiffness about 10% of locally available boatbuilding hardwood
- The Young's modulus is about 800MPa, which is slightly lower than the reported values for new HDPE in literature but within acceptable boundaries.
- Tests are in relatively high temperatures, which has a greater detrimental effect on plastic than wood. Initial tests at lower temperatures, using ice packed around the test specimens, show slightly improved stiffness.

Figure 23: The 3-point structural test rig (left), a 4” x 4” HDPE laminated beam (right)

Figure 24: Selected Load-Deflection Test Results of 4” x 4” sections with different materials and constructions

## Propulsion

Whilst the focus of Flipflop is the use of recycled plastic as a construction material for boatbuilding and other carpentry products, the project opens up broader environmental and sustainability considerations. A specific and important challenge identified in the local Lamu maritime community is the cost, availability and distribution of fuel for inboard and outboard engines on almost all boats. Boat fuel in Lamu currently costs about 250 Kenyan Shilling (\$1.50) per litre, the price of which has reportedly more than doubled within a year. This is putting significant pressure on local maritime activities, especially fishing and local transport. Added to this, distribution of fuel is via open poured jerrycans, outboard engines are often old and noisy, and there is notable pollution in waterways also used for swimming and agriculture. Examples of conventional outboard use are shown in Figure 25. This local challenge is likely repeated in many other LMIC coastal communities. This also intersects with the global challenge of fossil fuel use and the impacts of this on the climate emergency.

Flipflop are addressing this challenge by trialling the use of a 6kW battery-electric outboard coupled to a solar panel charging system as a complete independent power system for their recycled plastic water taxi (Figure 26). The advantages of the water taxi as a use case for solar power is the size and arrangement of the boat, and the relatively short journeys. The 8kWh outboard battery provides sufficient power for an estimated 10 km at normal cruising speeds on a single charge. A canopy will be installed in the stern area of the boat to house 1-2kW of solar panels, which will be tested to determine whether the acquired charge power is sufficient to maintain 100% operability without resorting to mains charging.

**Figure 25: Typical water taxi with 15hp Yamaha outboard and sun canopy (top left), jerrycan refilling of petrol from floating station (top right), fishing dhow with auxiliary sail used to save fuel (bottom left), A Lamu style and Mozambique style dhow on a sunset cruise with tourists – sail propulsion but outboards in reserve (bottom right)**

**Figure 26: The Flipflop water taxi equipped with a 6kW battery-electric outboard**

## CONCLUSIONS

Flipflop shows the synergistic power of imagination, passion, capability, creativity and practicality in a marine design context. The paper shows that novel marine design approaches, such as implementing a circular economy approach at a local scale, is effective in responding to global environmental crises such as plastic pollution. In the Flipflop approach, waste has become a precious resource. It is collected, processed and remade into a valuable product that retains heritage whilst embedding innovative cutting-edge technologies. Whilst this process can be used for replacing timber in many applications, the iconic design of a traditional sailing dhow is a powerful tool that impacts on community, enterprise and engagement for environmental sustainability. Looking to the future, Flipflop has plans to build a larger sailing dhow, which is hoped will circumnavigate the world taking the message of plastic pollution and local circular economy to coastal communities everywhere. Closer to home, the aspiration is to export this knowhow and technology to other communities in East Africa and eventually further afield.

# Early Marine Systems' Design – Cracking the wicked problem - The case of a novel biomass harvesting vessel.

Per Olaf Brett<sup>1,\*</sup>, Jose Jorge Garcia Agis<sup>2</sup> and Benjamin Lagemann<sup>3</sup>

## ABSTRACT

*Several IMDC contributions have argued for a better approach to capture stakeholders' expectations in vessel newbuilding projects' execution. The appropriate processes of requirements elucidation are, however, often forgotten or insufficiently handled in traditional ship design and customer-designer settings. Such situations most often reveal a situation in which both "tamed" and "wicked" problems are addressed and must be dealt with properly and effectively at the earliest stage of the process. This paper shows how such problems can be addressed by using the existing multidisciplinary methodology. A practical approach consisting of a set of methods, tools, and work processes integrated into the Accelerated Business Development (ABD) approach is applied to a specific use case, a next-generation factory stern trawler development.*

*A detailed step-by-step story of the early vessel design process – requirements elucidation in parallel with concept design solution development – is outlined following a narrative approach. The process being described covers how necessary support information, stakeholders' expectations identification, business-related analyses, specific design layout, onboard comfort, and fish process handling and storage are dealt with effectively and efficiently. This case study exemplifies specific solutions to better handle particularly wicked problem situations, but also tamed problems are addressed systemically.*

*The paper concludes by showing how a final ship design solution can look like and consequently be prepared for and to be built. The handover process and documentation from requirements capture and concept design solution development to further basic design activities are highlighted. The case vessel at hand won the prestigious "ship-of-the-year" award in Norway in 2023. The paper critically discusses what are likely to be the most important factors leading to this outcome.*

## KEY WORDS

Ship Concept Design; Vessels Design Solutions; Stakeholder Requirement Elucidation; Accelerated Business Development; Novel Stern Trawler Design

## INTRODUCTION

### Loopholes still exist in early ship design processes...

Over the years, several previous IMDC papers (Ebrahimi et al., 2018; Ulstein & Brett, 2009, 2012, 2015) have discussed the topic of how to improve the customer-ship designer requirements elucidation process and project realization dialogue. Improved understanding of the issue, methodology, theory, and practical approaches have been developed, introduced, and partly applied in what we can call piloting initiatives, but few discuss their full-scale application. Many of the useful

\* Corresponding Author

contributions still treat this early phase of ship design very superficially and new methods to improve the situation have proven to be very "toyish" in the sense that they are mere conceptual ideas, initial and very generic and generalized examples of applications, at best, providing relative indication values because of simplistic analyses or simulations with "dummy" variables applied. Some of them are, however, well documented in open sources and available for experience capture and repeat studies, but their real-life applications are scarce (Curry et al., 2017; Garcia et al., 2019; Pettersen et al., 2018; Rehn et al., 2016).

Introducing a novel work process in a conservative business environment represented by the mainstream naval architecture and marine engineering fraternity can be a long and bumpy road to pave. Thus, it should be of no surprise to anybody that progress in the refinement of the current naval architecture and marine engineering discipline, is a gradual and step-by-step process, much influenced by different cultural and regional practices, and specific shipping sector and industry segment preferences. Frequently, it has been indicated that a proper customer–ship designer interaction process is partly neglected, or simply missing altogether (Ulstein & Brett, 2009, 2012, 2015). It is argued by some, that this discrepancy is due because such interaction is being considered too complex or too intrusive to effectively capture the vital and critical information elements of a new building project. Consequently, the outcome of such vital processes, so far, has proven to be meagre, and the following concept and basic design work correspondingly uncertain, risky, and costly. Despite these pledges to the ship design community to pay more attention to this early part of the ship design process, recent industry experiences have not shown significant improvements, according to the authors' observations. There are exceptions though. One of these exceptions is the story being told in this article – explaining in more detail and chronological order how novel systemic-based requirement elucidation and new building project information solicitation can be carried out successfully. The reason for addressing this topic one more time is the belief that practical applications of novel approaches in ship design, like the accelerated business development approach of Ulstein, might bring more understanding to the benefits of approaching tame and wicked problem-solving holistically and as early as possible in the concept vessel design process. The paper shows what is going on in practice, who are the actors, what is the program, what are the interphases and interrelations in the process, what are critical inputs, control functions, resources, transformations, outputs and finally, outcomes of the communication and information sharing efforts. How can this comprehensive and collaborative setup enhance and progress future early concept ship design, and thus the quality of the basic design and detailed engineering downstream initiatives, finally leading to better ships are elaborated upon in this article and specific results documented and discussed.

Furthermore, this article shares reflections on commercial, operational, and technical aspects relating to early conceptual ship design and the requirement elucidation process between the customer and the ship designer. It contrasts how theory and practice can go "hand in hand" with significant real-life process achievements as a result. When following a new building project initiative over a longer period and trying to describe in more detail what is happening along the way, it is hopefully obvious to the reader that such a longitudinal study (Huber & Van de Ven, 1995) presented in a 20-page article cannot go into all details about the events and happenings. The authors of the article have, therefore, taken the liberty to condense the actual process that took place in the early phase of the project, trying to focus on what turned out to be the most important events, discussions and under way conclusions, and leaving out minor details.

This article addresses the challenge of the naval architecture and marine engineering community about the fact that, although many authors and scholars on the subject promise early-stage ship design improvements, most of them end up starting their storytelling with the "pre-defined" box of design requirements. That is, presumably all relevant and critical requirements have already been identified and documented, ready for the designer to work on, without any further checks and balances. This can be seen as a quick way to avoid or escape wicked problem aspects. Nevertheless, the authors of this paper experience that not going through these early extra rounds of clarifications has in some cases led to catastrophic or at least substantial project development failures. We try to show how such ineffective ship design processes can be avoided and original expectations be met.

### **This story begins - customer inquiry...**

The telephone is ringing: "Hello, Brett speaking." – "...Mr. Brett, I have been asking around already, talking to three ship designers and they have not been interested in exploring my ideas about a novel next-generation factory stern trawler. They want to sell me their existing designs, which are the best on the market, they say and are not interested in spending time and money on exploring our new ideas. - That's not what we want, I told them, Mr. Brett. My customers want a novel vessel solution that can secure high-quality catch and make sure the fish products are being presented at the counter of the fish mongers on the Continent, such that I can achieve extra profits compared to the other trawler fishermen out there. Honestly speaking, I don't think they understand our ideas and expectations in the first place, but we have some ideas worked out already based on our best knowledge and experience from many years of trawling. ... Are you guys willing to help us explore these ideas and develop a new vessel concept that can meet our overall expectations?" – "...Yes, we are. When can we get together and start

the development process? We think we have the right apparatus, skills, and experience to assist you... You are more than welcome to see us quickly."

## Project milestones – how did it go...

Seven years later, the novel factory stern trawler is just about to be launched and put into service. After six months of structured, facilitated, and continual documentation of business concept development, market, and business performance yield evaluations, onboard studies, idea exploration workshops, functional modelling and simulation, and vessel concept development, the stakeholders' expectations and requirements' elucidation were considered fully captured and a feasibility study concluded. Hence, a vessel concept design documentation package could be delivered to the naval architects and marine engineers to start their basic design process and later a detailed engineering process.

One more year was spent developing the basic design of the vessel together with the exploration of the novel fish catching and handling system at the stern, combined with the new fish processing factory solutions. Another year was used to engineer the whole vessel system in detail and be ready for contracting and construction at the yard. Yet another year was, however, consumed to identify, negotiate, and placing the new building order at agreed upon price, finalise financing, and secure the right suppliers for the extensive equipment systems development and delivery.

This article concentrates on the very early phases of a marine systems design process and particularly outlines how well-documented facilitation techniques can be used to master tamed and wicked problems, which almost always are present in various ways in vessel new building projects to be carried out. The rest is history and not part of this article's story. Figure 1 shows the macro activity of the use case study indicating the timing and resources consumption of the key events of the process.

**Figure 1: Key events in the project development and equivalent resource consumption.**

## The "tame" and "wicked" problems – how do we go about them...

Solving "tame" problems in early marine systems design is typically handled traditionally by addressing the problem at hand with one part of the problem that can be isolated and fixed by simply eliminating the problem, treating or mitigating the problem, transferring the problem (to a collaborating partner or insuring the latent risk involved), and or finally tolerating that the problem exists, but might not after all mean a lot of risk to the project realization process (Head, 2022). Typically, the process starts with a given, not necessarily verified requirement list and specific input as to the gross size of the vessel, its functionality, and special features desires. Relevant and preferred suppliers are identified and listed for later contact and project dealings. Then a traditional "circular" or iterative basic design approach in line with the design spiral (Garcia, 2020; Ebrahimi, 2021) is carried out producing one or more comparative vessel design solutions, within a set of pre-defined target specifications. A final decision about the preferable design solution is taken and the project is ready for launch.

Typically, our traditional and well-proven approaches to naval architecture and marine engineering's role are proven to be efficient in solving such linear and analogue problems. Many articles over the years have confirmed this observation (Andrews, 2018).

"Wicked" problems, however, represent issues that are different - emergent and systemic - and thus require changes in multiple systems or development logic constituting the problem at hand. Systemic, in the sense that you can't fix them by fixing the parts, you can only try to change the system of systems to dissolve them (Rittel & Webber, 1973; Head, 2022). You must change your approach from fixing parts to trying to re-organize the system(s) functionally, utility, capacities and space allocation, technologically - new equipment and their integration, commercially - a new business setting and performance yield offering, and or operationally - for example, higher operability, because no amount of increasing or improving the parts makes an integrated whole, which results in the emergence of new levels of improvement. It is only by improving the organization of the parts or sub-systems that you can increase and grow the integrity of the whole ship as a system and get the emergence of the system's overall performance, i.e. regeneration of the vessel solution as an integrated system.

One way to effectively map and handle the wicked problem situation is, therefore, to begin with a process of discovery or elucidation (Adi & Stoeckle, 2022). Begin with the current, observable facts and ask "why" - going backwards in time to create a chain of causality - causal maps exploration - what is related to what and how. Remember, each cause also has an effect in such circumstances. The next step is to predict what will happen going forward in time and ask, "what if" and "what next". By asking what next and if and continuing the chain of events, we can get sets of ongoing future consequences - causal maps of the situation at hand including, but not limited to the already known domino effect of our present decisions and actions (Sarkar & Kotler, 2018).

"Are these challenges one problem or several problems to handle, and is it at all possible to expect a rational and elucidated handling of the nature of such a wicked problem situation?" (Andrews, 2003). Andrews continues: "Identifying what is the nature of the problem is the main problem, and that attempting to do so without recourse to potential material solutions verges on making a difficult operation impossible". The wicked problem is, therefore, much more than identifying all the expectations, requirements, and needs of the ship owner and or close by stakeholders - it is truly about identifying what is the nature of the greater problem, what is the main problem. The nature of the greater problem is an all-encompassing feature including the life-cycle aspects of the vessel concept design solution, and we are, therefore, of the opinion that also such features as the market situation, the economic situation in general and the involved firms' condition - desires, qualities, capacities, capabilities, experience, and robustness, play a significant part in the overall nature and dynamics of the "wicked problem" identification and description challenge.

It is still a limiting consideration and an interpretation of the original "wicked problem" concept (Rittel & Webber, 1973), which prevails in the ship design world among naval architects and the like (Brett, Carneiro, et al., 2006; Ulstein & Brett, 2009, 2012, 2015). This is demonstrated by the repeated rationalization of the solution space: Setting strict and limiting boundaries to the solution space, taking for granted that the functional expectations and requirement description of the customer are properly documented, and validated, and that the parametric set of ship dimensions are well balanced and verified, thereby, partly avoiding the complexity and uncertainty aspects of the new building project at hand. It is also seldom understood and practised that the solution space will change over time because of good and bad times (Epoch-Era) and other unforeseen events (Gaspar et al., 2012; Keane et al., 2015) influencing the life cycle performance of the vessel designed. Thus, future projects require an identification and mapping of the likely life cycle use of the vessel design solution and its utility functionality. Only in a few use cases known to the authors, have the overall medium to long-term market situation, commercial use, and corresponding built-in utility functions of the vessel design solution been explicitly handled as a decisive factor defining the final life-long solution space. More recently, the decarbonization of the shipping fleet has emerged as yet another extremely difficult problem to solve and entails a life cycle dilemma for the actors involved in the project development discussions and decision-making.

The paper is structured as follows: First, the premisses for the article are outlined - is it possible to handle tamed and wicked problems after all, arising in concept ship design contexts and if so, by which method(s) and approach(es)? Second, the story of a real design project is told. We conclude and discuss why the applied process is a preferable way of performing ship design solution work in the future.

## **One approach doesn't fit all situations...**

Yet, it is the opinion and experience of the authors that effective early-stage ship design process approaches must be aligned with the nature of the customer inquiry to the naval architect and marine engineer, and tuned to the specific context or business situation the inquiry is generated from.

The StO, CtO, and EtO terms are archetype design and production approaches being described in complementary design literature (Semini et.al, 2014). Their interpretations are StO or MtS - Standardize to Order or Make to Stock, CtO or AtO - Customize to Order or Assemble to Order, and finally, EtO - Engineer to Order, with StO being the most downstream position and EtO the most upstream position in the ship design value chain. The basic idea behind these terms is to understand the

characteristics and attributes of the final ship products being produced and offered. These terms are used in the next paragraphs to categorize and describe different customer-designer (C-D) relationships.

The more specialized the product, the more flexibility is needed, and the more the customer or the relevant stakeholders must be involved in the development process. The more standard the ship design solution, the more downstream and little involvement of the customer is necessary, yet existing and in-depth market and product knowledge and expertise is very high – you get what we offer you. Typically, the downstream-oriented processes lead to shorter lead times, higher delivery reliability, and lower costs; in contrast, the upstream-oriented approaches allow a higher degree of customization, increased reliance on customer participation and continual decision-making, longer lead time, higher costs – the solution is developed as you go.

Over the years, the authors have experienced many different customer-designer relationships and types of inquiries, which probably can be categorized into five different archetypes (Lageman, et.al, 2024):

- C-Ds1: “I want this particular vessel; can you design it for me?” – triggers normally an EtO vessel design solution process...
- C-Ds2: “Do you have a solution that can do...” – this triggers normally a CtO vessel design solution process...
- C-Ds3: “Can you help us respond to this tender” – this triggers normally a StO vessel design solution process...
- C-Ds4: “I have a promising idea about a new vessel design we would like to order; can you develop it for us” – triggers normally an EtO vessel design solution process... and finally,
- C-Ds5: “We have an interesting business proposition to offer you – do you want to be part of the project-making initiative” – triggers normally an StO (CtO) vessel design solution process...

These five C-D archetypes of inquiries, typically, require or dictate a different dialogue with the customer and the follow-up process of the project initiated by the inquiry. Since the dialogue and the follow-up process of the project are different, we are of the opinion that also the overall approach of the dealings of the projects must follow different approaches concerning – what information to identify, collect, collate, and store, who are the most important stakeholders involved and what decision-making processes will most likely take place or should take place, how far is the customer willing to stretch when it comes to costs and price, what are the premises for the project realization, involved presumptions and assumptions – the project boundaries for defining the ship design solution space. Unconventional situations require alternative responses. Hence, the naval architect and marine engineer must develop sufficiently flexible and adaptive behaviours to master such a variety of customer-designer settings. Fast adoption of new work processes and use of novel design tools, including generative artificial intelligence, become a must. So is also real-time handling of big data and statistics – multi-variate regression analysis (MVRA), analytical hierarchical process (AHP), neural network (NN) techniques, and the like.

The use case to follow aims to show how such flexibility, adaptability, and adaptation capabilities are used to make successful early concept ship design projects come to fruition.

### **But some approaches for improvement are better than others...**

Knowledge about the project requirements and or expectations is normally spread over many actors being involved in realizing the ship design initiative. The actors in such processes are ship owners, operators, charterers, brokers, investors, designers, consultants, ship equipment suppliers, classification societies, flag states, and other more peripheral stakeholders in the value chain. None of these parties has alone or isolated the full picture and specific knowledge on assessing a ship's commercial, operational, and technical performance in a broader business concept realized. Culture, traditions, and specialization over many years among actors in the overall realization value chain are most likely to blame for not bringing these actors closer together and making them more effective in communicating with each other. Historically, separate documents like outlines, contracts and/or building specifications and drawings have constituted the communicational instrument and transactional document among the players in the overall decision-making process. Owners' specifications are typically formulated based mainly on their experience in ship operations. Ships are in operation all the time, but new building projects commonly take place only every 5 to 7 years period with that ship type and capability. Expanding on what is, or has been, the experience of the past is more typical than what it is that we need. Designers, on the other hand, typically optimize a vessel concerning preferred engineering criteria, such as installed engine power, speed, or lane meters, and not infrequently their production facilities. If more specific and complimentary project information is necessary, ad-hoc inquiry sessions are typically held with different information sources both firsthand and secondhand type. More often than is admitted, solutions developed along these lines are presented as best practice and state-of-the-art, without really meeting preferred requirements following a sound set of rationales and scientific reasoning. Too often it is forgotten to ask the wicked problem solver questions – why, what if, and what next? As such, they are not grounded on proper explanatory theory and methodology capturing the total complexity and broader context of a true business idea realization. Quite typically, the business development process, fleet and/or ship design integration and their respective decision-making processes are separate and fragmented with little interaction across the stakeholders' boundaries. Furthermore, existing embedded design processes with yards and ship design firms and logistics performance

cannot normally be directly compared against operational performance parameters, which work against the pre-conditions for the achievement of effective design and marine systems' service solutions. Additionally, the nature of ad-hoc solutions is that they must be elaborated under the pressure of time, and therefore these solutions themselves very often contribute to deficient designs and extra costs.

All stakeholders' expectations must be integrated into the overall development and decision-making process. The required elements for effective decision-making are not always quantifiable and many of them are purely qualitative considerations, highly subjected to personal perception and appreciation of things and stories. This paper, again, suggests that an integrated and complementary analysis tools package should exist as part of an overall systemic approach to handle this complexity. This can support more effective decision-making in marine systems and concept ship design developments.

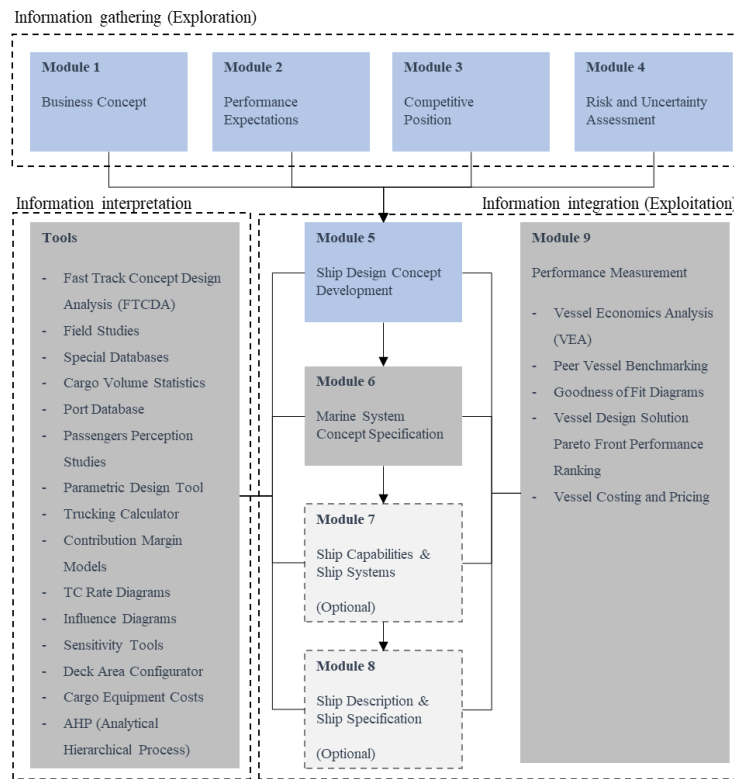

### **The way forward – the ABD-approach as mitigating methodology...**

The ABD approach is both a communicational and a decision-making support methodology to be used among all the actors in the total decision-making process of a marine system realization. Its role is to record and guide the complex information-gathering and decision-making process when a new building project takes place, particularly in the early phases of such project execution. Expectations, requirements, assumptions, presuppositions, limitations, and project boundary restrictions are described and kept readily available for further and later interpretation of the results of the feasibility analyses being carried out, and finally benchmark what is a better vessel design solution (Ulstein & Brett, 2015). Various influences among system variables are identified and measured concerning their interrelationship strength or correlations. Sensitivities are also estimated and studied. The ABD approach is the structure (process guide) within which the various methods, analysis techniques, supporting default values, preliminary design tools and work procedures are found and elaborated upon. Over time, an experienced database is built up to be used as a benchmark, as well as a best practice repository for faster business development-oriented concept ship design solutions (Brett et al., 2018a).

The owner-designer interaction is often complicated by the owner's focus on previous solutions and gradual improvements thereof. Designers, on the other hand, tend to optimize the design towards specific technical Key Performance Indicators (KPIs) and their production facilities. The ABD approach counteracts these discrepancies and inefficiencies and secures holistic management of complex data in the form of analysis metrics, models, maps, film/video, statistics, sensor signals and the like. In short, the ABD approach is a methodology that is developed to structure the process of turning a business idea and vessel design concept into reality, which includes a concept ship design solution or a smaller portfolio of promising solutions, which can easily be turned into a comprehensive detailing of a ship description and specification. Thus, ABD provides a structure to the process of identifying promising ship solutions that fit into the commercial and operational context in which they shall operate.

The ABD approach is organized as a guideline consisting of 9 modules ensuring a comprehensive and structured approach for capturing the commercial, operational, and technical context of the ship design(s). Using the method contributes to reducing uncertainties in marine business development projects. Figure 2 shows the structure of the ABD approach as it is practised today and in this use case study, highlighting in blue the modules described in this paper. A more detailed description about the different modules can be found in previous IMDC papers (Brett et al., 2006 & 2018; Garcia, 2020; Pettersen et al., 2018). In this paper, the practical application of it about a specific concept ship design project is elaborated upon.

The approach advocates that a new or improved marine solution system, where the ship plays a significant role, shall fulfil the needs and expectations of all the involved stakeholders in the best possible way. We have carried out more than 20 such ABD processes over the last 15 years, on our development projects (C-Ds5) and together with customers (C-Ds4). Comprehensive data analytics processes, field studies, statistical regression studies, AIS observations and recordings of vessel types to understand their real-life operational patterns over time have been carried out as typical complementary fact-finding in such ABD approaches. In addition, it has been necessary to expand the ABD toolbox with a Fast Track Concept Design Approach (FTCDA) (Ebrahimi et al., 2018). This simulation tool combines multivariate statistics, network data resources ship design expertise and classic naval architecture and marine engineering methods from all disciplines to accelerate effective decision-making in vessel design. The FTCDA is an integration tool which gathers information elements from the ABD approach and uses these inputs to balance one or more ship design solutions applied in Module 5 of the ABD methodology. These concept design solutions are then benchmarked by a performance yield indexing matrix with relevant existing peer vessel alternatives. Hence, the concept design solution is validated, and vessel features verified such that the overall performance of the vessel can be rectified if inferior or undesirable performance yield is the result. Typically, final vessel design solutions are to be spotted and selected in the vicinity of relevant performance-based Pareto fronts' knuckle points (points of diminishing returns). A more detailed explanation of the FTCDA is to be found in other IMDC papers (Ulstein & Brett, 2012). All this work is done before any principal drawings are carried out for the vessel.

**Figure 2: The ABD approach structure of activities.**

The implementation of an ABD approach in early design phases has demonstrated three principal advantages: more robust decisions, and higher quality vessel design solutions - due to the availability of additional information at an early stage of the concept design process. Other achievements include a significant reduction in response time and committed resources and the capability of evaluating (visually and analytically) multiple design solutions. In addition, it brings the possibility of performing sensitivity analyses of cost, capacities, and capabilities towards specific design parameters. Complementary use of the FTCDA, ABD and other data-driven analytics tools allows us to validate and verify promising solutions very quickly. This again, has dramatically reduced the response time with customers at the concept design solution stage.

### **Apply structure and formats with care and pragmatism...**

Yet, when an ABD approach is carried out in real life, adaptations and practical adjustments when applying the facilitated methodology are necessary. With more than 15 years of experience in performing such project-customized approaches, it is clear that a few very important principles and practices still apply for the methodology or approach to function the way it is developed. These principles and practices are:

- i) Be loyal to the holistic or systemic principles of systems theory and management – the whole is more important than the details of the individual parts...
- ii) Be sure you cover the intent of the 1 to 8 modules – a structured approach for information gathering and step-by-step decision-making with as little room for reconsidering previous decisions as possible – a red thread of decision-making logic should be visible as the overall process progresses. Module 9 is only a "toolbox" of different analysis tools and techniques to support the effective decision-making process feeding in and out of the other 1 to 8 Modules.
- iii) Always apply the wicked problem solver: the why's-, the what ifs-, and the what-next questionnaire...
- iv) Record and document everything that is said and decided...
- v) Be sure there is progression in all workshops...even if important challenges must be left behind – you can always go back when your info box or repository is expanded to the extent necessary
- vi) Be sure you perform the ABD process in an appropriate setting... - room for everyone to think, read, discuss, and write as well and electronic multi-display facilities are readily available.
- vii) Relevant executive management of the customer firm must be present – In addition, support personnel and or specialists could be present.

- viii) Educated pragmatism should be applied – when the development process takes a new direction be sure you let go about the structure but not intent, and only to the extent that serves the purpose of arriving at the goal of the project.
- ix) Identify critical "white spots" – areas of interest where information is lacking partly or completely and search for improved knowledge in these areas that can have a vital effect on the final decision-making in the project.
- x) Develop and expand causal maps of obvious and not-so-obvious causal relationships among project output and outcome-sensitive factors.
- xi) All agreed-upon project activities and information sharing must be carried out on a "free will" basis when the direction and intent of development is agreed.
- xii) Customers should be willing to share, normally considered proprietary and partly confidential commercial information.
- xiii) Agree upon deliverables throughout the ABD process and be sure mutual project performance expectations are adjusted and balanced.
- xiv) Make sure you can justify the project partnership and execution from a policy, strategic, expertise, experience, and economic sustainability perspective.

In addition to these principles, several practices have proven to work well and support the ABD approach. It is important that:

1. Sketches of ideas are made along the way.
2. A design protocol is established and kept up to date during the process to document all underway decisions.
3. A consistent presence in workshops of executive decision-makers and their invited specialists.
4. Preparation between workshops and regular exchange of preliminary project material developed.
5. Continual documentation of discussion of options, limitations, and reservations' - flipcharts and operative marker pens are crucial – tape-recording can be used for safeguarding information – and to avoid unnecessary repetition in consecutive workshops.
6. Workshops are held to the convenience of the customer, but preferably not more than two to a maximum of three weeks in between workshops – they can be half a day or a full day session.
7. Arrange as many workshops as found necessary to capture all important information and make customers/stakeholders comfortable about the information robustness and methodological rigour, but not more – once every month over a three to six-month period is feasible, sometimes more often when arriving faster at promising solutions.
8. Typically, it can be useful to discuss and agree upon various exit possibilities along the way of project execution, to be triggered if one of the parties becomes uncomfortable in the process or for other reasons the project has to be brought to a stop.
9. Bring along as much relevant background information and documented experiences as you can think of – electronically or on paper.
10. Identify, make available and test relevant data sources.
11. Look for opportunities to make pre-studies of known or identifiable information about typical issues, problems, and accidents – "learning" events relating to the vessel segment to be studied and critically scrutinized.
12. Investigate opportunities if it is possible to arrange for shorter or longer site field trips onboard similar or related vessels to better reveal facts about the vessel's operation and "life onboard".
13. Behave like a professional process consultant – be sure your attitude and behaviour vis-à-vis the customer are proper and will motivate the customer to continue the process. Provide useful information elements, critically analyse and diagnose the information shared, ensure effective support for ideas development and make the process a comfortable one. Recommend alternative solutions and discuss how they can be realized – a process consultation does not assume that the customer knows what is wrong what the challenges or problems are, what is needed to mend the situation, or what the consultant or customer should do to improve the situation. Let the common diagnosis and suggestions for improvement – the intent, help the project to plan how to achieve the goals of the project initiative and improve the situation (Schein, 1988).
14. Perform as many relevant pre-analyses of the data repository as found useful for the coming study at hand – too much is better than too little.
15. For new market segment entry make an extra effort to study the macro and micro commercial, operational and technical aspects of the segment and behaviours over at least 10 years and preferably 30 years overview can be quite useful.
16. Be sure you make a thorough update of the customers' existing fleet, operations, technical preferences, and commercial performance.

It is also important to adopt and adjust the use of analysis tools and simulations as necessary and useful. Minor to moderate changes also must be made to the process of documentation of process progress. Typically, more formal report formats of the MS-Word-type have been exchanged with the use of MS-PowerPoint as the prime communication tool. The whole process

must be carried out with a high degree of pragmatism. In the use case story being presented in the following, these principles and practices are largely followed.

As previously mentioned, the ABD approach is not a universal tool for any ship design requirement capture or elucidation situation. It is particularly valuable, in customer-designer situations C-Ds4 and C-Ds5, described more in detail in paragraph "One approach doesn't fit all situations..." (page 6) of this article. Typically, the first category is generated by a customer project inquiry and not a customer design inquiry (C-Ds1, a broker inquiry (C-Ds2) or a vessel tender inquiry (C-Ds3). These latter three categories from experience do not require the full ABD approach to be handled properly. They can in most cases be carried out with an ABD-light methodology application – by specialised questionnaires and requirements checklists, for example. The C\_Ds5 situation, on the other hand, is what in more recent times has been described as project making activity and will almost always require a full ABD process to be performed, documented, and used for the promotion of the initiative of a promising marine system business proposition and its corresponding ship design solution(s).

The use case reviewed and discussed in this article is typically, a C-D4 (EtO) situation. Before starting to elaborate on the C-D4 (EtO) use case, we review the broader ABD-based pre-analysed business environment for the Factory Stern Trawler market segment.

### **The context and subject – why a factory stern trawler focus and what are we up against...**

It is expected that aquaculture and ocean fisheries will have to cover a major portion of the growth in seafood demand in the future, as it is said to have less effects on the reduction of fish stocks, but ocean fisheries are also expected to contribute. Firstly, by improvements in the exploitation of current fish biomass (using fish oil, fish meal and other products), and secondary by exploitation of biomass species (mesopelagic). Both factors could contribute to the growth of biomass food produced from the sea while maintaining the level of capture and reproduction of resources. (Garcia et.al, 2018)

The need for more effective vessels producing higher quality biomass motivates a renovation and renewal of the fleet – a fifth generation of factory trawlers. This new generation should be characterized by fishing efficiency, with a focus on fish product quality and better exploitation of fishing captures, flexibility from the number of products, species and waters or regions, and the best possible quota utilization.

Another factor spurring a fleet renovation is the poor energy efficiency and environmental footprint of the current trawler fleet, as compared to more modern pelagic trawlers or purse seiners (Ziegler et al., 2013). The replacement of environmentally harmless refrigerants, used by many of the vessels in the current fleet, could reduce the carbon footprint of factory trawlers by up to 30% (Ziegler et al., 2013).

### **History and introduction to factory trawlers – what to be prepared for...**

The Food and Agriculture Organization in the United Nations (FAO) identifies 11 types of fishing vessels (Thermes et al., 2023). Of these, there are three that represent most of the fleet and represent the three principal fishing techniques: seiners, trawlers and liners. Figure 3 includes a short description of these three categories represented by the most popular vessel type under them. The type of fish or protein to catch, the area of operations, and the quota assigned are the main drivers in the selection of what vessel type to go for. Hence, seiners are used primarily for pelagic species, while trawlers and liners are used for mesopelagic and demersal species.

**a. Seiners - Purse seiner/pelagic trawler:**

- This combination of fishing gear requires that the deck arrangement and equipment be planned for dual use. As the power requirement for trawling is higher the vessel is usually designed as a trawler with a suitable combination winch for both methods

**b. Trawlers - Stern trawler:**

- On stern trawlers the trawl is set and hauled over the stern. These vessels are fitted with trawl winches and equipment necessary to haul the net on board and lift the cod-end over the deck. Freezer trawlers are outfitted with refrigerating plants and freezing equipment. The holds are insulated and refrigerated

**c. Liners - Longliner:**

- The number of hooks and lines handled depends on the size of the vessel, the degree of mechanization, and crew size
- The wheelhouse can be situated aft or forward, but on larger vessels, the bridge is generally placed aft. In most cases the gear is hauled from the bow or the side with a mechanical or hydraulic line hauler and the lines are set over the stern

1. Beam trawlers
2. Otter trawlers
3. Pair trawlers
4. Side trawlers
5. Stern trawlers
6. Outrigger trawlers
7. Freezer trawlers
8. Wet-fish trawlers

**Figure 3: Main categories of fishing vessels and sub-categories of trawlers.**

Due to their catching efficiency, stern trawlers are among the most populated vessel types. Ranging from smaller vessels focused on coastal operations and with cargo holding keeping fish on ice, to large units equipped with factories capable of processing the capture and freezing it. This fleet has evolved significantly since the first units were built in the 50's, characterized by the combination of a stern ramp and onboard processing. The vessels built after 2010 are considered the fourth generation of factory stern trawlers. With a focus on fuel efficiency, the vessels of the fourth generation have engines with up to 20% lower specific fuel oil consumption than those of the third generation (Fernandez et al., 2014), representing a major improvement in the vessel's economics and emission footprint. According to (CRISP, 2015), the newer tonnage is 50% more efficient in terms of unit fuel consumption used per kilo captured fish/biomass and resulting in a fishing business which is 5-15% more profitable. The same article highlights some of the improvements from this generation, such as hull shape design and factory processes, including robotized freezers and storage. However, methods for fish handling are still poor and little evolution has taken place over the past 60 years (CRISP, 2015), resulting in more than 15% dead fish before the fish can be processed.

We advocate, therefore, that the design of the next generation of factory stern trawlers, the fifth generation, should focus on fishing efficiency, looking for maximizing revenue and profit through improved quality of the end biomass product by flexibility dictated by the number of products, species, and waters (regions) to be explored and a best possible quota utilization. It requires therefore to integrate technical, operational, and commercial perspectives, and a better collaboration of the different stakeholders in the early stages of the ship design process. It is our proposition, that a shipowner will not invest in a new vessel if he or she cannot see an economic benefit from it. Hence, our approach must ensure that such an intent must be met.

## USE CASE STUDY

The use case in this paper is a written description of how the customer-ship designer setting works in real life in a new building project context. It outlines, from the users' point of view, the realization of an ABD approach in developing a concept vessel design solution within a given business concept framework. This use case is represented as a sequence of simplistic steps, beginning with exploring the ABD module one to eight guidance and ending with a proper business concept description and the handover documentation of a fit-to-purpose ship design solution, ready for detailed design and finally a new building project realized at a yard.

### Project initiative background...

Inquiry from customer: "Do you want to participate in a joint industry project to develop the next generation factory stern trawler with novel fish catching and process treatment equipment and ship factory arrangement?" - As previously stated, we quickly responded to the customer and accepted their invitation. There were three main reasons for this fast response. Firstly, we had for some time seen that the market demand for larger fishing boats was expanding – so the market potential looked promising, and we needed an additional new ship segment to be consolidated into our existing, but declining product and

service portfolio of existing ships. Secondly, we love innovation challenges and could see a fine possibility to grab this chance to develop something novel and groundbreaking and demonstrate our vision – "turning visions into reality". Thirdly, re-vitalize and leverage our strong fishing vessel newbuilding project delivery history, totalling 63 vessels, including trawlers, longliners and purse seiners.

Our project involvement strategy was, however, accepted under one very important premise: The FST concept design solution had to represent something completely new – just making a copy of the most recent FST design solutions of our competitors was not an option. If we should go along with this customer inquiry and offer to run a full ABD process on a no-cure-no-pay basis, we should also retain the rights to the design solution for repeat sales, either on our own or together with the customer. Perhaps we could even use the customer to promote the eventual successful and attractive design.

The customer insisted that we listen carefully to their ideas and expand upon those ideas for the realization of the project. Then, whatever additional ideas we might have to enhance their ideas and conceptual thinking was much welcomed.

Both parties accepted the preliminary terms and mutual project exit possibilities were agreed upon. Consequently, a Memorandum of Understanding, a Cooperation Agreement, and a Concept Design Agreement were agreed upon and signed. When the Basic Design work started an additional Agreement for Front-End Engineering and Design contract was also signed.

The project initiative was started, and 6 consecutive ABD workshops were carried out within half a year, to identify, collect and collate relevant vessel concept design solution project data. Two field study trips were carried out – one visit to an FST in port alongside the quay and one three-day trip offshore at a fishing site to acquaint with the FST operations and test new ideas from people onboard FSTs.

### **Preparations for the kick-off meeting...**

Less than a week after our two telephone discussions, a project kick-off meeting was agreed upon and held at the ABD facility room of the designer. Four executives from the customer and 6 representatives from the designer firm met to clarify the project terms, a presentation of the customer business idea and proposition was given, and a quick review of the ABD approach was performed.

Within the next 4 weeks, a first full-day ABD workshop at the designer premises was arranged to primarily find out: What is the project idea? What is the project background? Who will be the permanent participants (decision-makers)? Who will participate in what, when, and in what way? What relevant skills, expertise, and knowledge are available for problem-solving challenges? What is the project schedule? What could be the project milestone plan forward? How much time can be spent and the time availability of key decision-makers? What is the project funding capability of the project initiative? Who are the relevant and preferred suppliers to work with, when do we introduce them to the project initiative, and who will contact them? What do we know about the project challenge at hand? Where can we find relevant and useful problem-solving background material? How do we involve our people – experts, specialists, and facilitators (consultants)?

Agreed upon information exchange, collection, collation and storage of the various background documents, analyses reports, drawings, miscellaneous illustrations, and other materials were carried out and a common project development Sharepoint site was established.

### **ABD Module 1, 2, 3, and 4 work – a brief synopsis...**

Module 1 sets out to develop a realistic and well-thought-through description of the business concept, a clear statement as to what is the business proposition that the customer wants to pursue. Critically assess the realism and feasibility of the business concept and proposition by answering key questions about the various aspects surrounding the business concept. In Module 2, the objective is to identify all important project stakeholders that are affected and/or involved in the overall project to be realized and assess their individual and collective expectations towards the concept vessel design solution to be developed. Also identifying the competitive position and context of the proposed project business concept is important and is handled by the guidelines of Module 3. Assess what the potential is for the business concept to be successful, given the competition it will face. Identify competitive issues and aspects that will influence the development of the vessel concept design solution. Module 4 assists the ship design process by identifying important aspects that represent a risk for the project to be realized. A risk aspect in this context is any element that poses a threat to the successful development and execution of the vessel concept design solution. Module 5 identifies and assesses different and promising vessel concept design solutions utilizing relevant specialized and proprietary ship design tools listed in Module 9 of the ABD methodology in addition to "standard" naval architecture and marine engineering methods (Papanikolaou, 2019).

Modules 1, 2, 3, and 4 are critical to the follow-up work to be carried out in Modules 5 to 8. In this use case, only project work related to Modules 1 to 5 is presented and reflected in the article discussion. Fragments of the overall approach relating to these 5 modules are primarily depicted to give association to the more detailed work taking place in the real-life set of ABD workshops carried out. Brief comments have been inserted where found necessary and useful to link the various tableaus and make a continuous use case story.

## ABD Module 1, 2, 3, and 4 work – results...

Firstly, we had to define the scope of the project. The fishing company had experience, and quotes, for ownership and operation of factory stern trawlers targeting white fish (cod, pollock, haddock) and shrimp. In line with the ABD procedure, the customer presented their original business idea and project intent. Very clearly, they stated and documented, what the direction of the innovation should take: To develop a new factory stern trawler vessel concept different from a traditional stern trawler concept into a new biomass production platform/floating factory to secure a differentiated biomass product from a quality standpoint. Furthermore, to secure full biomass utilization of any catch and increased utilization of more sustainable species' catch including new technology and novel catch processing and handling equipment – restitution tanks for live fish catch, hydrolysis of enchilada, CO<sub>2</sub> freeze, filleting and separation, and a protected shrimp factory. Additionally, the vessel solution should be optimized from an energy consumption standpoint and alternative decarbonized fuel solutions should be considered. Maximum safe operational robustness should also be achieved.

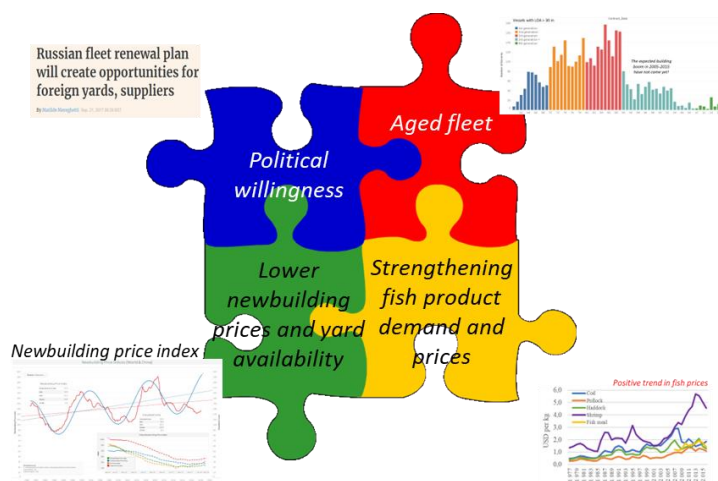

The business proposition for the development of the 5<sup>th</sup> generation factory stern trawlers extracted from Module 1 was then framed as follows:

*"Maximizing revenue and profit through improved quality of the end product by flexibility from nos. of products, species and waters and a best possible quota utilization."*

The business proposition relies on three main opportunities identified in the wild fish market segment:

1. 100% resource utilization of the raw material currently being extracted from sustainable Norwegian marine resources.
2. Producing high-quality and differentiated products in the catch line.
3. Increase in the exploitation of sustainable stocks that are lower in the marine food chain (mesopelagic).

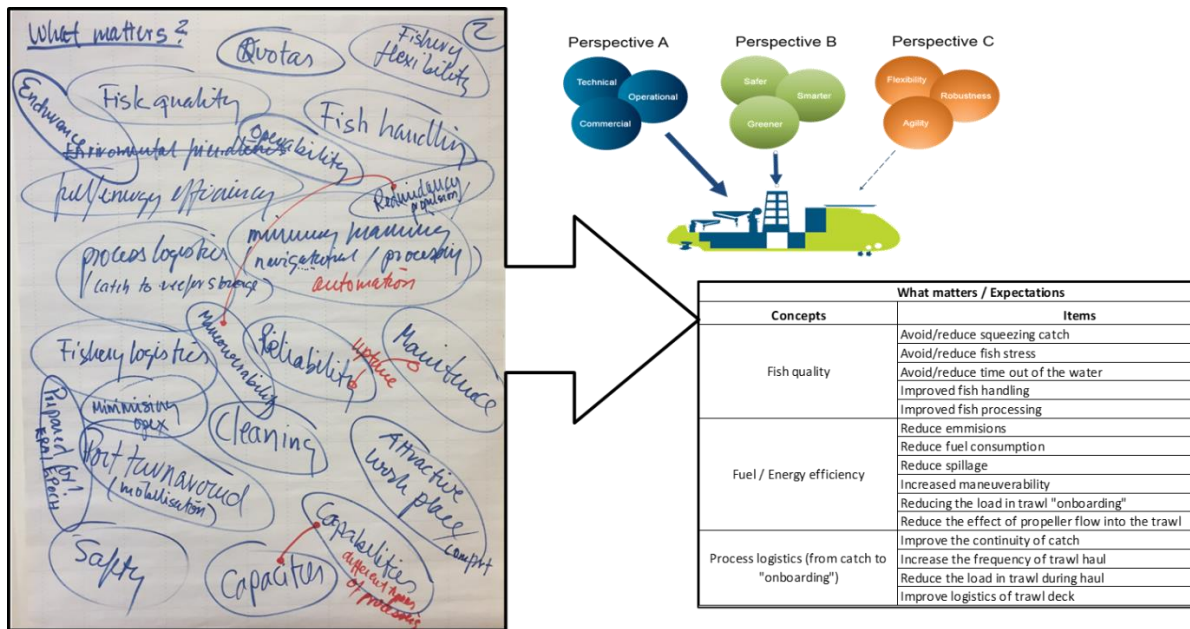

That, together with the market situation (rising fish prices, relaxation of fuel prices and political willingness) and the stagnation of the fleet and vessel design developments, had motivated a rising interest in a renewal of the factory stern trawler fleet in the coming years.

**Figure 4. Contextual factors supporting the robustness of the business idea.**

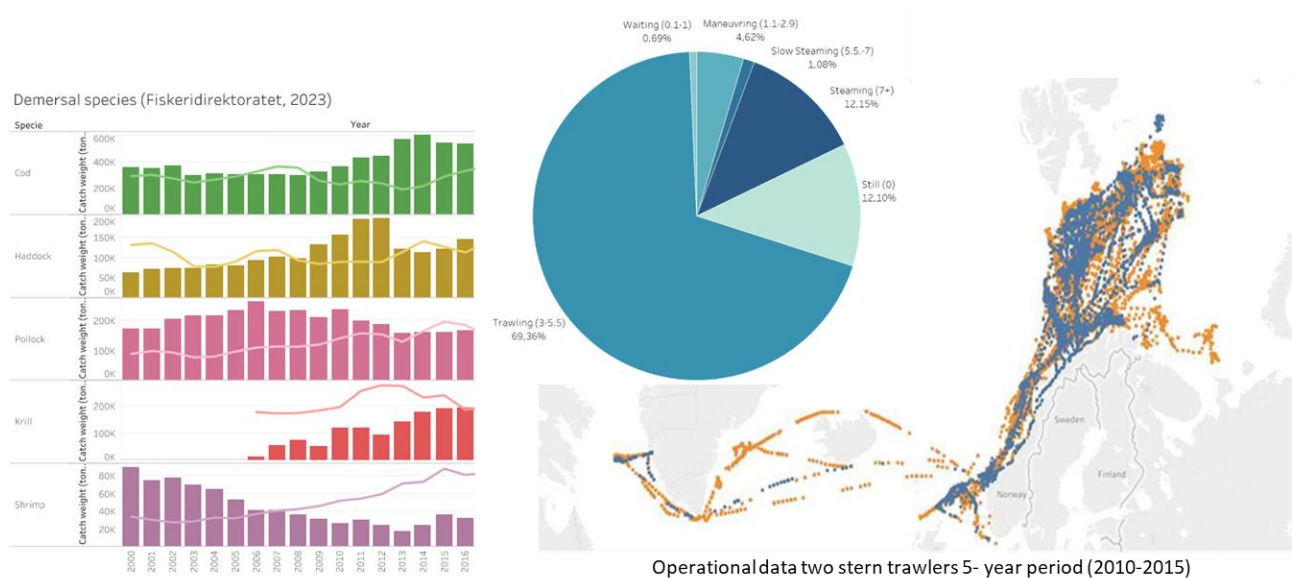

The business proposition came hand in hand with a set of expectations for the vessel design. The expectations were captured during the initial ABD workshops. Firstly, with an unstructured brainstorming to capture important expectations from the different stakeholders and actors involved (captain, chief, financial manager, end consumer of fish, etc). The different expectations were thereafter structured and further described by items that could related to the systems, functions, and performance elements of the vessel, as described in Figure 5.

**Figure 5: Identification of stakeholder expectations for a 5<sup>th</sup> generation type FST.**

Ahead of initiating a design development process, the ABD process involves a familiarization with the existing vessel operations and the context in which they are carried out, including commercial, operational, and technical aspects. Figure 6 exemplifies some of the support documentation extracted for project challenge identification and broadening the elucidation of the project solution space and later important vessel concept design solution development decision-making. Some of the analyses included an analysis of vessel operations and the development of operational profiles, a study of the quota system and expectations on quota developments, and fish price developments. Furthermore, it was clarified what to fish and where to fish. Similarly, analysis work was performed to identify a complex fish quota (Norwegian) arrangement, which was found to have a major impact on the FST vessel design solution. Figure 6 is a collage of the module 5 analyses.

**Figure 6: Collage of analyses performed during the ABD process.**

The understanding of the market was strengthened by an analysis of the market competition performed as part of Module 3. For this purpose, the project performed a deep analysis of the existing fleet, including analysis of trends on main vessel parameters (length, beam, cargo hold capacity, etc), a clustering of the factory stern trawler fleet (Figure 7), and a review of competing designers and relevant building yards.

**Figure 7: Overview of the stern trawler fleet categorized in clusters by length overall and beam.**

A vital aspect of developing such a novel vessel design solution is to map the causal models of revenue and cost drivers and enablers. Figure 8 depicts the two causal maps for revenue-making and cost-driving factors of the FST model. The different factors contributing to revenue generation and vessel expenses are categorized by the degree to which the project can influence them – high (green), medium (orange), and low (red) influence.

**Figure 8: FST vessel revenue-making and cost-generation models.**

The project carried out an onboard field study to establish a broad and deep understanding of the FST operation and feedback on vital operational vessel design features for improvement. Field studies are a structured process to capture "hands-on" information from vessel operations. The methodology is well documented in previous literature (Gernez et al., 2014; Lurås & Nordby, 2014) hence, it is not detailed described in this article. Figure 9 summarizes special aspects and design features relating to the bridge, accommodation, fish handling, fish factory, fish equipment deck, and finally, the trawl concept and reception facility, to be carefully looked at and improved as part of developing the novel 5<sup>th</sup> generation FST.

Deck operations

Fish factory

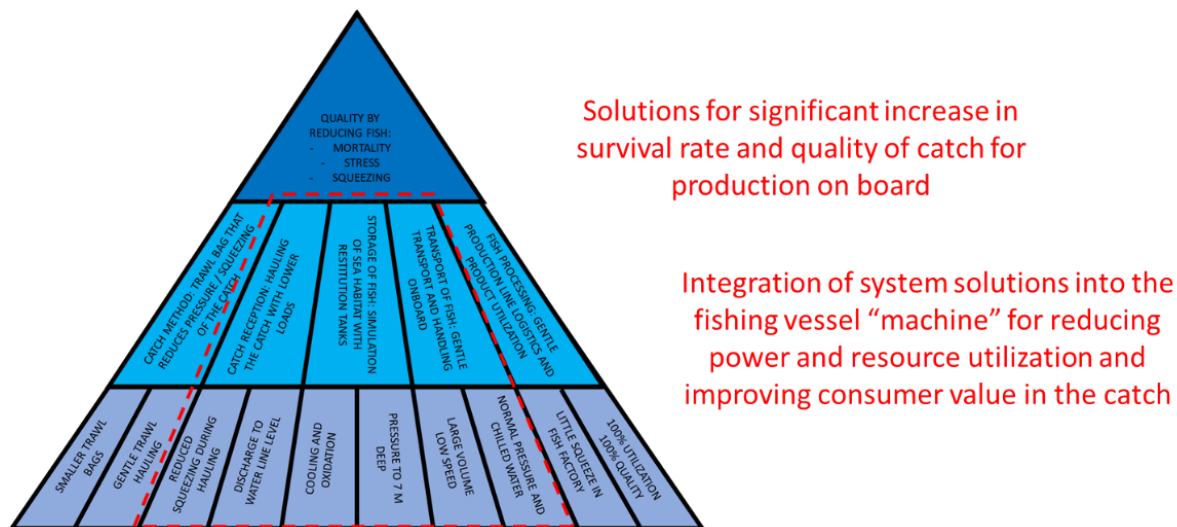

Bridge layout

**Figure 9: Main evaluation areas during the field trip.**

The project also carried out an evaluation of risk and uncertainties (Module 4) related to the vessel business case. This process has been previously described in an IMDC publication (Garcia et al., 2018). The evaluation included the development of a simulation model to explore the impact of externalities on the cash flow of the vessel while in operation.

There is only one last element required before the traditional design work (naval architecture and marine engineering calculations) starts: defining a design strategy and tactics that cater for the achievement of the business proposition and guide the designers during the conceptualization and detailing of the vessel design solution. Figure 10 exemplifies the breakdown of our design strategy and tactics related to enhancing the quality of the fish product.

**Figure 10: Design strategy and tastings for enhancing fish quality.**

## **ABD Module 5 work – a promising vessel concept design solution is emerging...**

The objective of Module 5 work of the ABD approach is to describe, supported by conceptual drawings and supporting analyses, different but promising solutions meeting the initial and underway stated expectations and requirements and assess these solutions by a set of specific, pre-defined criteria. These criteria are metric interpretations of all the expectations and requirements available and are relevant for proper and robust decision-making as to what is the better ship concept solution of the ones proposed. In this way, the main attributes, unique features, and performance yield can be compared and benchmarked in a micro and macro contextual way.

The design development (Module 5) started by framing the business proposition on tangible needs and expectations, that are thereafter elucidated in design parameters that define the boundaries of the design solution. Figure 11 exemplifies this process as a mind map leading from performance expectations (extracted in Module 2) into a vessel design definition. This process also requires identifying critical functions of the vessel platform. The project also depicted the early ship function diagram of the main and most critical functions of the novel vessel design to be explored (Figure 11 – right) and concluded as a part of the vessel concept design solution configuration.

### Project key performance indicators (KPI)

$$P.U.I. = \frac{(\text{Bollard Pull}) \times (\text{Reefer storage hold}) \times (\text{Speed}) \times (\text{Endurance})}{(\text{Total power})}$$

$$S.U.I. = \frac{(\text{Reefer storage hold}) \times (\text{Crew}) \times (\text{Nos. nets x size}) \times (\text{Nos. fish products}) \times (\text{Fuel tanks}) \times (\text{Fresh water}) \times (\text{Port turnaround})}{(\text{LOA} \times \text{B} \times \text{D})}$$

$$F.P.P.I. = \frac{(\text{Nos. fish product processes}) \times (\text{Live fish tanks}) \times (\text{Nos. trawl types})}{(\text{Lightweight}) \times (\text{Factory operators})}$$

$$G.S.C.I. = \frac{(\text{Speed}) \times (\text{Ice class}) \times (\text{Fishing criteria}) \times (\text{B/T} \times \text{B/L})}{(\text{Lightweight}) \times (\text{Power})}$$

## The ABD use case aftermath...

Seeing the opportunity to launch a new ship segment in the Ulstein portfolio of services and designs it was decided to immediately expand the ABD approach findings into a suite of FSTs based on the ABD work process findings. Three different sizes were explored and parametrically adapted – Coast, Ocean, and 7SEAS. In addition, three different branding concepts were introduced – high, medium, and low-standard outfitting solutions. The unique features of the novel 5<sup>th</sup> generation FST portfolio, including all three versions of the novel FST concept, were extracted and made into strong selling points. Figures 17 and 18 present these ideas in a pictorial format.

## CONCLUSION

This paper summarizes and describes a real-life ABD-guided development of a "family" of FST vessel concept design solution(s). The paper shows how a final ship design solution on a conceptual level, can look like, and consequently be built. This comprehensive and rather laborious article is developed with the principle of "seeing is believing" in mind. Over the years, so many interesting and most likely useful ship design approaches have been introduced and argued for as a must-have to state-of-the-art naval architecture and marine engineering practices. However, many of these methods are still only fragmentary. They tend to address only parts of the whole ship design process, rather than trying to deal with the full work process – concept, basic design, and detailed engineering. Many of the contributions are also very "toyish" in the sense that they have only been tested out as pilots and quite frequently user simulations have been based on "dummy" variables and the like. Practical real-life applications are scarce and therefore, custodians of the marine community have only to some extent, included them in their naval architecture and marine engineering toolboxes and daily ship design practice. For this paper, we felt it was important to share and demonstrate that in some cases, some of these novel approaches can be used in real-life situations. Yet, with the danger of exceeding the paper limit for IMDC papers, it was still considered useful to share pictorially, real project development experiences with the ship design community. We have shown in an anecdotal way, how the ABD approach can be executed, and findings meaningfully be used to produce successful vessel concept design solutions.

The paper starts with a recapitulation of what is still missing, or which loopholes still exist in the early ship design process. The tame and wicked problem aspects are addressed, and the authors argue that with the introduction and application of the much-referred and reviewed ABD approach in several IMDC papers, it is practically possible to master both tame and wicked ship design problems. A particular real-life use case of an ABD approach application has been introduced and reviewed in the paper. How it all started and how the process was continued are briefly documented and commented on.

The paper commences with a discussion about the fact that not all approaches fit all situations. Likely reasons for this are elaborated upon. The comprehensive (and successful) demonstration of the ABD approach in this paper makes a case for holistic design methodologies that explicitly address customer interaction and requirements elucidation as well as technical, operational, and commercial aspects in one go.

## Practical implications to ship designers...

Although this particular use case study realization took a very long time, such an observation is, to our experience, uncorrelated with the ABD approach application. The ABD-approach-assisted novel vessel concept design solution development took place

well within the timeframe experienced in other ABD projects we have arranged and performed – typically 4 to 6 months. Also, the separate basic design job was carried out within normal time limits. The extreme project time spent was primarily due to project externalities, such as customer firm upheaval, sickness, tightening market conditions and extreme price increases with corresponding slow and costly financing opportunities and other matters outside the control of the project. The authors argue that the ABD process went very smoothly and the customer in question was an ideal partner "playing by the ABD rules". They were highly motivated to pursue the goals and intent of the project. They were very patient and receptive to new approaches. Even when this was the first time, they tried to follow the systematic procedure. They were very disciplined with the process, open-minded and willing to go with the flow of the ABD approach regimen. An enormous amount of information sharing took place, resulting in a wider educational business operation both on the customer's side and the designer's side. Hence, it can be concluded that the ABD approach to the project was an effective one. It is also a learning process that more vessel innovation projects could benefit from a similarly facilitated ABD approach. As stated earlier in the paper, it is typically C-Ds4 and C-Ds5 customer-ship designer settings that easily lend themselves to ABD approach applications and where extraordinary ship design process effectiveness could be expected. In other situations, the ABD approach might be found too time-consuming or resource-demanding, and the customer or project owner might not be willing to adapt to the new way of doing things.

The example described in this paper, together with the authors' experience, suggests that this type of ABD-based project can be suggested and carried out in many more new building situations with substantial gains to all parties involved. Although the ABD approach has not yet been applied in a Navy vessel situation, to the knowledge of the authors, it is strongly recommended that such a new application test is initiated and reported. The more real-life projects being carried out and reported, the faster and more qualified ABD-approach "facilitator-pilots" are developed for the renewal and enhancement of the ship designer community.

Again, we can see the role of the naval architect and marine engineer being strengthened as an integrator of the ship design project – administering the new building project development on behalf of the customer, but at the same time, the architect must also develop stronger interpersonal and social expertise and skills to better facilitate these complex and uncertain development processes. That is, more naval architects and marine engineers need to expand their multi-disciplinary expertise and skills to better support such new development of the discipline, topic, and related subjects, not at the expense of deep discipline knowledge – but in addition. More than ever, it is suggested strongly that "the ship designer of the future" must master equivalent expertise and knowledge within the fields of commercial, operational, and technical challenges related to a new building project realization. Thus, a new type of competent naval architects and marine engineering candidates must be developed through academic training and put into practice in situations different from the past (Asbjørnslett et al., 2022).

It becomes clearer to the authors that the traditional transaction-based ship design approach, where two parties deal with each other via a negotiation-based information-sharing process, does not work very efficiently – particularly not where and when novel innovations are to be developed and realized. Consequently, the traditional information exchange formats in ship design settings need to be improved or completely substituted. The same applies to the contractual formats being applied today. Finally, but not least, various new forms for "open book" partnerships can or must be established between project parties – open book means full trust between parties, no hidden agenda or desires and free information sharing even of traditionally considered confidential information.

### **Implications to academia...**

Academia should, therefore, extend or establish and offer multi-disciplinary training courses and marine technology educational programs with content and learning objectives to match this new situation. Some Naval Architecture and Marine Engineering schools are already trying out such multi-disciplinary educational programs with course syllabus including own and cross-institutional/faculty complimentary courses and students' participation. The suggested change in design practice is likely most effectively achieved through the influx of freshly educated, multi-disciplinary designers who are trained in ABD-like design approaches.

### **What are some personal experiences to share...**

While the overall ABD approach has worked very well and successfully in the described project, there are always things that can be improved on. In the opinion of the authors, establishing the facilitator and complete ship design team as early as possible in the process and earlier than was practised in this project would have helped. Thus, the ABD team from the ship designer side should be fixed and be a fixed group along the way. Also, more in-house, multi-skilled and experienced naval architects and marine engineers would have helped the process carried out. It is not very productive to involve basic design engineers now and then – they should be a permanent part of the ABD team and participate in the process from the very beginning and all along the way. If the customer is lean, the ABD team should follow the project into the premises and internal discussions of

the customer and partly become their permanent project support – avoid retaining a two-avenue process with transactional negotiations taking place between the customer and ship designer as the basic design and detailed engineering stages take place.

## CONTRIBUTION STATEMENT

**Per Olaf Brett:** Conceptualization; data curation; structure and argumentation; methodology; writing – original draft.

**Jose Jorge Garcia Agis:** Conceptualization; data curation, writing – review.

**Benjamin Lagemann:** writing – a review.

## ACKNOWLEDGEMENTS

This work reports on advances made in the Ulstein Group ASA and its affiliated companies as to how to modernize and enhance existing vessel concept design theory and practices, activities normally, performed together with customers. A sincere thank you to all of you. Much of the theoretical and methodological foundation and the exploration of improved vessel concept design is based on previous developments much of it being presented and discussed in previous IMDC 2006, 2009, 2012, 2015, 2018, and 2022 proceedings. This time the authors have intended to share first and foremost some practical experiences with applying novel naval architecture and marine engineering methods, theory, and approaches to demonstrate their applicability. Without the opportunity to consult with and exchange ideas around the topic, with colleagues at the Department of Marine Technology, NTNU Trondheim this study and article summary wouldn't be possible.

This paper reflects and presents the authors' viewpoints about the integrated customer-ship designer setting study taking place for a unique real-life ABD approach application in which both authors participated as facilitators and analysts. A sincere appreciation of contributions from several customers and their executives and experts is also conveyed hereby.

# Capability driven vulnerability analysis of a naval combatant

Czop, Michal<sup>1,\*</sup>; Megan, Demi van<sup>1</sup>; Droste, Koen<sup>1</sup>

## ABSTRACT

*This paper presents a fine-tuned approach to vulnerability assessment, focusing on protecting capabilities instead of individual systems and their components. The foundation of this method is a system model which uses functional chains to identify the contribution of individual systems towards to fulfilment of the ships capabilities. The key advantage of using functional chains is that by showing that individual functions can still be fulfilled, it is demonstrated that the vital capability containing those functions remains available. This paper first explains the theory behind the methodology and then demonstrates its working principles using a generalized case study for a single capability.*

## KEY WORDS

ship vulnerability; ship survivability; model-based system engineering; functional chains; naval design.

## INTRODUCTION

In naval design, survivability is a set of measures aimed at reducing the likelihood of being hit by a hostile effector and limiting the consequences of such damage. It can be divided into two sub-disciplines: susceptibility and vulnerability. The former includes managing the asset's signatures (radar, infra-red, acoustic, etc.) to prevent detection, confusing the weapon's homing systems (for example using decoys), or ultimately destroying the incoming threat. The latter i.e., vulnerability reduction, which is the focus of this paper, includes the measures which reduce weapon effects with the assumption that the vessel has already been hit.

There are multiple reasons to implement the vulnerability aspect in a modern naval combatant design. The overarching goal is to reduce the potential death toll amongst the crew, following the philosophy that while ships are replaceable, people are not. However, replaceable does not equal disposable, thus the second objective is to limit the extent of damage and decrease the risk of the loss of the asset. An additional benefit is that reduced vulnerability increases the availability of ship's systems in a damaged state, thus improving the prospects of completing mission objectives. It is worth noting, that the approach discussed in this paper is only relevant to threats on or above the waterline, resulting in kinetic damage, blast, and fragments emission. The underwater threats, such as mines and torpedoes, usually lead to a shock event affecting the entire vessel, which requires a fundamentally different approach.

## ESTABLISHED APPROACH TO VULNERABILITY REDUCTION

### Physical protection measures

Vulnerability reduction includes multiple distinct solutions which need to be considered at consecutive design stages. In the age of battleships, for the most part, this objective was fulfilled by heavily armouring the ships, which made them more resistant to (naval) gunfire. However, the technological landscape has completely changed; modern, more powerful weapons have

---

<sup>1</sup> Damen Naval (Vlissingen, Netherlands)

\* Corresponding Author: m.czop@damennaval.com

rendered this strategy ineffective and impractical. Additionally, the heavy armour comes with a major penalty to other design aspects, primarily signatures, weight, and space, thus increasing cost of construction and operation (due to increased fuel requirement). Nonetheless, certain impact protection measures continue to play a key role in limiting the extent of damage to the ship. Blast-, Fragment and/or fire retaining bulkheads and reinforced decks are applied in strategic locations to contain the effects of a hit to a limited part of the vessel. With increasing prevalence of asymmetric scenarios, it is becoming more common to additionally protect high value and/or heavily manned compartments with the aim of stopping the penetration of the ship's hull by smaller weapons fire. Similarly, sections of reinforced bulwarks as well as bulletproof vests serve to protect the personnel on the open decks against small-calibre gunfire.

## **System architecture measures**

In addition to shielding and containment, system architecture measures are implemented to improve resilience of the vital systems of the ship. This strategy drives the arrangement of systems by acknowledging that they may be partially damaged, therefore single points of failure must be avoided to reduce the impact of weapon effects. The established approach to this issue is designating a set of ship's systems as vital and ensuring there are multiple instances of each in the vessel with sufficient physical separation. This is the key distinction between availability and vulnerability analysis – two systems located in the same compartment are redundant from the availability standpoint, however they can be damaged by a single weapon hit. When selecting the locations of the vulnerability-redundant systems, longitudinal separation is preferred over vertical. This is not only because ships are usually longer than they are tall, but also due to the fact that bulkheads tend to offer more resistance to blast effects than decks do. For most support systems (providing consumables, control, cooling, etc.) the distribution infrastructure must also follow a redundant design to be able to service the dependent vital systems outside of the damaged section. This is achieved either by routing the main line through compartments well under the waterline with riser pipes extending upwards or by developing a ring arrangement for cabling and piping. Switchboards and valves are placed at selected boundaries allowing to isolate the damaged section and continue servicing the remainder of the vessel.

A ship contains multiple interconnected systems, very few of which are capable of functioning fully independently. The measures described above are effective at providing redundancy of individual systems, however on their own they fail to capture the interdependencies amongst them. For example, let us assume a vessel with a redundant electric propulsion system, powered by a ring-shaped distribution network with two generator sets in different areas of the ship. These generator sets have independent cooling circuits, which require uninterrupted supply of freshwater, delivered from either of two pumps located in a single machinery space, halfway between the generator rooms. In this case a single weapon hit can damage both pumps, not only indirectly disabling the propulsion system but also leading to a complete blackout. This is only an illustrative example – in complex naval platforms these interdependencies are often obscured by the sheer amount of complexity and interconnectivity of all systems on board.

Based on the arguments above, simply doubling and separating all the systems on the vessel may seem like the optimal solution, however the redundancy measures come with a severe penalty to weight, space, and cost. Consequently, a more in-depth analysis is needed to accurately select the systems and components to protect and develop a resilient design without compromising other design aspects.

## **CAPABILITY DRIVEN APPROACH**

The defining feature of capability-driven approach is that it shifts the focus of the analysis from protecting individual system components to protecting high-level (vital) capabilities of the ship. This chapter explains how these capabilities are described in a system model and mapped to the relevant systems, followed by the assumptions of the analysis and the principles of evaluating system performance.

### **System model as the foundation of analysis**

This paper presents an approach to the issues described above by basing vulnerability analysis on functional chains created with ARCADIA – a model-based systems engineering method developed by THALES (Voirin, 2017). The system model describes the capabilities of the vessel represented using functional chains. A functional chain consists of several functions which interact with each other, in essence describing the sequence of events/actions which need to happen in order to achieve a given desired capability. These functions are then assigned to (or allocated to) systems which execute them. This makes the interactions between functions become a representation of interactions (or interfaces) between systems. These interfaces are modelled as functional exchanges, showing both the functional and physical interdependencies between systems (Roques, 2017). This approach makes it possible to analyse the systems one-by-one and ensure a functionally resilient design regardless

of its complexity. The fundamental assumption is that if all functions in the relevant chain can be fulfilled, the capability in question is secured.

The vulnerability analysis is focused on the overall design philosophy of a system and location of components. The system model is constructed on an even higher level where each system as a black box with allocated functions. Generic representation of systems, functions, and functional exchanges is shown in Figure 1. In this diagram the crew is modelled as a logical actor (external to the system but interacting with it), whereas the ship is acting as a container for the systems being analysed. Both the logical actors and systems have functions allocated to them and interact with each other by the means of functional exchanges (shown as arrows), which represent an interaction (e.g., exchange of matter or information) between two functions.

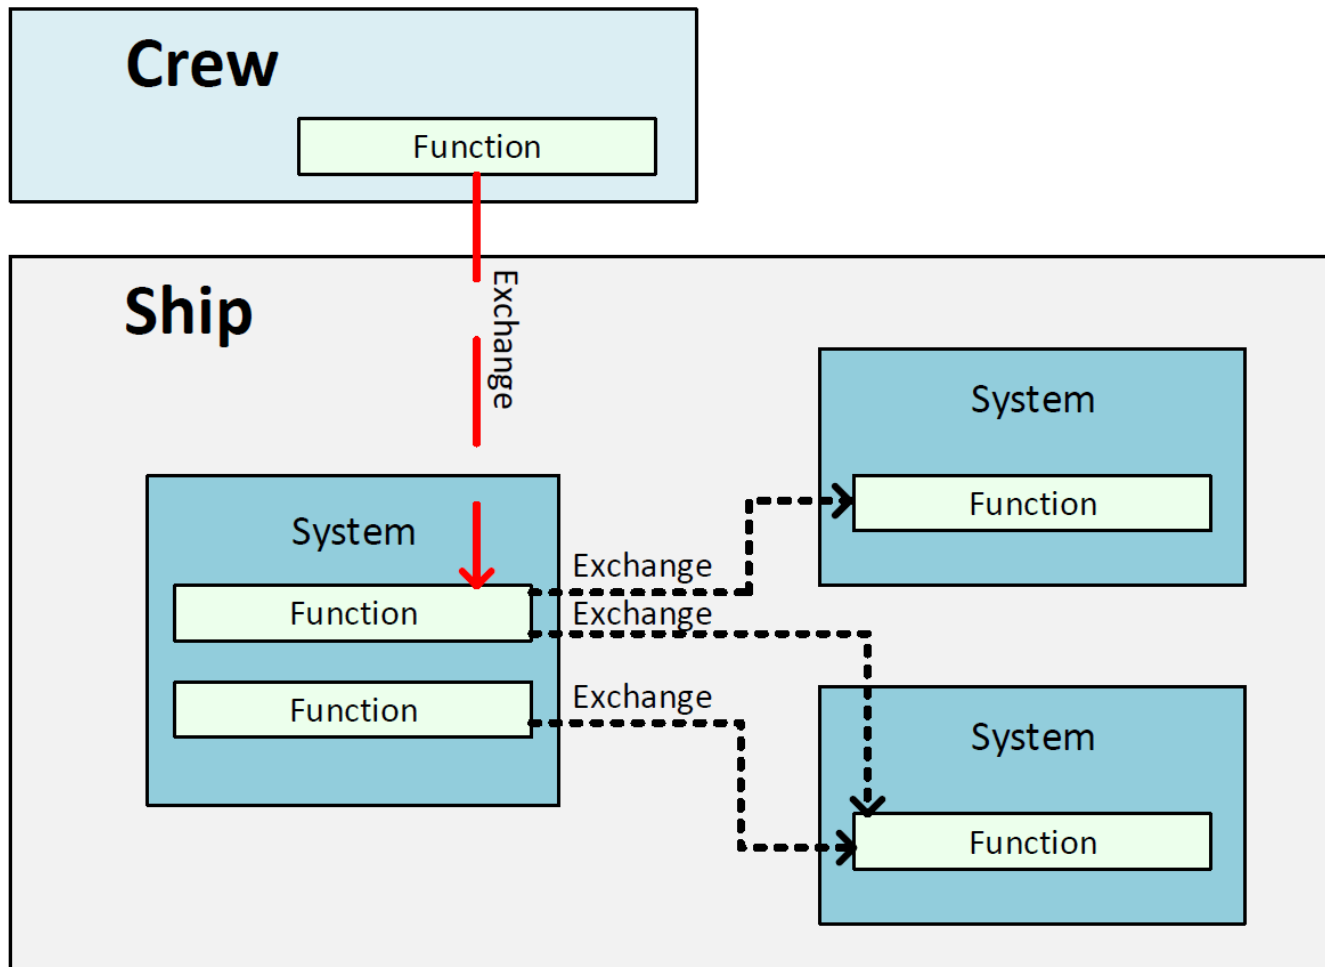

Figure 1. Generic representation of systems, functions, and functional exchanges

### Definition of residual capability

It can be expected a damaged ship will not have the same capabilities as an intact one. Thus, vulnerability reduction effort should start by defining the minimum required residual capabilities after a damage event. These residual capabilities describe which functionalities of the vessel must remain available even after sustaining damage. Normally, several capability levels will be specified, with fewer functionalities required for increasing severity of damage. In this paper, two levels will be used, corresponding to arbitrarily defined small hit and large hit. The assumptions relating to threats are discussed in the next section.

Based on the system model, the functional chains contributing to the specified residual capabilities are evaluated and the functions which need to be preserved are classified as vital. By extension, the systems fulfilling these functions are also classified as fully or partially vital, i.e., only the parts of the systems supporting the residual capabilities are considered vital. The degree to which a system can fulfil its function after damage (in degraded state) is referred to as residual performance.

At the initial design stages, the residual capability may be stated as simply as “The vessel shall be able to propel itself and control its heading after a small hit”. As the design matures and trade-offs are better understood, more precise level of residual performance can be specified, e.g., that the speed of 5kn must still be achievable after a small hit. As such, the capability-driven approach does not force a specific arrangement, instead giving system designers freedom to choose the best solution. As long as the residual capability objective can be met in the damaged state, the outcome of the analysis would be considered satisfactory.

## **Assumptions of damage effects**

As mentioned in the previous section, the residual capability levels correspond to threat levels, i.e., the assumed weapon threats from which the ship needs to be protected. The selection of these design threats and calculation of their effects is beyond the scope of this paper. To demonstrate the following stages of the analysis, two threat levels are specified: a small hit is defined as damage to one compartment (volume between two consecutive decks and two consecutive watertight bulkheads), whereas a large hit includes multiple compartments. The weapon impact can occur in any location above the waterline, resulting in an array of damage cases to be calculated and evaluated in the analysis.

Due to inherently unpredictable nature of explosions, it is infeasible to predict, which equipment in the damaged compartments will be affected. While there are methods which can provide a finer estimate of failure, they are overly time-consuming to be applied for every investigated damage scenario. Therefore, a conservative assumption is that all the equipment, cabling, and piping located in these spaces may be destroyed, reflecting the worst-case scenario. It is worth noting that less pessimistic assumptions can be made for small-calibre ballistic threats, but these are not considered in this paper.

## **Effects of damage on residual capability**

The damage effect analysis is used to determine the residual performance of the ship after battle damage and, if it is not satisfactory, the measures required to increase the survivability of the ship. All the vital systems are individually analysed for the impact of each damage case. Two types of system degradation are considered after battle damage: through direct damage, when system components are located in an affected compartment, or degradation following a failure of a support system (providing an essential consumable or control to the system in question). The indirect cases are mentioned during an analysis, but mostly function as a quality check, since they will also be identified when the damage effects on the relevant system are evaluated. In certain cases, the loss of a function might be acceptable as long as it can be compensated by another system, thus avoiding a complete loss of the vital capability, since there is a functional back-up.

Vulnerability analysis generally focuses on the worst-case scenario for each system. In practice, residual performance after a hit is likely to be higher than the guaranteed minimum. Besides proving that the minimum required performance is met, the capability-driven approach gives the designer and the user comprehensive understanding of the consequences of damage in various areas and the potential impact on damage control and residual capability. To demonstrate the practical implications of this theory, the next part illustrates the strategies and principles listed above in a case study.

## **GENERIC CASE STUDY – FIRE FIGHTING**

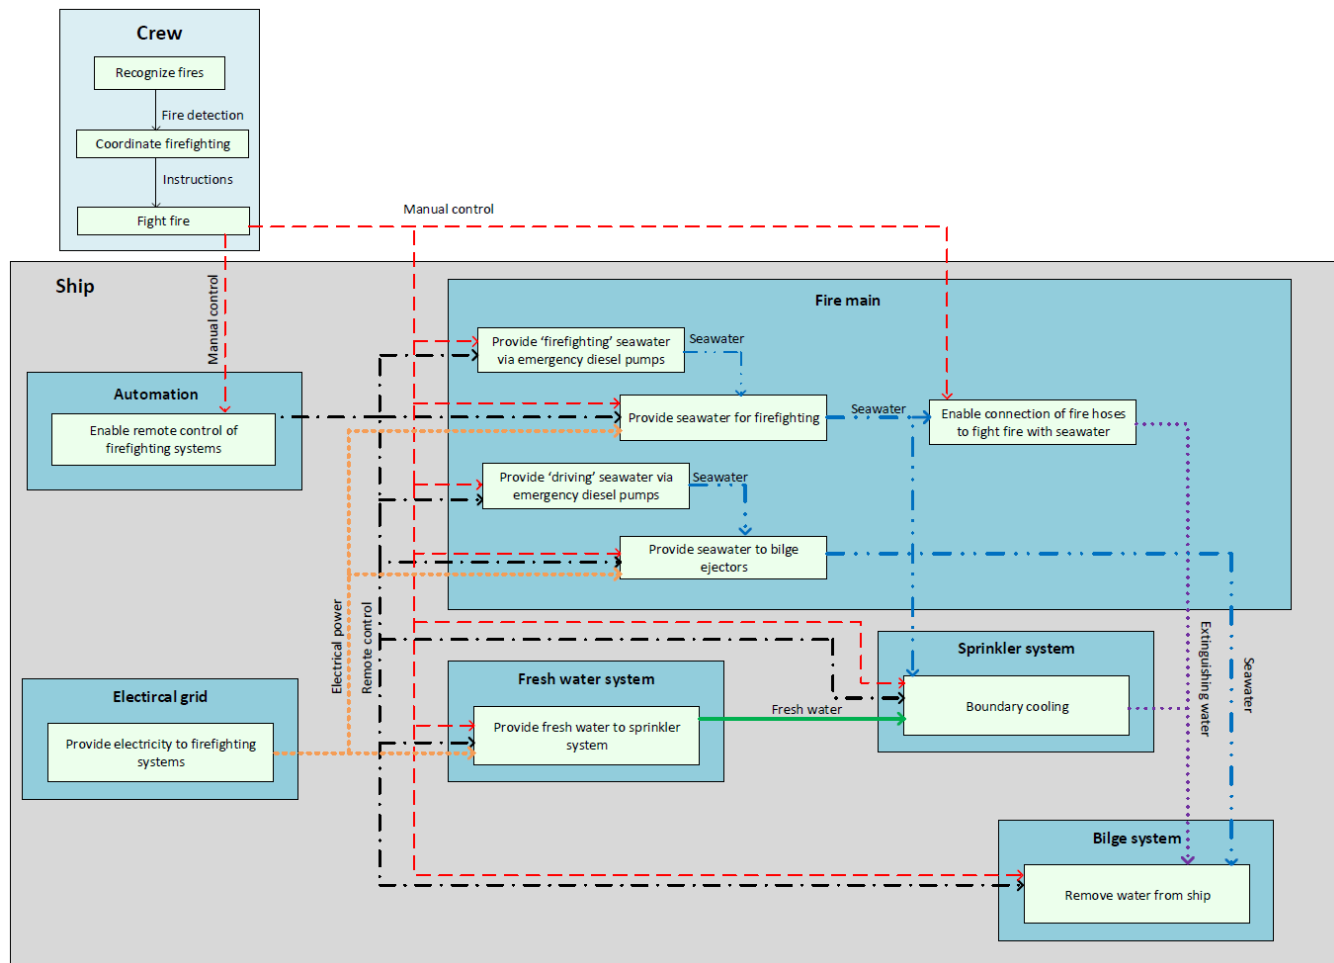

This example shows the analysis of a simplified firefighting case on a fictitious ship. The goal of the analysis performed in this case study is to demonstrate that the residual capability of firefighting remains available after battle damage by proving that all functions contributing to this capability can still be sufficiently fulfilled. A large hit damage case was chosen, as it affects a wider range of systems, therefore making the vulnerability analysis more complex. Both the damage case and the functional chain describing the capability are provided as an input and their development is not discussed in detail.

The following sub-sections correspond to the three steps of the process: functional chain analysis, damage extent analysis, and damage effect analysis.

### **Functional chain analysis**

The functional chain analysis breaks down the process of firefighting into the contributions of the different systems and/or actors. Following the specification of residual performance level required, the system model describing the normal operation is adapted to only contain the functions required after battle damage. Figure 2 shows the functional chain describing firefighting during normal operation, with different line styles corresponding to different exchange media. The interactions between the crew and the functions assigned to the crew are outside of the scope of this paper and are therefore modelled in a

very simplistic manner. The detailed explanation of contributing systems and functions is provided in the subsequent paragraphs.

**Figure 2. Simplified diagram of functional chain Firefighting**

### Firefighting during normal operation

In this scenario, the ship is sailing through friendly waters on the way to a deployment area. It is a quiet night and most of the crew are resting, except those on watch. During a routine patrol of the vessel, a petty officer smells a hint of smoke in the passageway and follows the scent to find that a fire had broken out inside an unmanned machinery space. The fire is clearly too big to put out with a fire extinguisher, so he immediately reports this to his superior officer. The alarm is raised and the officer gathers a firefighting team, coordinates a response strategy, and the crew promptly start firefighting using the onboard systems.

On this ship, fire hoses serve as the primary means of firefighting. The crew will normally use the hydrant located in the affected compartment or, if inaccessible, connect the fire hoses to the hydrants in adjacent compartments. The fire hoses are sufficiently long to span multiple compartments.

If fire is present in a compartment adjacent to an ammunition store, the store will require boundary cooling as a safety precaution to prevent an explosion. This is achieved with a sprinkler system which can cool the room using the fresh water supply or seawater as an emergency backup solution. Activation of the system is done either from one of the command spaces via the automation systems or by a local panel.

The build-up of extinguishing water, from both firefighting and boundary cooling, is removed from the ship via ejectors which are part of the bilge system. These bilge ejectors utilize the Venturi effect to enable the intake of water. To do so a driving medium is required, which in this case is seawater provided by the fire main.

During normal operation, the crew will activate all the electric pumps required for water supply via the integrated platform management system (IPMS), or alternatively every system can also be manually activated on the location. Two diesel-driven seawater pumps are available in case of a power outage.

Coming back to the firefighting crew, with all systems are available and functioning correctly, it only takes a few minutes for the personnel to take control and safely extinguish the fire. None of the crew suffered any injuries, but the damage is significant enough that the vessel will need to stop for emergency repairs at a friendly port. After a few weeks, she will be able to sail again and resume deployment.

### Firefighting with a ship damaged in battle

Following the unscheduled maintenance due to the previous fire, the ship is back to full availability and continues the mission: protecting a vital trade route from pirates and other armed groups. Not long after the vessel and the crew arrive in the area, one of key countries in the region is shaken by a coup-d'état putting a hostile military dictatorship in power. The immediate collapse of diplomatic relations and escalation of the political conflict leads to something that would have been unthinkable just weeks prior. The hostile regime sends a barrage of anti-ship missiles towards the vessel. Three missiles are tracked and eliminated by the self-defence systems, but one gets through – the ship is hit.

After the initial impact, the crew promptly assess the severity of the situation. Again, a petty officer sees a fire inside the affected compartments and reports it to his superior. Clearly the blast has damaged most components, cabling, and piping in the affected compartments, so the performance of firefighting systems is now degraded. The question arises: will the crew be able to control and extinguish the fire?

To ensure that the vessel can fulfil the vital residual capability of firefighting, the relevant functions must be identified. They can be defined based on the normal operation, by determining which functions are considered essential after battle damage and, as such, require protective measures. This rationale causes several functions (from the 'normal' functional chain) to be labelled as non-essential. In this case, the loss of electrical power is acceptable thanks to the diesel-driven back-up for the electrical fire pumps. Similarly, remote control (provided by IPMS) is not essential since all required equipment can also be controlled manually.

The freshwater system has also been marked as non-vital, but for a different reason. The preferred medium for boundary cooling is indeed freshwater as it is less corrosive than seawater. Freshwater is however considered a limited resource as it takes time and energy to produce it, therefore the sprinkler system is also connected to the fire main as a backup, since seawater can be supplied virtually indefinitely. Marking the freshwater system as a vital system would imply that protective measures need to be provided to the system. This would likely entail either a redundant system layout or local protection. Both options would come with severe penalty to weight and space. The fire main is already designated as a vital system due to the seawater requirement of the hydrants and of the bilge system. Adding another consumer to the list will not result in a dramatic increase of the weight of the ship nor will it take significant space within. The preferred solution is to prioritize protection of one system instead of two.

All systems that are allocated a vital function are now considered vital systems. Therefore, the vital systems are the fire main, the sprinkler system and the bilge system. The remaining functions are considered required for the residual capability and are summarized (together with the systems they are assigned to) in Table 1.

**Table 1. Functions forming the residual capability Firefighting**

Vital System	Function
Fire main	Provide 'firefighting' seawater via emergency diesel pumps
Fire main	Provide seawater for firefighting
Fire main	Enable connection of the fire hoses to fight fire with seawater
Fire main	Provide 'driving' seawater via emergency diesel pumps
Fire main	Provide seawater to bilge ejectors
Sprinkler system	Room cooling
Bilge system	Remove water from ship

## Damage extent analysis

During the damage extent analysis, the areas that are affected by weapon impact are determined, based on the specified design threat, vessel arrangement, and a set of assumptions. Only one battle damage event is considered at a time and the secondary effects, in this case fire, will only affect the damaged area.

In the scenario being analysed, a single damage case is evaluated; a missile hit in compartment C IV. This is considered a large hit affecting multiple compartments. The damaged area of the fictitious ship used in this case study is shown in Figure 3.

Figure 3. Side view of a vessel showing large hit damage

## Damage effect analysis

All the vital systems are individually analysed for the selected damage case. Firstly, a brief description of the functions allocated to the system and the minimum expected performance of the system is provided, followed by description of the system layout and dependencies, and lastly performance after damage is discussed. The systems are discussed in the order of increasing complexity and the number of dependent systems: the sprinkler and the bilge systems are analysed first, followed by the evaluation of the supporting system fire main.

### Sprinkler system

The sprinkler system only has one function which is to cool the ammunition room in case of fire in an adjacent space. This is also considered to be the minimum required functionality.

The layout of the system is given in Figure 4. To fulfil this function the system consists of branches with open nozzles (modelled as black bulbs) within the ammunition store. A valve is opened to allow seawater to enter the branches from the fire main (red flag).

## Legend

- Seawater
- ✱ Sprinkler
- ◀◀◀◀◀ Incoming connection from the fire main

**Figure 4. Layout of the sprinkler system**

According to the system model, the sprinkler system is dependent on the crew, the automation system, the freshwater system, and the fire main. The sprinkler system requires the crew to activate the system and the fire main to provide a cooling medium to function properly. Automation, the electrical grid, and the freshwater system have been marked as non-vital and thus should be assumed to no longer provide any support towards the sprinkler system, i.e., full degradation is allowed. The dependencies of the system have been summarized in Table 2.

**Table 2. Dependencies of the sprinkler system on other systems**

System	Provision towards the sprinkler system	Allowable degradation	Effect of full degradation
IPMS (Automation)	Means of starting/stopping the boundary cooling.	Full degradation allowed	The crew will have to start and stop the system locally.
Crew	Means of starting/stopping the boundary cooling.	No degradation allowed	No means of starting or stopping the system.
Freshwater system	Provision of fresh water as a cooling medium.	Full degradation allowed	The sprinkler system will use seawater as a cooling medium.
Fire main	Provision of seawater as a cooling medium.	No degradation allowed	The sprinkler system no longer receives a cooling medium.

The system itself is located outside of the damaged area and therefore remains intact. This damage case does not prevent the system from fulfilling its function and therefore the performance is sufficient.

## Bilge system

According to the system model, the bilge system is required to remove the water that has collected on A-deck from the ship. After battle damage, the source of this water will be from both boundary cooling and firefighting. The minimal required performance after any damage case is the ability to remove water from every watertight zone. The system layout of the bilge system is shown in Figure 5.

**Figure 5. Layout of the bilge system**

The system consists of four bilge ejectors which remove water from their corresponding compartment via suction lines (marked blue). Additionally, each ejector can drain the adjacent compartment forwards of the one it is placed in via an emergency suction line. The ejector located in compartment A II also has a suction line connecting to the aftmost compartment. When a valve is opened, the driving seawater (marked red) flows through the bilge ejector which starts removing water from the compartment. The mix of removed and driving water (marked purple) is then ejected from the ship via check valves in the decks directly above the bilge ejectors.

The bilge system depends on the crew to activate the system and on the fire main to provide a driving medium. Similarly to the sprinkler system, the IPMS is not required thanks to the back-up local control. Table 3 gives an overview of the system dependencies.

**Table 3. Dependencies of the bilge system on other systems**

System	Provision towards the sprinkler system	Allowable degradation	Effect of full degradation
Automation	Means of starting/stopping the bilge system.	Full degradation allowed	The crew will have to start and stop the system locally.
Crew	Means of starting/stopping the bilge system.	No degradation allowed	No means of starting or stopping the system.
Fire main	Provision of seawater as a driving medium.	No degradation allowed	The bilge system will not be able to remove water without a driving medium.

One of the check valves and its connected piping is damaged in this example. Thus, water cannot be removed via that compartment. However, the emergency connection is still available to remove water from compartment A IV.

The system can still remove water from every watertight compartment. The minimum performance is thus met, and the degraded state is considered acceptable.

# Fire main

Most functions for this residual capability are assigned to the fire main. These functions can be summarized as providing seawater to the firefighting systems and allowing the connection of fire hoses. The minimum performance of this system is more complicated than the previous two systems as the fire main is a support system. The layout of the fire main is shown in Figure 6.

**Figure 6. Layout of the fire main**

Fire hoses are the primary means of firefighting, the minimum performance for the fire main is therefore the availability of a functioning fire hydrant in at least one compartment adjacent to every damaged compartment.

The bilge system needs a driving medium and is required to remove water from every zone, however that does not imply that seawater must be available in all zones. For this damage case, the minimum performance of the fire main is the availability of seawater in zone II, III, and V, so that water can be removed from every zone. Lastly, the minimum requirement derived from the sprinkler system is the availability of seawater in compartment B III.

The system consists of four electrically driven pumps and two emergency diesel driven pumps. To fight fire, boundary cool one room, and remove water from the ship, a single pump (electrically or diesel-driven) is required. A valve is provided whenever the fire main penetrates a bulkhead and all riser pipes are fitted with a valve at A-deck. A little flag is added to signify when a riser pipe is connected to a different system. Hydrants are provided in every compartment. Table 4 gives an overview of the dependencies of the fire main.

**Table 4. Dependencies of the fire main on other systems**

System	Provision towards the sprinkler system	Allowable degradation	Effect of full degradation
Automation	Means of starting/stopping the (emergency) pumps.	Full degradation allowed	The crew will have to start and stop the system locally.
Crew	Means of starting/stopping the (emergency) pumps.	No degradation allowed	No means of starting or stopping the system.
Crew	Manual connection of the fire hoses and firefighting.	No degradation allowed	No means of fighting fire.
Electrical grid	Provision of power towards electrical firefighting pumps.	Full degradation allowed	Emergency diesel driven pumps will provide seawater for firefighting.

The system requires electrical power for its four main pumps. The generation of power is not guaranteed as it is not marked as a vital system for firefighting, as such it should be assumed that the main pumps are not available. The crew will therefore activate the emergency diesel-powered pumps.

Two riser pipes are located in the damaged area, so these riser pipes will be closed off to isolate the damaged part of the system. The function to fight fire with hoses remains available as the compartments adjacent to the damaged area are equipped with working hydrants that can provide seawater. However, seawater cannot be supplied to the sprinkler system in compartment B III or the bilge system in compartments A III & A IV, since they are connected to the closed-off riser pipe. The functions “Provide seawater to bilge ejectors” and “Provide seawater for firefighting” are not fulfilled. This is not an acceptable performance, thus adjustments to the system are required to improve the availability of seawater.

The supply of seawater towards the bilge system must be evaluated. As discussed before, part of the bilge system is located in the damaged area, therefore the bilge ejector located in compartment A IV will remain unavailable even if seawater is supplied. However, the ejector located in compartment A III has an emergency suction line to compartment IV. Both compartments A III and A IV can thus be emptied if the bilge ejector in compartment A III is supplied with seawater. An additional valve could increase the availability of the seawater supply.

The supply of seawater to the sprinkler system must not be compromised. A solution could be either a second pipeline routed to the sprinkler system or smart placement of an additional valve. The pipeline is not the preferred solution as it adds additional weight, takes up space and further adds to the complexity of the system. The recommended solution would be placing an additional valve in the riser pipe located in compartment B III above the connection to the sprinkler system, as shown in Figure 7. This would ensure the availability of seawater to both the bilge system and the sprinkler system. With the additional valve implemented all functions assigned to the fire main can be fulfilled to an acceptable standard.

**Figure 7. Placement of the additional valve based on vulnerability analysis**

## Firefighting after battle damage

Luckily for the crew, this comprehensive system vulnerability assessment had been completed on the design stage and the additional valve is present. The commanding officer leading the firefighting operation is well-aware of the design of the vessel and the damage control response required to ensure the performance of the firefighting systems.

The officer orders one of his crewmates to close the valve in the riser pipe located in compartment B III and open the valve connected to the sprinkler system located in the same compartment. He directs another crewmate to open the valve connected

to the bilge ejector located in A III. Two people are sent to start the diesel-powered pumps and the remaining firefighting crew are set to fight the fire within the compartment using the fire hoses. Even with fewer systems available, the crew are able to extinguish the fire successfully, keeping the ammunition store intact.

Since the ship sustained severe structural damage from the missile impact, she will require major repairs before returning to service. The important thing is that the platform was salvaged and the crew members are able to make it home safe and sound and live to sail another day.

## CONCLUSIONS

The example showed that with minimal changes to the design, the survivability of the ship could be significantly increased, whilst avoiding unnecessary penalties to other design aspects. It is worth stressing, that the example only considers one capability, a small selection of systems and a single damage case. Naturally, the complexity of the analysis increases as more vital capabilities, systems, and damage cases are included. Nonetheless, by employing the approach presented in this paper, it is possible to break up the analysis into manageable parts and evaluate ship's resilience in a logical and structured manner. The functional model serves as an excellent tool to determine how degradation of individual functions is detrimental to the required residual capability. Overlaying this information with the calculated damage extents results in an analysis that focuses on the protecting the functionality of the ship rather than individual components. This fine-tuned approach to vulnerability analysis makes it possible to deliver more resilient and better optimised designs in a cost-efficient manner.

# A comparative analysis of side and stern installation of a monopile lifting operation using a heavy lift crane vessel

A.M. Elzinga <sup>1,2,\*</sup>, J.D. Stroo <sup>2</sup>, and A.A. Kana <sup>3</sup>

## ABSTRACT

*This paper compares two 2XL monopile installation methods: at the leeward side of the heavy lift crane vessel and in the recess at the stern of the vessel. The multi-body system of the vessel, monopile, crane, and mission equipment induces interaction and resonance behaviour. Operational limits are assessed at the crane tip and pile gripper during upending and lowering of the monopile. Stern installation provides a larger operability window during upending compared to side installation. During the lowering stage, the operability depends on the monopile submergence: side and stern installation provide a comparable operability. Considering both stages, stern installation shows promising results.*

## KEY WORDS

Heavy lift vessel; monopile; installation method; allowable sea states; time-domain simulation

## INTRODUCTION

The offshore wind energy sector is rapidly growing with an increase in the capacity of offshore wind turbines (OWT). This implies an increase in size and weight of OWTs. Additionally, there is a tendency to locate offshore wind farm sites further offshore. More consistent wind speeds, and therefore better quality wind resources, and more space are available further offshore. Sites with a water depth of less than 70 metres are suitable for OWT-fixed bottom foundations. The increasing capacity and greater water depth at OWT locations result in increasing OWT, and therefore also the foundation of the OWT (Ulstein, 2019). A commonly applied fixed-bottom foundation is the monopile. 65% of the fixed-bottom foundations worldwide are monopiles (MP). In the planning phase, 88% of the fixed-bottom foundations are monopiles, due to their simplicity, ease of installation, and relatively low costs (International Energy Agency, 2019; Liu, 2021; Ramírez et al., 2020). Over the past years, the diameter of an MP, an indicator for its size and weight, increased from an average of 5 metres to 10-12 metres. Monopiles are categorised into L, XL, XXL (2XL), and XXXL (3XL) monopiles. 2XL monopiles have an average diameter of 10 metres and a weight of around 2500 tonnes (Stroo, 2023a).

Monopiles are typically installed from jack-up vessels, which provide a stable platform. However, these vessels are limited in terms of water depth, seabed conditions, and crane capacity. The ever-growing monopiles need to be installed from floating vessels, such as a heavy lift crane vessel (HLV). Heavy lift crane vessels are not dependent on the water depth, seabed conditions, or the crane capacity due to the absence of the extendable legs of a jack-up vessel. During installation, the heavy lift crane vessel forms a multi-body system with the crane and monopile, inducing coupled dynamic behaviour. Pendulum effects of the monopile might occur. The current method to install an MP from a heavy lift crane vessel is at the

leeward side of the vessel. The monopile is placed transversely on deck and upended to a vertical position at the starboard side of the vessel, after which it is lowered towards the seabed. The vessel creates a shielding effect. This method is called side installation. A new development is stern installation (Stroo, 2023b). The MP is placed longitudinally on deck and is upended in the centre line of the vessel. The lowering of the MP takes place in a recess at the stern of the vessel, creating a shielded environment. This principle can be compared to the installation concept of pipe layers.

The lowering stage of the monopile installation is considered as a critical event (Li et al., 2015; Guachamin-Acero et al., 2016; Chen et al., 2022). The multi-body system of the vessel, monopile, crane, and mission equipment induces interaction and resonance behaviour might occur. Therefore, it is important to assess the operational limits. Moreover, it is required to assess these limits during marine operations in the planning phase. The purpose of this paper is to present a comparison between side and stern installation using a heavy lift crane vessel during upending and lowering of an XXL monopile (2XL MP) in terms of operational limits.

## METHOD & TOOLS

A general evaluation method is defined to establish the operational limits of an installation method, which can be applied parallel to multiple installation methods. Two different installation methods are evaluated for the same vessel and mission equipment. The design of the hull and mission equipment, such as the crane and pile gripper, are not a part of this study. Therefore, this evaluation method focuses on the effects of different installation methods on the dynamic behaviour of the coupled HLV-MP system.

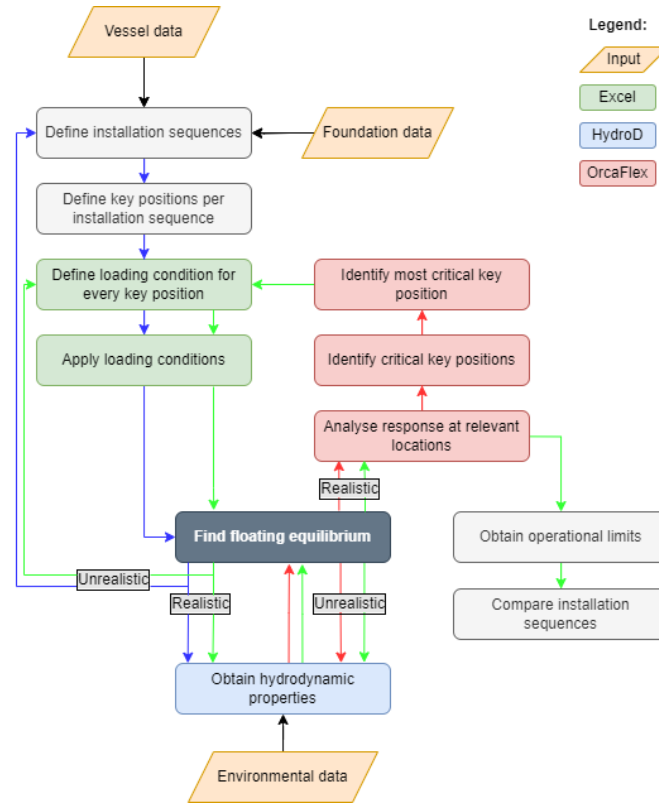

The installation sequence of the method needs to be defined, where after the key positions of the sequence are established. The loading condition of every key position is calculated and the loading conditions are applied. The floating equilibrium needs to be found for every loading conditions. If realistic, the hydrodynamic properties of the loading condition are generated. The response at the relevant positions, obtained by numerical simulations, is analysed of which then the key critical positions are identified. The most critical positions may be reviewed again in more detail. The operational limits are obtained from the response, leading to a comparison between the two monopile installation methods. The method is presented in a flowchart in Figure 1. The loading conditions are based on existing loading conditions, generated in DELFTship. The applied loading conditions are calculated in Excel, which is also used for pre- and post-processing the results. HydroD, a diffraction programme, is used to calculate the load and displacement RAOs, added mass and damping matrices. The numerical time-domain simulations are performed in OrcaFlex, a package for dynamic analysis of offshore marine systems.

## CASE STUDY

Hornsea Offshore Wind Farm on the North Sea is used as a reference project. Monopiles are installed at a water depth of 68 metres, the largest known water depth for MP installation, based on 4C Offshore data (2022). The environmental data is based on the wind and wave characteristics of the North Sea. The JONSWAP spectrum is applied as wave spectrum. For the wind speed spectrum, the NPD wind speed spectrum is applied. For side installation, the wave direction is 210° to create a shielding effect, according to the angle definition as defined in Figure 2. For stern installation, the wave direction is 180°. Wave spreading and current are excluded. Significant wave height,  $H_s$ , values of 2 and 3 metres are chosen. Figure 3 shows the seasonal mean  $H_s$ , with the upper red dot representing Hornsea Wind Farm. During spring and summer, a mean  $H_s$  of 1.5 metres is observed. During autumn and winter a mean  $H_s$  of 2.5 metres is observed.

The spectral peak period  $T_p$  is varied between 5.0 and 15.0 seconds, as presented in Table 1. This range is chosen based on wave scatter diagram, as presented in Figure 4, and the hindcast data of Hornsea Wind Farm. The shorter wave periods around 5.0 to 8.0 seconds occur more frequently on the North Sea, due to the relatively small water depth. However, the larger wave periods are included in the case study to assess the dynamic behaviour for these environmental conditions and to put the results of the shorter wave periods into perspective. Additionally, by simulating these larger wave periods on purpose, the critical conditions can be assessed.

The multi-body system consists of a vessel, monopile, crane, and pile gripper ring. The reference vessel is a heavy lift crane vessel developed by Ulstein, HX118, with a recess in the stern for both side and stern installation. The characteristics are presented in Table 2. The monopile is a 2XL monopile (Table 3). The mission equipment consists of a crane and a pile gripper ring, which is acting as a hinge. The mass moments of inertia of the crane boom and pile gripper ring are calculated using thick-walled theory of a cylinder. This complete multi-body system is visualised in Figure 5.

## MODELLING OF COUPLED HLV-MP SYSTEM

This section discusses the modelling of the case study. The loading conditions for both installation methods are covered. Additionally, the modelling of the input data in OrcaFlex is presented, together with the used simulation approach.

### Installation sequence

The upending and lowering process for side installation is schematically represented in Figure 6. Five loading conditions are set up: the monopile in horizontal position, the monopile 45° upended, a fully upended monopile, the monopile halfway the water depth (35 metres of submergence), and finally the monopile 3 metres above seabed (65 metres of submergence). The upper part of the monopile is guided by the crane. The lower end of the monopile is placed into the pile gripper, which acts as a hinge, and upending frame. The upending frame prevents the monopile from sliding through the gripper. After upending, the upending frame is removed by rotating 90°. When the monopile is fully upended, the monopile is still in the frame of the pile gripper ring. This results in a level of submergence of 5.56 metres. The pile gripper is lowered towards the water surface, the bottom support is opened and then the monopile is lowered.

The loading conditions corresponding to each stage of the installation sequence are established and are presented for side and stern installation in Table 4. The loading condition depends on the position of the monopile, and is defined for the stages depicted in Figure 6. The coding *GE-03-80%* stands for general departure empty, consumable tanks filled at 80%. *LI* implies a lifting condition with the main crane. The load is 2300 tonnes, at a certain radius from the centre of rotation of the crane in the horizontal plane. The lightship weight and deadweight are based on the loading conditions of the reference vessel HX118. The inertia terms are simplified by only taking the Steiner terms into account. The buoyancy of the partly submerged monopile is also excluded. The luffing and slewing angle are calculated based on the angle convention as depicted in Figure 2. The transverse centre of gravity (TCG) and longitudinal centre of gravity (LCG) are set to have zero list and trim by using a nonlinear solver varying the water ballast (and anti-heeling tanks). This nonlinear solver is a Generalised Reduced algorithm, which is an extension of the simplex method for linear programming (Lasdon et al., 1978). The corresponding vertical centre of gravity (VCG) and free surface moment (FSM) are calculated, based on International Maritime Organization (IMO) rules (International Maritime Organization, 2022).

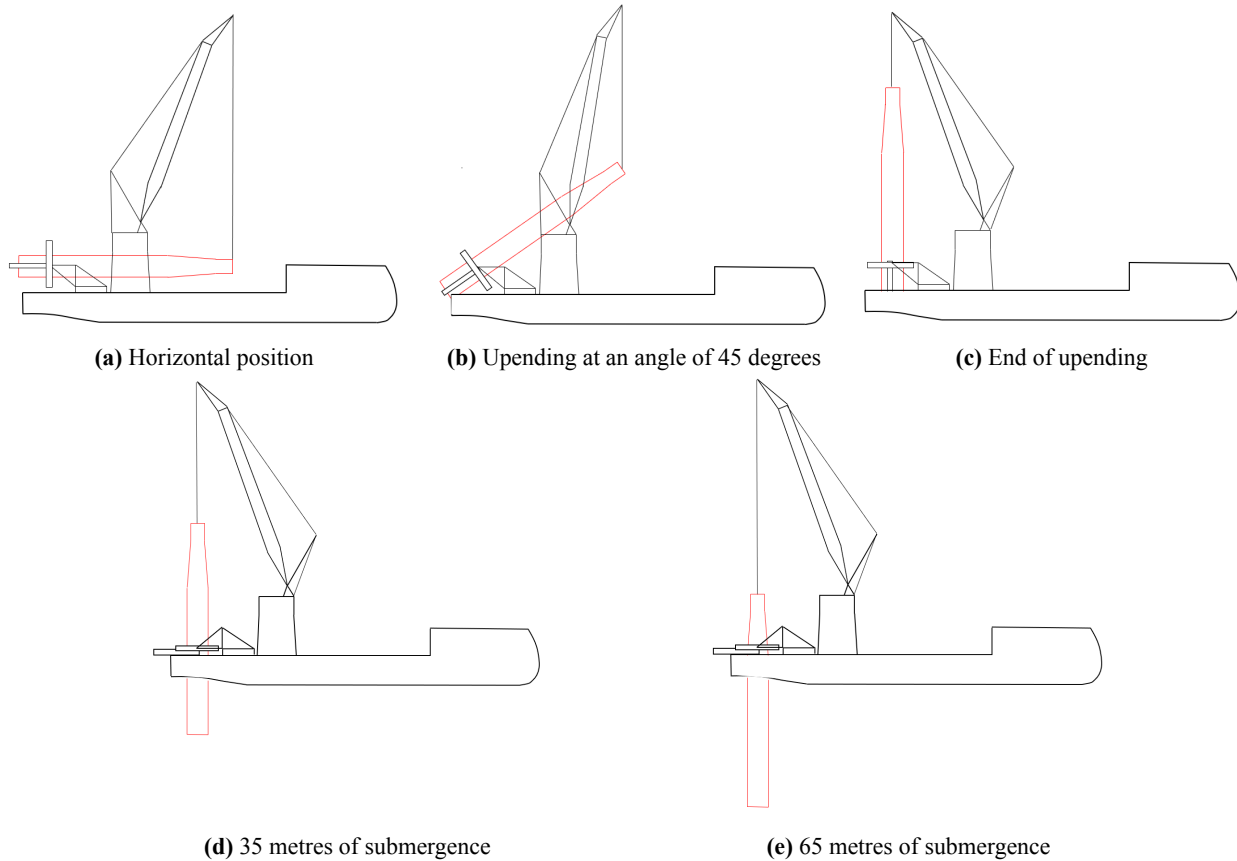

**Figure 6: Stages of upending and lowering of a monopile towards the seabed for side installation**

The installation sequence of stern installation is similar to side installation. The schematic representation of stern installation is depicted in Figure 7. The crane is at the same position as for the side installation. The pile gripper is placed at the centre line of the vessel in front of the recess. The monopile is upended in the centre line of the vessel in a similar way as pipe-laying vessels. Stern installation provides a sheltered installation position. The loading conditions for stern installation (Table 4) are established similarly to the loading conditions of side installation.

**Table 4: Loading conditions for side and stern installation**

	Position MP	Side installation	Stern installation
1	Horizontal position	GE-03-80%-LI: 2300t@63.8m, 243°	GE-03-80%-LI: 2300t@63.8m, 221°
2	45° upended	GE-03-80%-LI: 2300t@50.7m, 235°	GE-03-80%-LI: 2300t@27.9m, 247°
3	Fully upended	GE-03-80%-LI: 2300t@31.6m, 159°	GE-03-80%-LI: 2300t@47.8m, 303°

## OrcaFlex model

The installation sequences including the generated hydrodynamic properties are set up in OrcaFlex. The multi-body system is modelled identically for side and stern installation except for the location of the monopile and pile gripper ring. The properties of the vessel, mission equipment and monopile are identical as well. This section describes the important modelling choices regarding the monopile, mission equipment, wave shielding, and simulation approach. Based on this model set-up, time-domain simulations are performed.

## Monopile

Depending on the position of the MP, the MP is modelled differently to incorporate all the relevant hydrodynamic information. When the MP does not have any water contact, the monopile is modelled as a line object, as presented in Figure 8. A line is a flexible linear element in OrcaFlex which can be used for ropes, chains, but monopiles as well. The chosen line type is a general pipe with the inner and outer diameter and structural properties inserted as defined in Table 3. When the MP is (partly) submerged, the monopile is modelled as a hybrid buoy-vessel-line object. The spar buoy accounts for the viscous drag and inertia regime, while the vessel accounts for the diffraction regime. The vessel object also includes the tip vortex damping derived from model tests and CFD tests in a cooperation with Ulstein Design & Solutions, Huisman Equipment and Heerema. The vessel object is part of a multi-body group, together with the vessel itself. This multi-body group allows interaction between these two objects, such as wave shielding. Additionally, the multi-body group defines properties such as the frequency dependent added mass and damping matrices of the monopile and the vessel, and the hydrostatic stiffness are also defined in this multi-body group. The line object acts as a sleeve and models the contact with the pile grip-per ring. The vessel and line object are rigidly connected to the 6 DoF spar buoy. The hybrid modelling for the submerged monopile is shown in Figure 9.

**Figure 8: Modelling of monopile in OrcaFlex as line object for horizontal and upended monopile**

**Figure 9: Modelling of monopile in OrcaFlex as hybrid buoy-vessel-line object for partly submerged monopile**

The spar buoy creates the possibility to include the corresponding drag coefficient, added mass, slamming coefficients, and more accurately the buoyancy force. The spar buoy is discretised into multiple cylinders to better control the buoyancy force. The hydrodynamic loads on spar buoys are calculated with Morison's equation (Morison et al., 1950). The added mass and drag forces are applied on the submerged parts. When the object is partly submerged, the forces are scaled to the proportion of cylinder volume of the submerged buoy. The interaction effects on the fluid forces between the vessel and the monopile are imported from HydroD. A special multi-body group is created to take these effects into account.

The Morison equation for a fixed object in an oscillatory flow is shown in Equation 1. The first addend represents the fluid inertia force, related to the water particle acceleration, while the second addend represents the drag force, related to the water particle velocity. For a cylinder with a diameter  $D$  Equation 1 is rewritten to Equation 2.

$$F = \rho \cdot C_m \cdot V \cdot \dot{u} + \frac{1}{2} \cdot \rho \cdot C_d \cdot A \cdot u \cdot |u| \quad (1)$$

$$F = \rho \cdot C_m \cdot \frac{\pi}{4} \cdot D^2 \cdot \dot{u} + \frac{1}{2} \cdot \rho \cdot C_d \cdot D \cdot u \cdot |u| \quad (2)$$

When the object itself also moves with a velocity  $v(t)$ , the Morison equation is rewritten to an equation with three addends. (Equation 3): respectively the Froude-Krylov force, which is proportional to the fluid acceleration relative to the earth, the hydrodynamic added mass force, which is proportional to the fluid acceleration relative to the body, and lastly the drag force:

$$F = \rho \cdot V \cdot \dot{u} + \rho \cdot C_a \cdot V \cdot (\dot{u} - \dot{v}) + \frac{1}{2} \cdot \rho \cdot C_d \cdot A \cdot (u - v) |u - v| \quad (3)$$

### ***Mission equipment***

The crane consists of a slewing column and a crane boom. The slewing column rotates, however the vertical position remains identical. Therefore, the slewing column is not separately modelled in terms of mass and mass moment of inertia, but included in the vessels mass and inertia. The crane boom however changes in the x, y, and z direction which affects the mass moment of inertia and the loading condition. The crane boom and crane hook are separately modelled. The crane hook is connected to the monopile with 4 springs. The crane hook has 6 degrees of freedom to model the behaviour of the crane hook as realistic as possible.

### ***Wave shielding***

Wave shielding is a phenomenon of diffraction of the incoming waves by the presence of a hull or object. For side installation, the monopile is lowered at the leeward side of the vessel. For stern installation, the monopile is lowered in the recess of the stern. The position and behaviour of the monopile is influenced by the presence of the vessel. The wave shielding reduces the overall dynamic forces that act on the subsea asset when it is lowered due to the decrease of the displacement, velocity and acceleration of the waves (Li et al., 2014; Amer et al., 2022). It is modelled in OrcaFlex by sea state RAOs defined for vessel objects in multi-body groups. These RAOs depend on the wave direction, wave frequency, velocity potential and velocity potential gradient, and are generated in HydroD. Shorter waves are more affected by shielding, because the vessel tends to follow the motion for longer waves. The hull of the vessel and the vessel object of the monopile are modelled in a multi-body group which allows to account for the interaction between these two objects, and therefore for wave shielding.

A comparison of the monopile force is made between CFD tests and the OrcaFlex simulations. The CFD tests are performed internally at Ulstein, for a wave height of 4.65 metres, corresponding with the highest wave height for  $H_s$  of 3 metres, and a wave period of 7.0 seconds, using Airy wave theory (Stroo, 2022). The water depth is 50 metres and the monopile of 100 metres is fixed at the seabed. The wave direction is  $210^\circ$  for side installation. For stern installation, the wave direction is  $165^\circ$ . The MP force for side and stern installation is divided by the MP force without the presence of a vessel. The wave height, wave period and wave direction of the CFD tests are implemented in the OrcaFlex files to enable a comparison. The loading condition of the monopile 3 metres above seabed is used as a basis. Between the CFD and OrcaFlex are multiple modelling differences: the position of the monopile is slightly different for side and stern installation, the loading conditions are not identical, and diameter of the MP is 10 metres for the CFD tests and 11 metres for the OrcaFlex simulations. The results between the two methods are presented in Table 5.

**Table 5: Comparison between maximum horizontal force for CFD tests and OrcaFlex simulations for side and stern installation, with a wave direction of respectively 210° and 165° with a wave height of 4.65 metres and wave period of 7 seconds**

	CFD	OrcaFlex
$\frac{F_{MP_{stern}}}{F_{MP}} [\%]$	24%	31%
$\frac{F_{MP_{side}}}{F_{MP}} [\%]$	33%	35%
$\frac{F_{MP_{stern}}}{F_{MP_{side}}} [\%]$	74 %	89 %

The results for side installation for the CFD tests and OrcaFlex correspond, with a difference of 2 %. The differences in results for stern installation are larger, due to difference in modelling the recess for the CFD tests and OrcaFlex. The sea state RAOs of OrcaFlex are generated in HydroD, which cannot deal with the sides of the recess. This leads to the difference in MP forces for stern installation. A more accurate modelling of the recess in HydroD will probably provide a larger reduction in MP force and larger shielding effect for the OrcaFlex simulations.

### *Simulation approach*

The upending and lowering of a monopile is a nonstationary process. Two approaches to simulate nonstationary processes are proposed by Sandvik (2012):

1. Steady-state simulations in irregular waves of the most critical vertical positions of the object.
2. Simulations of a repeated nonstationary lowering process with different irregular wave realisations and for every simulation an analysis of the extreme response.

It was shown that the second approach, to have a repeated nonstationary lowering process, results in more realistic results compared to the steady-state simulations. The first approach creates a build-up of oscillation which is not observed in reality. However, steady-state simulations in the time domain are applied due its relatively fast, effective and simple way of modelling an installation sequence, compared to modelling a nonstationary version of the same installation sequence. By simulating different loading conditions of the installation sequence for various environmental conditions, the critical situations for different  $T_p$  and  $H_s$  can still be distinguished. For further research, setting up simulations with a nonstationary lowering process are recommended and interesting to analyse differences between the steady-state simulations and repeated nonstationary lowering processes.

The duration of the simulation is set at 1800 seconds, which is found to be a sufficient representative of a sea state reference period, which is 3 hours. Besides the actual simulation time of 1800 seconds, a build-up period of 50 seconds is applied, which provides a smooth build-up of sea conditions to avoid transients when the simulation starts.

Due to the stability, the implicit time integration method is applied with a constant time step. A time step sensitivity analysis is conducted for 0.01, 0.10, and 1.00 seconds, as presented in Figure 10a, Figure 10b, and Figure 10c. A trade-off between capturing all the relevant effects and the computational time led to a time step of 0.1 seconds. A larger time step results in less computational time, however the difference in results between 0.01 and 0.10 seconds is found to be small enough. Therefore, a time step of 0.1 seconds is found to be sufficient.

A sea state reference period takes 3 hours. For the numerical simulations a simulation time of 1800 seconds is set. In Figure 11a, Figure 11b, and Figure 11c, a comparison between a simulation time of 1800 seconds and 3 hours are displayed for the loading condition where the MP is submerged for 5.56 metres, with a  $H_s$  of 2 metres and a  $T_p$  of 12.8 seconds. The total energy of the 3 hours run seems slightly higher for the dynamic x and y than for the 1800 seconds run. In addition, for the dynamic x and y, there are some differences in the curve of the graph due to possibly more scatter of waves, which are

or are not in the simulation. For the dynamic y, the natural frequency of the MP seems more dominant, which explains the better correspondence compared to the dynamic x. In conclusion, the differences in spectral density are found to be negligible enough to continue with the 1800 seconds simulation time while also taking into account the longer computational time which is needed for 3 hours simulations.

**Figure 11: Dynamic x, y, and z at the monopile tip [m]**

## DOUBLE PENDULUM CALCULATIONS

The multi-body behaviour of the crane boom with the monopile, rigging and crane hook results in resonance behaviour when the peak period of the wave coincides with the natural periods of system. The eigenfrequencies are determined to explain behaviour observed in the results. The natural periods are analytically derived for a double pendulum. The double pendulum includes the characteristics of the falls, crane hook, and 2XL monopile, but neglects the presence of the pile grip-ring. A schematic representation is presented in Figure 12.

For the double pendulum, there are two angles of inclination,  $\theta_1$  and  $\theta_2$ . The small angle approximation is also applied for the double pendulum. The equation of motion is solved with the assumption that the solution is a sine-function. This results in Equation 4, which is an eigenvalue problem with two degrees of freedom.

$$\mathbf{K} \cdot \mathbf{x} = \lambda \mathbf{M} \cdot \mathbf{x} \quad (4)$$

The natural periods are calculated for multiple levels of MP submergence and graphically displayed in Figure 13. The two natural periods of the monopile do not coincide between 0 and 65 metres of MP submergence. The first and second natural period flip between 15 and 20 metres of submergence, because the natural period of the falls and the monopile, and therefore the rotation point, change over a different submergence levels. The difference between the natural periods increases when the monopile is more submerged.

**Figure 12: Schematic representation of the double pendulum with the characteristics of the falls, the crane hook, and the 2XL MP without the pile gripper ring**

**Figure 13: Natural periods for multiple levels of submergence of the monopile**

The double pendulum calculations include the added mass. When the monopile is more submerged, the added mass is larger. The rotation point shifts downwards, and the added mass shifts upwards over the length of the monopile (Dam, 2018). These shifts reduce the distance between these two points and therefore reduces the inertia moment. The influence of the reduced arm is larger than the increase in added mass, since the length is squared. Therefore, the mass matrix reduces, resulting in a decrease in natural period. This effect corresponds with the results of the double pendulum calculation.

### NATURAL PERIODS HLV & MP

The natural periods of the vessel and the monopile are relevant for the analysis of the operational limits. The natural periods for the vessel for heave, roll, and pitch for side and stern installation are presented in Table 6. These periods are obtained from the vessel RAOs generated in HydroD. The natural periods for the MP for sway, heave, and roll are shown in Table 7.

**Table 6: Natural periods of the vessel for side and stern installation, based on vessel RAOs depending on corresponding wave direction**

HLV	Heave	Roll	Pitch
Side installation	13 s	13 s	13 s
Stern installation	14 s	-	14 s

**Table 7: Natural periods of MP, based on MP RAOs, for fully upended MP**

MP	Sway	Heave	Roll
	6 s	6 s	6 s

## OPERATIONAL LIMITS

The operational limits are considered for the mission equipment, and are based on the following key indicators:

- Off- and sidelead at the crane tip in vessel x- and y-direction
- Dynamic amplification factor of the crane
- Dynamic utilisation factor of the crane
- Dynamic utilisation factor of the interface loads at the pile gripper ring in global x- and y-direction

The results for side and stern installation expressed in terms of these key indicators.

**Figure 14: Locations for response analysis with the position of the pile gripper ring at starboard of the vessel for side installation and at the recess for stern installation**

## Crane tip forces

The crane tip forces in x, y-, and z-direction in the global coordinate system are necessary to obtain the operational limits in terms of a off- and sidelead at the crane tip, and the dynamic amplification factor (DAF) and dynamic utilisation factor (DUF) of the crane tip. The off- and sidelead are calculated with respectively  $F_x$  and  $F_y$  of the global coordinate system. The DAF and DUF are assessed using  $F_z$  of the global coordinate system.

### Off- and sidelead

The sidelead ( $\phi_{crane}$ ) and offlead ( $\theta_{crane}$ ) at the crane tip are the maximum allowable angles when hoisting or lifting a load, and are defined based on the global coordinate system of the vessel. The maximum values of the off- and sidelead are provided by the manufacturer of the crane.

The sidelead of a crane consists of a static and dynamic part. The static sidelead is the heeling of the crane. The dynamic part of the sidelead is the dynamic angle between the vertical and the hoist tackle, resulting from swinging of the lifted load due to slewing and/ or drift-off of the vessel (Huisman, 2021).

Similarly the offlead consists of a static and dynamic part. The static offlead is the trim of the crane. It is the angle between the crane slewing axis and vertical, as a result of the static inclination of the vessel, and is in plane of the boom. The dynamic offlead is the dynamic angle between the vertical and the hoist tackle, as a result of swinging of the lifted load due to slewing and/or drift-off of the vessel, which is in plane of the boom (Huisman, 2021).

For the crane with a maximum capacity of 5000 tonnes at a radius of 36 metres in horizontal plane, used in this case study, both the off- and sidelead have a maximum angle of 3.5°, including a maximum of 1° from the crane heel or trim, as provided by the crane manufacturer. For this crane capacity condition, the off- and sidelead are equal. Therefore, the maximum off- and sidelead at the crane tip are also set to 3.5°.

From the  $F_x$  and  $F_y$  of the crane tip, the off- and sidelead are calculated to check whether the maximum limit is exceeded as presented in Equation 5 and Equation 6.

$$\phi_{crane} = \arctan\left(\frac{F_y}{(M_{MP} + M_{rigging}) \cdot g}\right) \quad (5)$$

$$\theta_{crane} = \arctan\left(\frac{F_x}{(M_{MP} + M_{rigging}) \cdot g}\right) \quad (6)$$

### ***Dynamic Amplification Factor (DAF)***

The DAF is a dimensionless ratio representing the dynamic hook load at the crane tip to its static hook force as described in Equation 7 and Equation 8.

$$DAF = \frac{\text{Dynamic hook load}}{\text{Static hook load}} \quad (7)$$

$$\text{Static hook load} = (M_{MP} + M_{rigging}) \cdot g \quad (8)$$

DAF is used for lifting operations to account for global dynamic effects (DNV, 2021b). This DAF should be determined by either specific analysis of the operation or by model testing. Depending on the location of the operation and the static hook load (SHL), the factor varies: offshore operations require higher DAFs compared to inshore or onshore, and for larger static hook loads the DAF becomes less. For this offshore marine operation with a 2XL MP, the maximum DAF is 1.15 based on the regulations of DNV (DNV, 2021b).

### ***Dynamic Utilisation Factor (DUF)***

The DUF is the dimensionless ratio between the dynamic vertical force on the crane tip and the maximum crane capacity as presented in Equation 9. This factor is introduced due to cases when the mass of the lifted load is relatively low compared to the crane capacity, but the DAF is already close to its maximum allowable limit. The DUF derived from the vertical dynamic crane tip force needs to be less than 1.00. The DUF is internally used at Ulstein and not described in literature.

$$DUF = \frac{\text{Dynamic hook load}}{\text{Crane capacity} \cdot g} \quad (9)$$

## Pile gripper interface loads

The interface loads between the monopile and the pile gripper ring are considered as well. The pile gripper ring used for heavy lift crane vessels is specialised construction equipment. Therefore, there are no explicit regulations according to a class society like DNV. A DUF for the pile gripper ring is introduced in Equation 10 and Equation 11 to assess the lateral forces on the pile gripper ring. This DUF is the dimensionless ratio between the lateral force in the global coordinate system and the working load limit (WLL) in global x- and y-direction. The WLL for the pile gripper ring is not provided by the manufacturer for this case study, but a value is chosen based on the industry experience of Ulstein for global x- and y-direction.

$$DUF_{pile\ gripper\ ring\ x} = \frac{F_x}{WLL} \quad (10)$$

$$DUF_{pile\ gripper\ ring\ y} = \frac{F_y}{WLL} \quad (11)$$

The DUF for the pile gripper is only applied when the MP is lowered. During the upending of the monopile, the pile gripper is not acting as a gripper. The mass of the MP is then divided between the crane and a steel cradle with a rubber pad on which the MP partly rests. This implies the DUF to be irrelevant for the loading conditions during the upending of the monopiles.

## RESULTS

The results are presented per key indicator and  $H_s$ . The key indicators are calculated based on crane tip forces and pile gripper contact forces, which are the Most Probable Maximum (MPM) for each  $T_p$ . The MPM is an extreme value statistic, based on the Rayleigh distribution. In Table 9, Table 8, and Table 10 an overview is presented for which loading conditions the maximum allowable limits are exceeded.

### Side installation

In Table 8 and Table 9 an overview of the operability per loading condition of the upended and lowered MP is presented for side installation for a range of  $T_p$  between 5.0 and 15.0 seconds. A checkmark implies that that specific operational limit based on the MPM of the crane tip force or pile gripper force is not exceeded for the entire range of simulated  $T_p$ . When the allowable limit is exceeded, the corresponding spectral peak period is mentioned.

In Table 8 the operability check for the upending stage is presented, solely for the crane tip, for the horizontal position of the MP and the MP 45° upended for side installation. The offlead is limiting for side installation for the horizontally placed and 45° upended 2XL MP. For the horizontally placed MP, the vessel RAOs experience a maximum around the range of 12 – 15 seconds. These maxima correspond with the maxima of the responses of the offlead. For the 45° upended MP, the sidelead is additionally exceeded at 15.0 seconds for side installation.

Based on Table 9, it is observed that the offlead,  $\theta_{crane}$ , is limiting the operability. For the fully upended MP, the limits for the offlead is only exceeded at a  $T_p$  of 7.2 and 8.3 seconds. For the MP halfway the water depth, the offlead is first limiting and afterwards the pile gripper loads in x-direction, the DAF of the crane tip and finally the sidelead for  $H_s = 3$  m. For  $T_p$  of 15.0 seconds for  $H_s$  of 3 metres, the DUF of the pile gripper in y-direction is exceeded. When the MP is 3 metres above the seabed, the allowable limits are not exceeded.

**Table 8: Operability with a maximum off- and sidelead of 3.5°, maximum crane tip DAF of 1.15, and crane tip DUF of 1 for range of  $T_p$  between 5.0 and 15.0 seconds for a horizontal placed and 45° upended 2XL MP for side installation and stern installation**

Crane tip	$H_s = 2$ m	$H_s = 3$ m	$H_s = 2$ m	$H_s = 3$ m	$H_s = 2$ m	$H_s = 3$ m	$H_s = 2$ m	$H_s = 3$ m
	Side installation		Side installation		Stern installation		Stern installation	
	Horizontal position		45° upended		Horizontal position		45° upended	
Sidelead [°]	✓	✓	At 15.0 s	At 15.0 s	✓	✓	✓	At 12.8 s
Offlead [°]	>10.6 s	>10.6 s	>11.7 s	>10.6 s	✓	✓	✓	✓
DAF [-]	✓	✓	✓	✓	✓	✓	✓	✓
DUF [-]	✓	✓	✓	✓	✓	✓	✓	✓

For the fully upended monopile, the natural periods of the double pendulum calculation of Figure 13 are approximately 16 and 19 seconds. These values do not correspond with the displacement RAOs of the vessel for heave, pitch, and roll which peak around the 13 seconds. The MP halfway the water depth experiences the largest responses for peak periods larger than 8.3 with in general a maximum response at 12.8 or 15.0 seconds. This corresponds with the natural period based on the double pendulum calculations in Figure 13, based on the level of submergence of the 2XL MP. In addition, the displacement RAOs of the vessel for heave, pitch, and roll peak around the period of 12.8 seconds. The RAOs and the natural period of the double pendulum reinforce the responses, thus the analysed forces, which eventually result in a peak in the operational limits. Lastly, it is important to consider that these long waves do not occur regularly on the North Sea based on the wave scatter diagram in Figure 4. When the monopile is almost at the seabed, the responses are below the allowable limits. The natural periods of the double pendulum of the rigging and 2XL MP are outside the range of the peak of the displacement RAOs of the vessel. The motion behaviour of the monopile is damped by the wave loads. The responses due to behaviour of the multi-body system do not exceed the operational limits.

**Table 9: Operability with a maximum off- and sidelead of 3.5°, maximum crane tip DAF of 1.15, crane tip DUF of 1 and pile gripper DUF for x- and y-direction of 1 for range of  $T_p$  between 5.0 and 15.0 seconds for a fully upended 2XL MP, a 2XL MP halfway the water depth, and 2XL MP 3 metres above seabed for side installation**

Side installation		$H_s = 2$ m	$H_s = 3$ m	$H_s = 2$ m	$H_s = 3$ m	$H_s = 2$ m	$H_s = 3$ m

## Stern installation

Table 8 also includes the operability for horizontal placed MP and the 45° upended monopile for stern installation. The offlead is not limiting the operability for stern installation for the horizontal placed MP and the MP 45° upended. The allowable limit for sidelead is exceeded at 12.8 seconds, for  $H_s$  of 3 metres, in case of the 45° upended monopile.

The operability overview of the lowering of the MP for stern installation is shown in Table 10. The allowable limits are similar to side installation. The offlead is governing the allowable limits for the lowering stage as it is first exceeded for a fully upended MP and the MP halfway the water depth. For the fully upended MP, only the maximum offlead is exceeded, and only at the spectral peak period of 7.2 seconds. A peak in the displacement and load RAOs of the MP is visible around 6 seconds (Table 7), which explains the increase in response for the smaller  $T_p$  in the range of 5.0 – 7.2 seconds. For the MP halfway the water depth, the offlead is limiting at first, after that the sidelead, and finally the DUF for the pile gripper and the DAF for the crane tip. The displacement and loads RAOs of the monopile are the largest in the range of 12 – 15

seconds, which explains the increase in response at these larger spectral peak periods. The MP 3 metres above seabed does not exceed the operational limits, similarly to the side installation. The load and displacement RAOs of the monopile are at a maximum around 21 seconds, which is outside the range of the spectral peak periods.

It is observed that similarly to the side installation sequence, the MP halfway the water depth exceeds the most limits, but only for larger  $T_p$ . This observation corresponds with the natural period of the double pendulum of 12.8 seconds in combination with the peak of RAOs of the MP and the displacement RAOs of the vessel for heave and pitch (Table 6). The vessel RAO is negligible for roll for head waves, which is the case for stern installation.

The operational limits during upending are presented in Table 8. Only the sidelead is exceeded at 12.8 seconds, which is the only case without a limiting the offlead. For stern installation, the offlead is restricted due to the position of pile gripper ring and the MP placed longitudinally in the centre line. However, a sidelead is possible, which explains the exceedence for the largest simulated  $H_s$  for the upended MP. The loading condition with the horizontally placed MP complies for every key indicator.

**Table 10: Operability with a maximum off- and sidelead of  $3.5^\circ$ , maximum crane tip DAF of 1.15, crane tip DUF of 1 and pile gripper DUF for x- and y-direction of 1 for range of  $T_p$  between 5.0 and 15.0 seconds for a fully upended 2XL MP, a 2XL MP halfway the water depth, and 2XL MP 3 metres above seabed for stern installation**

Stern installation		$H_s = 2$ m	$H_s = 3$ m	$H_s = 2$ m	$H_s = 3$ m	$H_s = 2$ m	$H_s = 3$ m

## Comparison side and stern installation

The 5 loading conditions of side and stern installation differ from the wave direction and the position of the monopile compared to the vessel. Other than that, the loading conditions are analogous and this is particularly visible during the lowering stage, for instance for the fully upended MP and the MP halfway the water depth for the offlead as shown in Figure 15. However, the responses during the upending stage show differences due to the change in position of the pile gripper ring and the monopile.

**Figure 15: Offlead [ $^\circ$ ] for  $H_s = 2$  metres for respectively side and stern installation with a maximum allowable limit of  $3.5^\circ$**

**Upending stage:** The off- and sidelead are the key indicators that are exceeding the maximum allowable limits during upending. The DAF and DUF of the crane tip are not exceeding limits for both installation methods, since the monopile also partly rests on a cradle. During upending the offlead is not exceeding the allowable offlead, however for the side installation it happens. For stern installation, the monopile is placed in the centre line of the vessel. The pile gripper constrains the

behaviour of the monopile so the offlead for stern installation is smaller during upending than for side installation. During side installation, chaotic double pendulum behaviour occurs when the monopile is in horizontal position, when the spectral peak period corresponds with natural period of the vessel.

**Lowering stage:** During the lowering stage, the offlead is governing for every loading condition. The case with the fully upended MP does not exceed the allowable limits for  $H_s = 2$  metres. In addition, the offlead is only exceeded at 7.2 and 8.3 seconds for  $H_s = 3$  metres. The RAOs of the monopile are at its maximum in the range of 5.0 – 8.0 seconds. The case with the MP halfway the water depth exceeds most limits compared to the other 2 loading conditions during lowering, starting from a  $T_p$  of 8.3 seconds for both side and stern installation. The natural frequency of the double pendulum coincides with the RAOs of the vessel and the spectral peak period, resulting in exceedence of operational limits in the range of 12 – 15 seconds. The sidelead for the MP halfway the water depth is exceeded for a smaller  $T_p$  compared to side installation. For both installation methods, the DUF of the pile gripper in x- and y-direction is exceeded. The case with the MP 3 metres above seabed does not exceed the allowable limits for both installation methods. The RAOs of the MP are outside the range of the  $T_p$  and the RAOs of the vessel. However, for stern installation, there is a maximum in response for the off- and sidelead visible at 8.3 seconds, and corresponding to that for the DUF of the pile gripper in x- and y-direction. This is still underneath the allowable limits, however, in the vessel RAOs graphs for this loading condition there is a local maximum visible.

## DISCUSSION

The results of side and stern installation show a difference in operability during upending: stern installation provides a larger operability window than side installation. The lowering phase shows a comparable operability window for both installation methods. Based on the results, for these applied allowable limits a comparison between two methods during upending and lowering can be made. Additionally, differences in responses between  $T_p$  and  $H_s$  can be observed from the results. This provides an insight into the performance of different methods and helps to gain understanding of the installation of 2XL monopiles. The operability, however, can change based on maximum allowable limits. This paper only zooms in on the operability of the mission equipment during upending and lowering. Current, directional wave spreading, and slamming are not included in the model. More accurate modelling of the recess in HydroD will provide a more realistic shielding effect for stern installation. Steady-state time-domain simulations are performed, which imply an unrealistic build-up of oscillation. For further research, it is recommended to include current, wave spreading, and slamming to have a more realistic model. Moreover, performing nonstationary simulations of both installation methods would provide a valuable and more realistic insight. Simulations of the monopile hook-up could provide further insight into the operational comparison between side and stern installation methods. Lastly, sudden loss of hook load scenarios are interesting to study in more detail. It is expected that stern installation provides advantages compared to side installation. For stern installation, the vessel will not experience any roll-back since the lifting operation is done at the centre line. For side installation, the roll-back can be severe because of the large amount of anti-heeling ballast.

## CONCLUSIONS

Concluding, the offlead is generally governing the operational limits for both side and stern installation except during the upending of the monopile with stern installation. For stern installation, during upending, the sidelead can be governing, due to the longitudinal position of the monopile. During upending, the differences in operational limits between side and stern installation are clearly visible: the offlead is limiting the operation only for side installation and not for stern installation. The operability during upending is larger for stern installation. However, during the lowering stage, both installation sequences show a similar course in the key indicators plotted against the spectral peak periods.

For the fully upended MP, the shorter spectral peak periods are critical due to the maximum in RAOs of the monopile. These periods coincide with the spectral peak periods that have a larger chance of occurring on the North Sea. However, the most critical loading condition is the MP halfway the water depth, the operational limits are most exceeded for both in-

stallation sequences, for  $T_p$  in the range of 12.0 – 15.0 seconds. The spectral peak period coincides with the natural period of the double pendulum system of the crane hook and the monopile, and in addition with the natural period of the vessel for heave, pitch, and roll. On the other hand, these operational limits are exceeded for  $T_p$  in the range of 12.0 – 15.0 seconds, which are long waves which do not occur frequently on the North Sea. When the monopile is almost at the seabed, the operational limits are not limiting the operation for both side and stern installation. The natural period of the monopile is then outside of the range of the spectral peak period and the natural period of the vessel.

Stern installation shows a larger operability window during upending compared to side installation. During the lowering stage, the operability differs per loading condition. For the fully upended monopile, stern installation has a larger operability window based on these allowable limits. The results for the monopile 3 metres above seabed are underneath the allowable limits for both side and stern installation. Considering both the upending and lowering phase of 2XL monopiles from heavy lift crane vessel, stern installation shows promising results in terms of operability.

# Design of Floating Installation Vessel for Offshore Installation of Floating Offshore Wind Turbines

Karl H. Halse<sup>1,\*</sup>, Sunghun Hong<sup>2</sup>, Behfar Ataei<sup>3</sup>, Ting Liu<sup>4</sup>, Shuai Yuan<sup>5</sup>, and Hans P. Hildre<sup>6</sup>

## ABSTRACT

*The installation of the present wind farms Hywind Scotland and Hywind Tampen are both carried out by towing the fully assembled wind turbine from the assembly site in the Norwegian fjords to the final offshore site. In the present study an alternative installation method is proposed where the fully assembled tower is transported to the site on the installation vessel and mounted onto the preinstalled floating substructure (a spar buoy). The paper presents a brief outline of the design process for the proposed concept and gives an overview of the work done to evaluate variations of the installation vessel and the proposed lifting mechanism. The paper is a summary of the results obtained by a project team in SFI MOVE addressing marine operations related to installation of floating offshore wind turbines.*

## KEY WORDS

Offshore installation; Wind turbines; Novel marine design concept; Wave-induced motion; Co-simulation.

## INTRODUCTION

Offshore Wind Turbines (OWTs) can be categorized into bottom-fixed and floating OWTs based on the type of foundation for the wind tower. Traditionally, the installation of bottom-fixed offshore wind turbines has been carried out using jack-up vessels with large cranes. As the offshore wind industry move to deeper waters, the bottom-fixed turbines gradually become less attractive and floating OWTs become the only possible alternative. The installation of floating OWTs can no longer be carried out by bottom-fixed jack-up vessels. The preferred installation method for floating OWTs has been to complete the assembly of the wind turbine in sheltered waters and tow it to the installation site. However, for offshore wind farms far from a coastline where the OWT assembly can take place, alternative installation methods are desired. As a part of the research project SFI MOVE (NTNU, 2024), a team of researchers has proposed an alternative installation process by designing an installation vessel which is capable of mounting the fully assembled wind turbine onto a floating substructure at the offshore installation site. This paper is a summary of the work carried out by the project team from SFI MOVE.

Floating OWTs needs to have sufficient buoyancy to carry the weight of the turbines and some kind of mooring system to facilitate station-keeping of the floating system. Figure 1 illustrates three typical floating OWT concepts which all have been built. The spar-shaped substructure is the one with most industrial application so far, and the work in SFI MOVE has used this concept to assess the feasibility of performing an offshore installation of a floating offshore wind turbine.

\* Corresponding Author: karl.h.halse@ntnu.no

The fundamental principle in the concept is to follow a procedure like this:

1. Tow-out of substructure – Horizontal towing of the spar-shaped substructures.
2. Upending and Mooring – Upending and mooring of the spar-shaped structures.
3. Assembly of OWT – Inshore assembly of the Offshore wind turbine (OWT) (tower, nacelle and blades).
4. Transport of OWT to site – Installation vessel to carry 3-4 fully assembled OWTs to the site.
5. Mounting of OWT – Installation vessel mounting the OWTs onto the moored substructure using a low-height lifting mechanism.

The work presented in this paper focusses on the last part of this procedure.

**Figure 1. Schematic of various floating offshore wind turbine concepts (From Jiang, (2021)).**

The paper is organized as follows: First an outline of how the design process evolved from the original idea to the development of the concept and the presentation of the final concept. The most important modelling issues and the critical response parameters are also described. Then the system modelling, and the various computer models are described. This includes how the relative motion between the two floating bodies are evaluated, how the dynamics of the lifted object influences the relative motion, and several other aspects which have been studied by the project team. The SFI MOVE project was an 8-year research project, and the various parts of the work have already been published. However, since the project lasted such a long period, and has resulted in several publications, the purpose of the present paper is to give an overall summary of the work done in the project. The new contribution from this paper is that it conveys the design strategy and concept idea in a condensed and more readable way, compared to the original and individual publications.

## DESIGN OUTLINE

### Original Idea

The underlying idea for the development of an installation vessel for floating wind turbines was to keep investment costs down. Hence, a relatively small vessel was proposed. To save time during installation, the idea of carrying more than one fully assembled wind turbine from the onshore assembly site and to the offshore was followed. Therefore, a vessel with sufficient weight-carrying capacity and sufficient stability characteristics was needed. To be able to perform the installation at the offshore site it is important to keep the relative motion between the lifted OWT and the floating substructure within some limitations. Consequently, we want to minimise the relative motions between the two floating structures, and we want to control the motion of the lifted OWT. Both improved stability characteristics and reduced vessel motions will presumably be achieved by increasing the vessel size. However, this alternative will come at an increased cost. The optimal ratio of vessel cost vs. vessel size is not investigated in this study.

The design of the proposed installation vessel was partly motivated by other recent studies by Huisman (Bereznitski, 2011) and Ulstein (Skipsrevyen, 2011), see Figure 2. In Huisman's concept a relatively small installation vessel is proposed and to ensure sufficient stability the vessel needs a large width which is achieved by using a catamaran hull. Ulstein has proposed a novel idea of carrying several wind turbines which can be installed from the same vessel. The concept proposed by SFI

MOVE builds on both these ideas and includes a catamaran hull to obtain sufficient stability with a relatively large deck area to cover 3-4 wind turbines.

**Figure 2. Huisman (a) and Ulstein (b) have both proposed concepts for installing fully assembled wind turbines onto floating substructures.**

**Figure 3. Huisman (a) and Offshoretronic (b) introduce different crane systems to handle the installation of wind turbines onto floating substructures.**

To lift the fully assembled tower from the installation vessel and onto the floating platform, some kind of lifting arrangement is needed. Again, the project found inspiration in existing solutions. Figure 3 shows two proposed alternatives from Huisman (2009) and Offshoretronic (2020). In the traditional lifting crane (like the one proposed by Huisman), the crane tip must be above the top of the tower. With the turbines gradually increasing in size, this leads to higher and higher cranes, which becomes more and more challenging from a stability perspective. In Offshoretronic's solution, the weight of the tower is carried by wires which are attached to a collar in the lower end of the tower. In this way, the lifting structure can be designed to avoid the extreme heights, thereby reducing the negative effect on the stability of the vessel. To avoid the extreme height of the lifting arrangement the proposed concept has a similar idea as the one proposed by Offshoretronic.

## Concept Development

An initial design of a floating installation vessel together with an initial design of a low-height lifting mechanism was proposed by Hatledal et al. (2017), see Figure 4. The concept included a catamaran hull as the installation vessel; with a dynamic position system for station-keeping. The low-height lifting mechanism included a gripper mechanism to reduce the relative motion between the floating installation vessel and the moored floating substructure (a spar buoy) and a hydraulically controlled lifting mechanism (see Figure 5).

Compared with traditional methods using jack-up vessels, this concept avoids the use of high and heavy offshore cranes and can transport and install the pre-assembled OWT's in an efficient manner. Consequently, the operational time has the potential of being reduced from "a few days" to "a few hours". A more comprehensive work on the same concept was carried out by Jiang et al. (2018). In this work the technical feasibility of the concept in terms of acceptable relative motions between the lifted OWT and the spar buoy was confirmed, but again rather high contact forces were found in the sliding gripper which connects the installation vessel to the spar-shaped substructure. The contact forces were too high in both the gripper mechanism and the lifting mechanism.

**Figure 4. Initial design of the offshore installation vessel (from Hatledal et al (2017)).**

**Figure 5. Illustrations of the gripper design and the lifting mechanism (From Hatledal et al (2017)).**

An improved concept was proposed to reduce the relative motion between the OWT and the Spar substructure. The lifting mechanism was updated and mounted on a motion-compensated platform which was designed to follow the wave-induced motions of the Spar buoy, see Figure 6. Following this approach, the concept evolved to an alternative where the low-height lifting gripper mechanism was replaced by a set of lifting wires in a low-height truss-frame structure and balanced by a set of stabilizing wires, as shown in Figure 7 (left).

**Figure 6. Illustrations of the modified gripper design and the motion-compensated platform.**

The relative motion is controlled by active winch control. Vågnes et al. (2020) studied the effect of including a preliminary active heave compensation (AHC) system based on a PID controller to control the relative vertical displacement between the mating points. The main conclusion to be drawn from that study was that by introducing the AHC system, the relative displacement was reduced by approximately 50% at the resonant periods. Xu et al. (2020) proposed a simple but more general 6DOF active compensation control algorithm for the system. This study confirmed the findings from the study by Vågnes et al. (2020) which was limited to control of the vertical motions only. Ren et al. (2021a) developed a control algorithm using singular perturbation theory to minimize the relative heave motions between the mating points of the OWT and the floating spar foundation.

**Figure 7. Improved concept with separate lifting and stabilising wires (left; from Vågnes et al (2020)) and the mechanical damping device between the catamaran and the SPAR (right; from Hong et al. (2022)).**

The idea of the SFI MOVE concept is that the installation vessel can carry fully assembled wind turbines to the site and that an offshore installation operation is carried out on site. A detailed procedure of the steps involved in this offshore marine operation is described in Hong et al. (2022). A short summary of the involved steps is given below.

1. **Mobilization.** Assembled offshore wind turbines (OWTs) are loaded onto the installation vessel.
2. **Transportation.** The installation vessel transports the OWTs to the operation site.
3. **DP activation.** The dynamic position (DP) system is activated for station-keeping of the installation vessel.
4. **Mechanical coupling on.** The mechanical coupling system connects the installation vessel to the spar buoy.
5. **Lifting and hovering.** One of the OWTs is lifted and hovers on top of the spar buoy. Active motion compensation is activated.
6. **Lowering and mating.** The lifted OWT is lowered and mated onto the spar.
7. **Mechanical coupling off.** The assembled OWT is now connected to the spar and the floating OWT is disconnected from the installation vessel.
8. **Next location.** The installation vessel moves to the next installation location.

**Figure 8. Side view (a) and Top view (b) of the catamaran installation vessel and the wave directions (from Hong et al. (2023b)).**

An illustration of the concept is shown in Figure 8. The concept allows the floating substructure (the spar buoy) to be preinstalled and moored at the installation site. The work presented in this study is limited to step no. 5 “Lifting and Hovering”.

The main dimensions of the installation vessel, the spar buoy and the wind turbine are given in Table 1.

**Table 1. Design parameters of the wind turbine, catamaran and spar (data from Hong et al, 2022).**

Parameter		Wind turbine	Catamaran	Spar
Rated power	[MW]	10	-	-
Hub height	[m]	119	-	
Rotor diameter	[m]	178.3	-	
Length over all	[m]	-	153	90
Width over all	[m]	-	60	14
Draft	[m]	-	8	70
Fairlead position	[m]	-	-	35
Body origin in global coordinate system	[m]	-	(63, 0, 0)	(0,0,0)
Center of Gravity (CoG)	[m]	(-0.3, 0, 84.2)	(-0.1, 0, 21.2)	(0, 0, -51.1)
Displacement	[ton]	1 302	18 309	12 642
Radius of gyration about CoG (Roll)	[m]	41.85	48.12	20.10
Radius of gyration about CoG (Pitch)	[m]	41.85	58.75	20.10
Radius of gyration about CoG (Yaw)	[m]	4.79	42.52	5.69
Roll-pitch inertia about CoG	[t m <sup>2</sup> ]	0	-76.4	0
Roll-yaw inertia about CoG	[t m <sup>2</sup> ]	-1.55 E4	-6.46 E6	0
Pitch-yaw inertia about CoG	[t m <sup>2</sup> ]	0	6.75	0

## Modelling Issues

The evaluation of the various concepts was based on modelling the complex dynamic system and a subsequent simulation of the dynamic behaviour of the system. Hence, the main part of this work has been to establish proper computer models of the various parts of the system. In the following the modelling of the main parts of the concept are discussed. Figure 9 illustrates how the main parts of the system can be isolated and modelled separately.

**Figure 9.** The system is comprised of two floating rigid bodies (ship and spar), a complex payload (wind tower) which is lifted and balanced by a set of wires all hydraulically controlled from several winches, and a mechanical connection system between the ship and the spar to reduce the relative motion between these.

In establishing reliable computer models of the total system, there are at least three main areas which needs to be addressed:

1. **Hydrodynamic modelling.** The hydrodynamic properties of two floating bodies (the ship and the spar buoy) needs to be established. To calculate the proper hydrodynamic loading for two rigid bodies floating close to each other, the hydrodynamic interaction between them needs to be accounted for. Furthermore, the sloshing mode between the two hulls of the catamaran must be included in the analyses and for the small water plane area of the spar buoy, the second order hydrodynamic loading may be important. In addition, the viscous effects of both the catamaran and the spar buoy should be accounted for in the modelling.
2. **Structural modelling.** The system may be modelled as two rigid floating bodies and one rigid lifted complex payload (the wind tower). The mechanical connections between the catamaran and the spar as well as the lifting arrangement connecting the catamaran and the wind tower need to be carefully modelled. In addition, the influence of the flexibility of the lifting mechanism should be considered. It is important to establish the eigenmodes of the complex system and thus to understand the dynamic characteristics of the system.
3. **Modelling of the control system.** There are several control systems which needs to be properly modelled. For the station-keeping of the installation vessel a dynamic positioning (DP) system needs to be modelled. During the mating phase, a proper winch control system needs to be modelled to reduce the relative motion between the spar motion and the lifted tower. Furthermore, it may be necessary to include an active control scheme to the mechanical connection between the catamaran and the spar buoy to reduce the relative motion between the two floating objects (thus reducing the relative motion of the mating points at the lifted tower and the spar).

For the modelling and analysis of complex multi-domain systems like this, several general-purpose simulation platforms exist like MATLAB/Simulink, Dymola, Algoryx, 20-Sim etc. On the other hand, there are also tailor-made time-domain simulation software to handle marine operations in the design phase. These software tools can handle hydrodynamic effects, structural dynamics, as well as hydraulic and control systems to some extent. However, none of these monolithic integrated solutions can handle high-fidelity and efficiency in a flexible way (Yuan et al. 2022).

### Co-simulation with FMI/FMU

It would be better if the whole system could be distributed to separate domain solvers, and then recollecting the various connecting parameters in a common general simulation. A practical problem with this idea is that there can be compatibility issues between the different simulator environments. To solve all of this, a co-simulation approach has been developed along with an interface standard called Functional Mock-up Interface (FMI). In an FMI-based co-simulation, the individual local domain models are compiled as Functional Mock-up Units (FMU). This approach also allows to protect the intellectual properties of individual models as the different FMUs only needs to share and exchange a limited set of parameters.

In Yuan et al. (2022) a framework to analyse the proposed installation concept using co-simulation following the FMI/FMU approach was presented, see Figure 10.

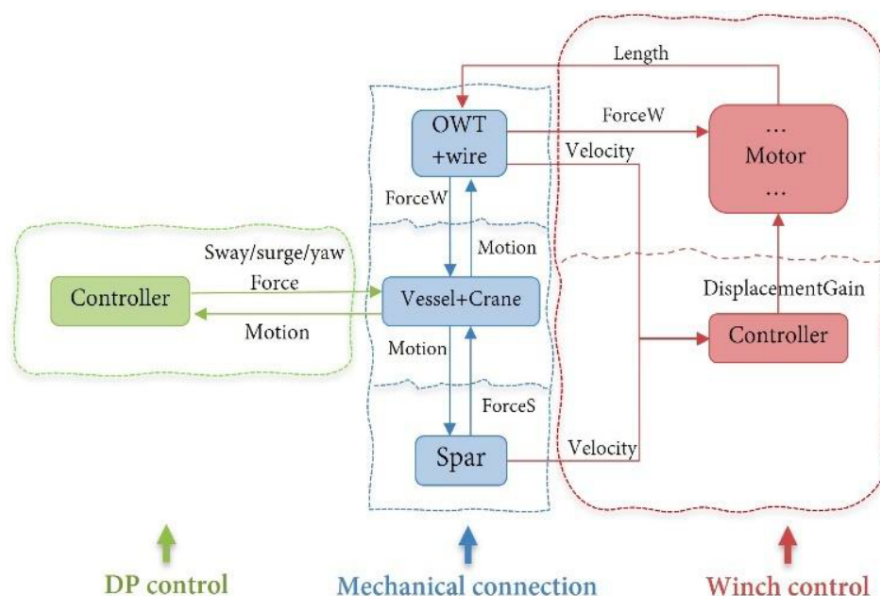

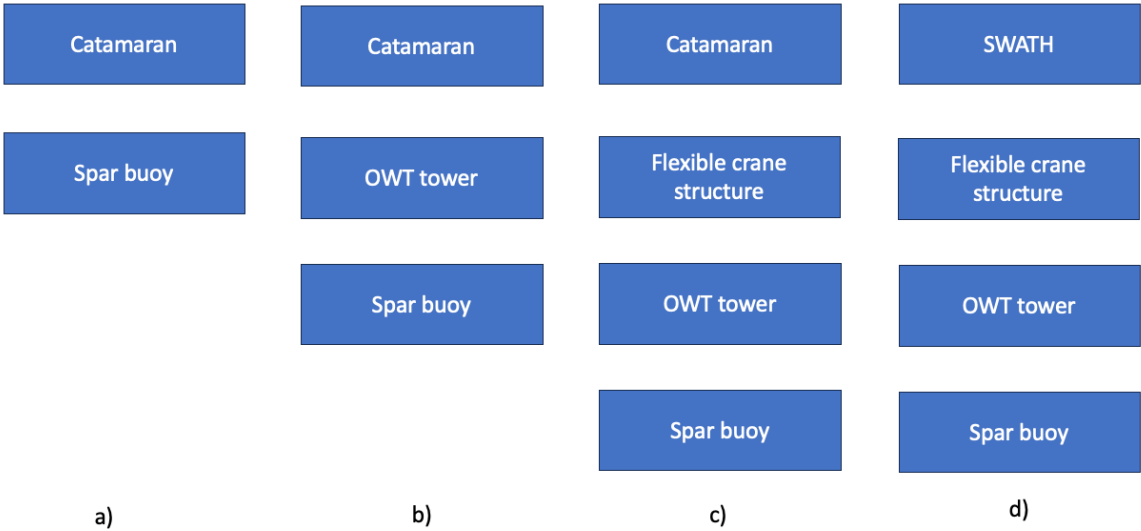

Figure 10. A framework for an FMI-based co-simulation of the installation concept (Yuan et al. 2022).

# SYSTEM MODELLING AND COMPUTER MODELS

Several studies have been conducted to evaluate the proposed concept, the methods used have some unique variations and are described in more detail in each of the studies, but the overall method is the same and is briefly described in the following. The critical response for performing a successful mating operation of the OWT onto the floating spar buoy is the relative motion between the bottom of the OWT and the top of the spar. The underlying processes for this relative motion are formed by the motion of the two floating bodies: the catamaran and the spar buoy. Hence, to get a thorough understanding of the dynamic responses of the concept, the first attempts were to study the relative motion between the stern of the catamaran (as if the lifted OWT was a rigid part of the catamaran) and the top of the spar buoy, see e.g. Hong et al. (2023b). In the next type of analysis, the OWT was a separate dynamic object hanging in a set of lifting wires, this adds complexity to the dynamic processes and the need to include a control strategy to the concept was recognised, see Ren et al. (2021b). It was also realised that with the high and slender crane structure lifting the OWT one could expect some dynamics from the crane structure. A study which compared the importance of including flexibility of the lifting crane structure was carried out by Ataei et al. (2023). And finally, as the dynamics of the lifting structure is one of the underlying dynamic processes dictating the relative motion between the OWT and the spar buoy, a study to compare the influence of using a different installation vessel was conducted. In Liu et al. (2023b) the relative motion between the OWT and the spar buoy when using a SWATH installation vessel was compared with the original catamaran installation vessel. The different scenarios are illustrated in Figure 11.

**Figure 11. The study includes analyses with various level of sophistication of the computer models.**

The proposed concept has primarily been studied by modelling and analysing the system using the features available in SIMO (MARINTEK, 2016). In Hong et al. (2023a) the modelling and analysis capabilities of SIMO were compared with the Orcaflex software (Orcina, 2024). The modelling capabilities in Orcaflex are slightly different than in SIMO but follows the same overall structure and the resulting response analyses gave no different conclusions than obtained from the SIMO analyses. SIMO is a time-domain simulation program for simulating motions and station-keeping of multibody systems. The installation vessel and the floating substructure (the spar buoy) were modelled as two rigid bodies connected by mechanical couplings. Thrusters and mooring system were added to the installation vessel and the floating substructure, respectively. The hydrodynamic properties including interaction effects were calculated using the Sesam module HydroD (DNV, 2024b). Wind coefficients have been estimated using the HAWC2 software (Larsen & Hansen, 2007). The panel models used in HydroD were established using the Sesam module Genie (DNV, 2024a).

## Relative Motion Between Installation Vessel and Floating Substructure

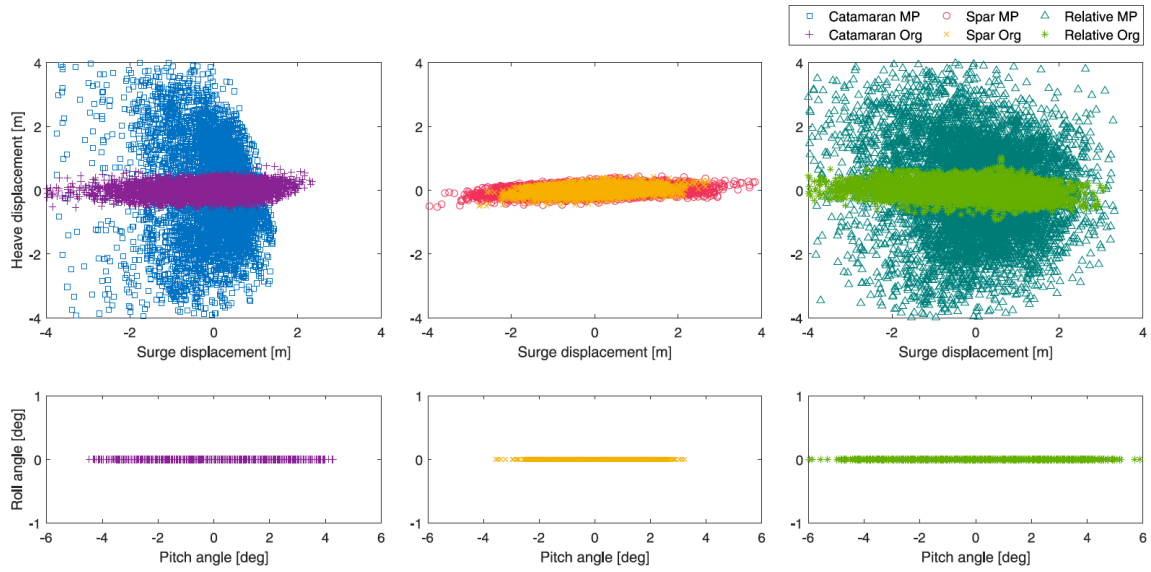

The first attempts to study the dynamic behaviour of the concept simplified the analysis model by assuming the lifted OWT to be a rigid part of the installation vessel. The idea was to study the relative motion between the two floating bodies.

**Base Case – Stern Installation.** The present work is focusing on step 5 **Lifting and hovering** defined above, and analyses were carried out (e.g. by Hong et al. 2022) to understand the dynamic behaviour of the concept and to evaluate the installation criteria to be used. The main critical response which has been studied in detail is the relative motion between the lifted OWT and the floating spar buoy. Figure 12 illustrates how the relative motion is defined and how it can be split into a horizontal displacement, a vertical displacement and an angular component. Comprehensive analyses have been carried out to study the relative motion between the bottom of the lifted OWT and the top of the floating spar buoy. As the underlying mechanisms for the relative motion are the wave-induced motion of the two floating structures (the installation vessel and the spar buoy), the initial efforts were to study the relative motion between the two mating points indicated in Figure 12 (a) between the OWT rigidly connected to the installation vessel and the spar buoy.

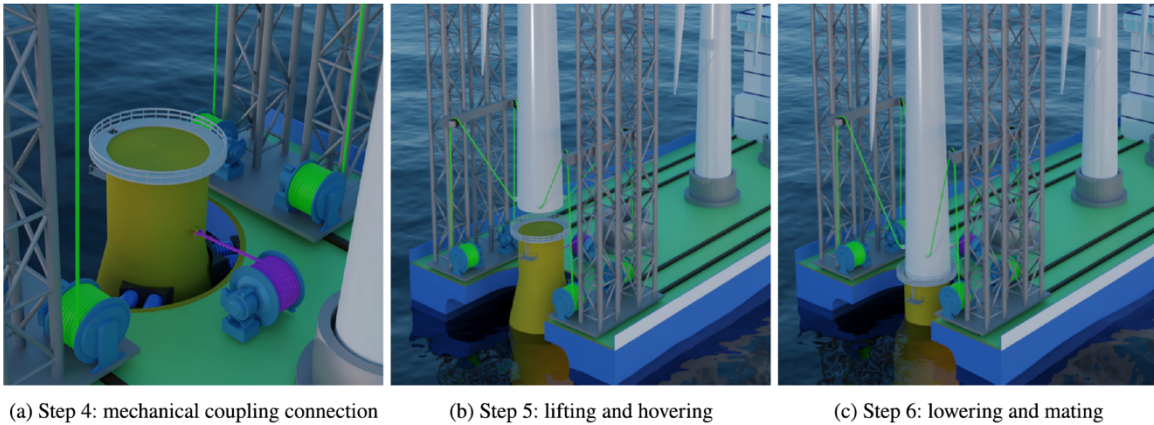

**Figure 12. The definition of the main critical response parameter; the relative motion between OWT and spar buoy (From Hong et al (2022)).**

In Figure 13 we see the footprints of a 1-hour simulation of the system. In the upper part of the figure, we see the heave and surge motion and in the lower part of the figure we see the roll and pitch motion. The wave direction is head sea. The pitch motion of both the catamaran and the spar buoy clearly dominates the response pattern. Since the mating point is located at the stern of the catamaran, the response at the mating point also has a significant pitch-induced heave component. For the relative motion at the mating point this results in quite severe motions both in the horizontal (surge) and the vertical (heave) directions.

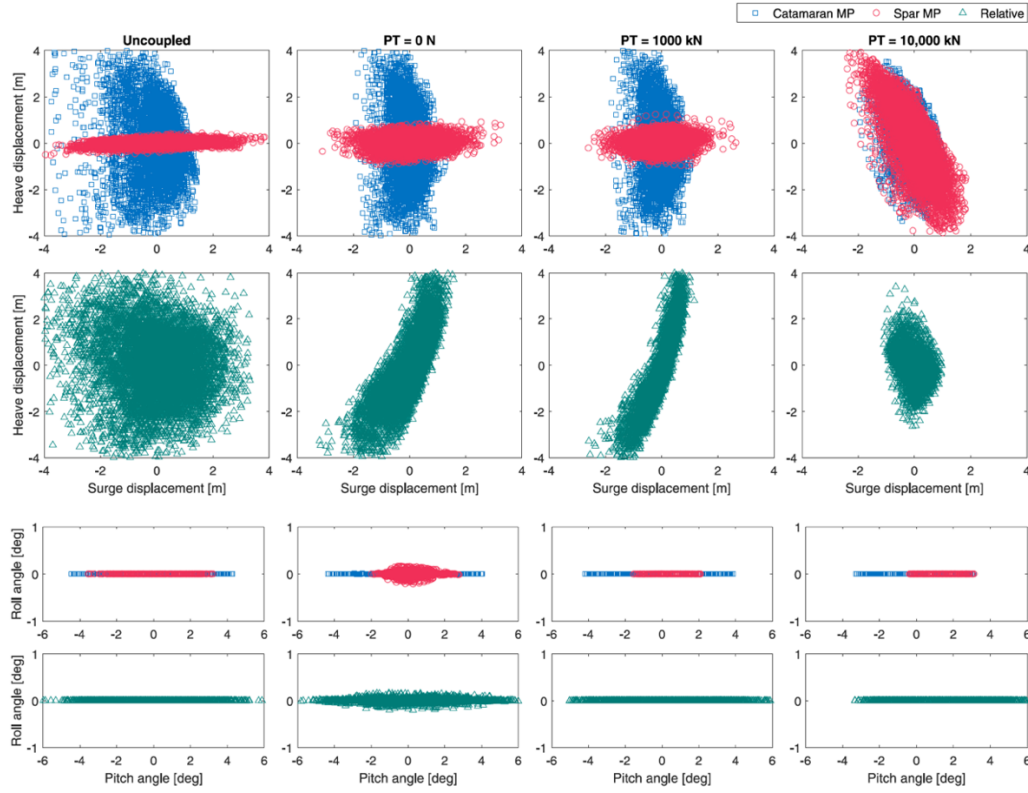

**Figure 13. Footprints of 1-h simulations for body responses at the mating points and the body origin of the catamaran and the spar as well as the relative motion between the two mating points. The results are shown without any mechanical coupling between catamaran and spar ( $\theta = 180^\circ$ ,  $H_s = 2\text{ m}$ ,  $T_p = 11\text{ s}$ ). (From Hong et al. 2022).**

The main challenge for the proposed concept was to reduce the relative motion between the lifted OWT tower and the floating substructure (the SPAR buoy). Figure 14 illustrates how the mating part of the operation can be carried out. In Figure 14 (a) we see how the mechanical coupling is defined, Figure 14 (b) shows the phase which is analysed in detail in this work and Figure 14 (c) shows how the OWT is mated on top of the floating spar buoy.

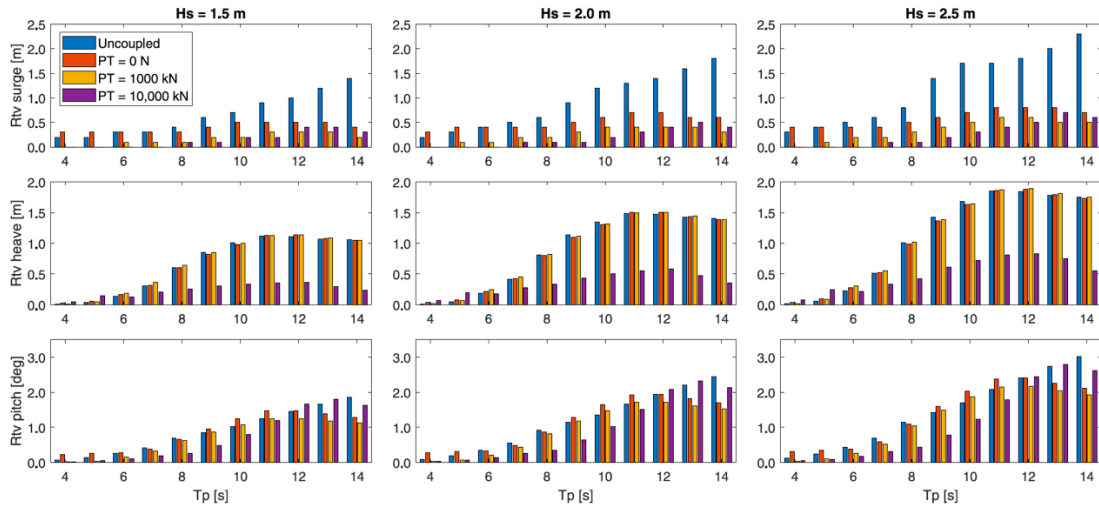

**Figure 14. Illustration of the main steps during the installation phase, (from Hong et al. (2022)).**

**Effect of Mechanical Coupling.** To reduce the relative motion at the mating point, Hong et al. (2021, 2022) introduced a mechanical coupling connection between the catamaran and the spar buoy, see Figure 14(a). The mechanical coupling system consists of fenders and pre-tensioned wires designed to create a condition where the two floating bodies remain in close contact, reducing the relative motions between the moored floating spar buoy and the DP-controlled floating installation vessel. Figure 15 provides a visual representation of the 1-hour simulation for different pretension levels in the wire system, with the blue squares and red circles representing the footprint of the catamaran and spar mating points, respectively, and the green triangles representing the footprints of the corresponding relative motion between them. Figure 16 further compares the standard deviation of the relative surge, heave and pitch motions for different pretension levels and wave conditions, highlighting the system's effectiveness in reducing relative motions.

**Figure 15. Footprints of 1-h simulations of the mating points with different mechanical coupling conditions ( $\theta = 180^\circ$ ,  $H_s = 2$  m,  $T_p = 11$  s). (From Hong et al. 2022).**

The simulation results provide clear insights into what effect the mechanical coupling has on reducing the relative motions. The introduction of the system significantly reduces relative horizontal motion, even in the absence of pretension, with a 60-83% reduction in the standard deviation of the relative surge motion depending on the wave condition and pretension. However, the pretension needs to be increased beyond a certain level to reduce the relative vertical motion. When the pretension is increased to 10,000 kN, the relative vertical motion is affected and reduced, and the standard deviation is reduced by 55-72%, depending on the wave condition. This reduction is due to the frictional force of the fender system, emphasizing the need for evaluation and development for durability and reliability. The relative pitch motion was less affected by introducing the mechanical coupling as can be seen from the bottom row of Figure 16.

**Figure 16. Comparison of standard deviation of the relative motions under varying pretension levels and wave conditions ( $\theta = 180^\circ$ ,  $H_s = 1.5 - 2.5$  m,  $T_p = 4 - 14$  s). Top row – surge; middle row – heave; bottom row – pitch, (From Hong et al. 2022).**

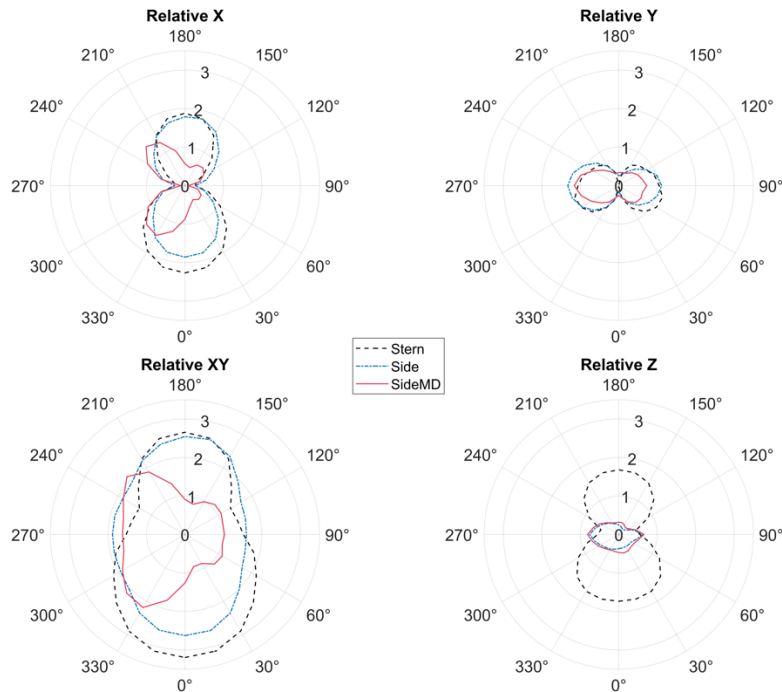

**Effect of Moving the Mating Location from Stern to Side.** The pitch motion of both the installation vessel and the spar buoy has proven to dominate the resulting relative motion between the OWT and the spar. To reduce the relative motion between the OWT and the spar buoy, this motivated a study of moving the mating location to the mid ship of the installation vessel. In Figure 17 (Hong et al., 2024) three different installation systems are shown: a) The initial stern installation, b) The side installation, c) The side installation with a mechanical damping system.

**Figure 17. An overview of the three alternative installation systems which are compared (from Hong et al. (2024)).**

In Figure 18 the relative responses (mean + st.dev.) for the three different installation systems are compared. From these results, we see that the relative vertical responses are clearly reduced when the mating location is moved from the stern to the side. However, the in-plane relative responses are not reduced simply by moving the mating location to the midship of the installation vessel. By including a mechanical damping system, the in-plane relative response is reduced significantly. Hong et al. (2024) have shown that the side installation alternative with a mechanical damping system has reduced the relative motion by 70-90% compared to the base case stern installation.

**Figure 18. Comparison of the relative response (mean + st.dev.) for the three different installation systems ( $H_s = 2.5 \text{ m}$ ,  $T_p = 10 \text{ s}$ ,  $\theta = 0 - 360^\circ$  in steps of 15 degrees)**

## Relative Motion Between Lifted Object and Floating Substructure

The lifted OWT forms a third moving body with its own dynamic characteristics. In Vågnes et al (2020) a study of the complete system including the dynamics of the lifted OWT was carried out. This was an initial analysis and not all design parameters were fixed. It was observed that the natural periods of the lifted OWT was clearly below the range of wave excitation, but it complicated the dynamic response pattern. An active heave compensation model was introduced in the analyses which reduced the relative motion significantly but to the price of increased tension in the lifting wires. The results were still promising, and it was decided to proceed with more detailed studies on the motion of the floating bodies as well as with the modelling of the lifting structure.

An active heave compensation control alternative was also studied by Ren et al. (2021a) and they confirmed the importance of reducing the relative motion between the OWT and the spar buoy by some kind of active control. In Ren et al. (2021b) an anti-swing control model of a fully assembled wind turbine lifted by several lifting wires from a floating installation vessel, was proposed. In this approach, the control scheme also manages to control the in-plane motion. The control scheme is based on the knowledge of inverse dynamics and range-based localization. It has a simple form without considering state-space equations but can effectively reduce the pendular payload motion without detailed system configuration.

**Effect of Including Flexibility in the Crane Structure.** In Ataei et al. (2023), the effect of including the flexibility of the lifting crane was studied. Compared to the case where the crane was assumed as a part of the rigid body vessel motion, the flexibility introduced increased responses and shifted the resonance frequencies considerably. In this work the truss-framed crane structure was simplified with a simple beam structure with equivalent constant cross-section properties. The principle is illustrated in Figure 19. The conclusion from this investigation was that the flexibility increased the relative response between the lifted OWT and the spar buoy. In particular, the relative alignment between the OWT tower and the floating spar buoy is increased when the flexibility of the lifting arrangement is considered. Furthermore, it is observed that the standard deviation of the forces in the lifting wires increases when the flexibility is accounted for.

**Figure 19. Modelling the flexibility of the high truss-shaped structures used to lift the OWT (Ataei et al., 2023).**

The behaviour of the truss-shaped crane structure was further studied by Gao et al. (2023). In their work the individual truss members were defined as illustrated in Figure 20. An additional observation from this work was that a particular concern should be raised about possible buckling failure of the lower truss members.

**Figure 20. Crane structure and wire systems**

### Design of Quick Connection Device – Impact Issues

To succeed with an offshore installation of fully assembled OWTs onto floating substructures, the connection between the two objects needs to be optimized. The current solution with grouted or bolted connections has inherent difficulties which needs to be improved if an offshore installation should be possible. Grouted connections are unsuitable as the grout needs substantial time to harden. Bolted connections require very low tolerances during the mating process, which can be challenging during offshore operations. Ateai et al. (2024) presents a concept where two conic cross-sections are forced into each other, and the load is carried by friction forces. Figure 21 illustrates the various phases during the mating operation.

**Figure 21. Overview of the mating operation stages.**

In Ateai et al. (2024) both global analyses to establish the relative motion between the two objects and local analyses to study the possible impacts and structural damage to the objects are performed.

### Effect of Introducing an Alternative Installation Vessel

The critical response parameter for using the proposed installation concept is to minimize the relative motion between the lifted OWT and the floating spar buoy. Since the wave-induced motion of both the installation vessel (the catamaran) and the spar buoy determines the relative motion between the OWT and the spar buoy, the idea of using an installation vessel less susceptible to wave effects than a catamaran, was attractive. The Small Waterplane Area Twin Hull (SWATH) concept was designed to bring the vessels natural periods out of the typical wave frequencies. Huisman Equipment B.V. proposed in 2011 to use a SWATH as an installation vessel for fully assembled OWTs (Bereznitski, 2011). Later this concept was reinvestigated and modified by Lee et al. (2020). However, none of these studies included the floating substructure of the OWT or the mating process in the analysis work.

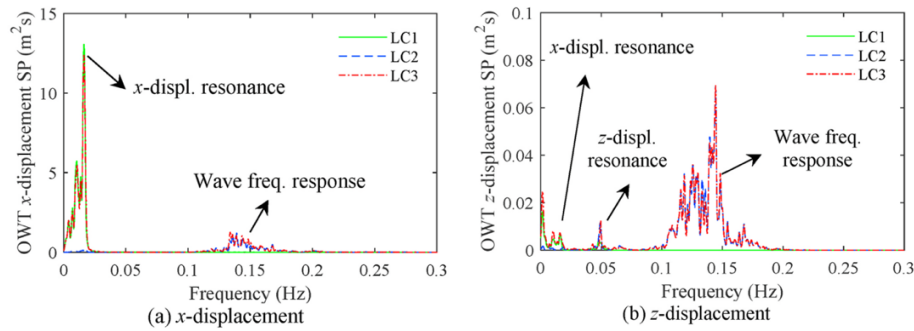

In the SFI MOVE program we have performed several studies to address the mating process. Liu et al. (2023a) studied the hydrodynamic performance of the SWATH and the response analysis of the coupled SWATH-spar system. A numerical model of a SWATH including second order difference frequency force effect and damping forces was established and compared with experimental data for a SWATH of comparable dimensions. The numerical model was modified to satisfy the criteria of weight-carrying capacity and hydrostatic stability for the proposed concept. Furthermore, a multibody numerical model for the SWATH-spar system was developed, where also the hydrodynamic interaction between the two floating bodies was included.

In Gao et al. (2023) the numerical model was developed further to include a structural model of the low-height lifting mechanism and a model of the lifted OWT. The environmental conditions were varied over a range of sea states also including wind loads in some cases, (see Table 2). The study was limited to wind and waves coming from the same direction (head seas).

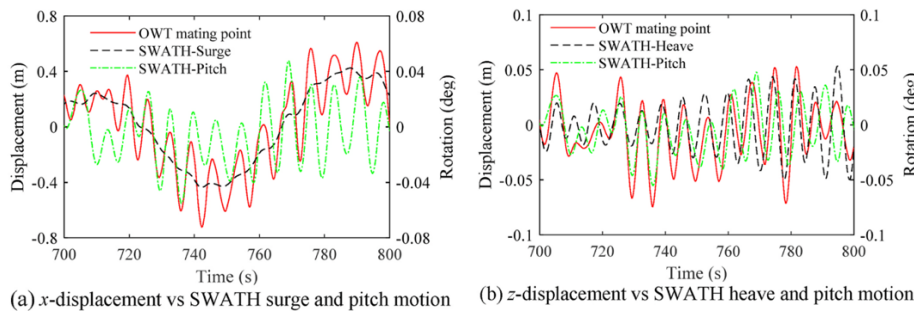

**Table 2: Loading conditions (LC) applied in the study by Gao et al. (2023).**

LC	$U_w$ (m/s)	$T_l$ (%)	$H_s$ (m)	$T_p$ (s)
LC1	7.0	24.8	-	-
LC2	-	-	1.0	7.3
LC3	7.0	24.8	1.0	7.3
LC4	5.6	28.0	0.5	6.8
LC5	8.3	22.9	1.5	7.7
LC6	7.0	24.8	1.0	[5,6,7,8,9,10]

Global dynamic response of both the OWT mating point motion, the lifting wire tension, and the strength of the lifting structure were studied. Both the wave and the wind spectra provide low frequency excitation forces to the system, and this study revealed that the wind-induced low-frequency motions of the lifted tower caused the SWATH to respond with low-frequent surge motions. In Figure 22, the displacement spectrum of the motion at the OWT tower mating point is presented, and for LC2, (without wind), the low-frequency response in x-direction is almost negligible.

**Figure 22. OWT tower mating point displacement spectrum. LC1 – wind only; LC2 – wave only; LC3 – both wind and waves included (from Gao et al., 2023).**

**Figure 23. Mating point displacement vs SWATH motion (LC3)**

Figure 23 show time series of both the mating point displacement and the SWATH motion. Here, we clearly see that the SWATH motion follows the low-frequent response of the lifted OWT tower. Although there also was a clear low-frequent response of the SWATH in surge due to waves only, this response was much smaller and did not cause a significant response of the OWT tower (see Figure 22).

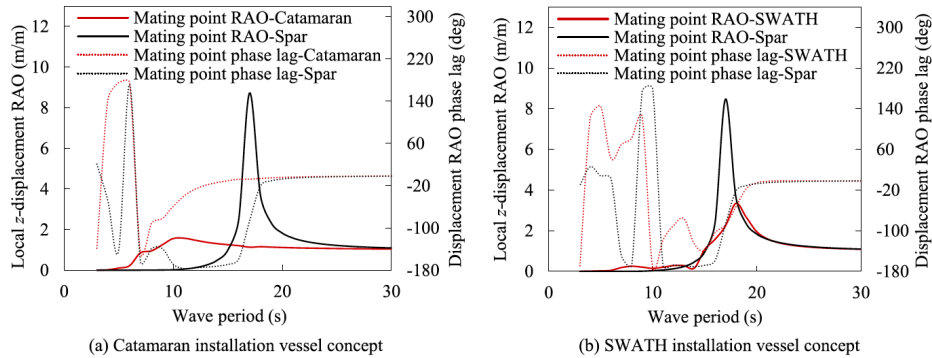

**Figure 24. Numerical model of the installation vessels and the spar buoy, (Liu et al. 2023b).**

Liu et al. (2023b) have compared the relative response of the two mating points by using the SWATH installation vessel with the relative response by using the catamaran. The numerical model of the two cases is shown in Figure 24. Figure 25 clearly illustrates the different behaviour of the two installation vessels. We see that the natural period for the SWATH in pitch is around 18 s and consequently outside the most typical wave periods.

The critical response parameter for the success of the proposed concept is the relative motion between the mating point at the spar top and the mating point at the bottom of the OWT. The motion RAOs for the vertical displacement of the mating points are shown in Figure 26.

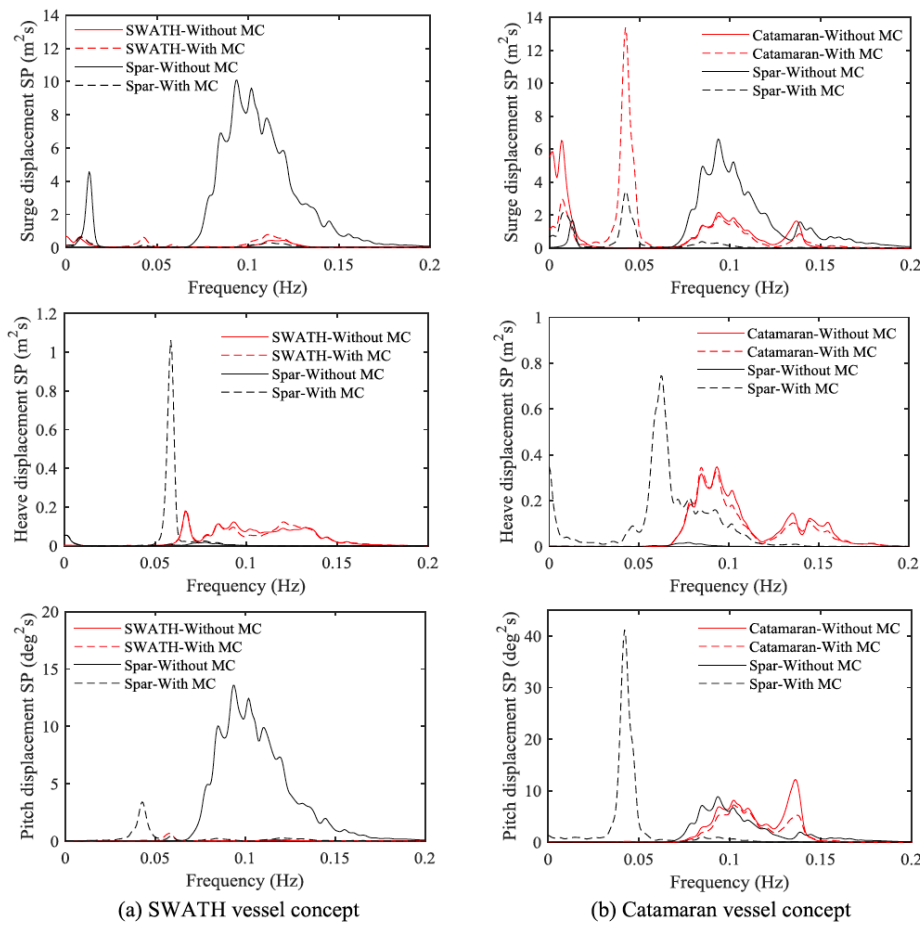

**Figure 25. Motion RAO comparison of the SWATH and the catamaran installation vessels, (Liu et al. 2023b).**

**Figure 26. Transfer functions for the vertical displacements of the mating points in the installation (Liu et al. 2023b)**

Considering a typical sea state with  $H_s = 2$  m and  $T_p = 9$  s, Liu et al. (2023b) studied the relative motion for the head sea condition. Figure 27 shows the resulting motion in terms of motion spectra for surge, heave and pitch responses both with and without a mechanical coupling between the installation vessel and the spar buoy.

**Figure 27. Motion spectra for the vessel and the spar with and without mechanical coupling (MC), head sea condition,  $H_s = 2$  m,  $T_p = 9$  s, (from Liu et al. 2023b).**

To improve the understanding of the differences of using the two different installation vessels as well as the importance of including a mechanical coupling between the installation vessel and the floating spar buoy, a series of loading conditions (LCs) were analysed in Liu et al. (2023b). The significant wave height was assumed to be constant in all cases ( $H_s = 2$  m) and the peak period was varied over five periods ( $T_p = 5$  s, 7 s, 9 s, 11 s and 13 s). The different loading conditions are numbered LC1-LC5. The standard deviations of the relative x- and z-displacement for the mating points are given in Figure 28 for both installation vessels and with/without the mechanical coupling.

**Figure 28. Standard deviation for relative response of the two mating points for both vessels (Liu et al 2023b).**

## CONCLUSIONS

A short summary of the most important findings from this study is given below.

- The proposed concept has shown to provide acceptable relative motions between the lifted OWT and the floating spar buoy, at least for wave headings mainly from bow and stern directions.
- The response pattern is dominated by the pitch motion of the installation vessel and the spar buoy.
- Because of the dominating pitch motion for the installation vessel, the position of the mating point will influence the relative vertical motion. Moving the mating point to the midship, reduces the relative vertical motion significantly.
- By introducing a mechanical coupling between the installation vessel and the spar buoy, the relative motion can be further reduced.
- By moving the mating point to the mid ship and introducing the mechanical coupling, the relative motion was reduced by 70-90% compared to the stern installation case.
- The flexibility of the lifting structure must be accounted for to provide precise dynamic response.
- The dynamics of the complex pay load can be controlled by a properly designed control algorithm.
- An alternative installation vessel less vulnerable to the wave excitation will improve the operability of the vessel.

The present base case for installation of floating wind turbines is to tow the fully assembled wind turbines from the assembly site in the Norwegian fjords to the final offshore site. The proposed concept has shown to be a promising alternative to the present base case.

# Concept Design of Typhoon Power Generation Ship Using System Simulation

Taiga Mitsuyuki<sup>1,2,\*</sup>, Haruki Ebihara<sup>3</sup> and Shunsuke Kado<sup>1</sup>

## ABSTRACT

*A concept of a typhoon power generation ship for utilizing enormous typhoon energy is proposed. This paper developed a system simulator for evaluating and designing the concept of a typhoon power generation ship using typhoon track history. A developed simulator was applied to the case study to design a typhoon power generation ship that operated near Japan. The case study showed that the annual power generation of the typhoon power generation ship tends to saturate and become constant earlier when the number of typhoons is small, in contrast to the improvement of power storage capacity. This result indicates that the appropriate size of the typhoon power generation ship exists at the current technology level.*

## KEY WORDS

Concept design; Typhoon power generation ship; System simulation.

## INTRODUCTION

In recent years, demand for renewable energy has increased in Japan to realize a sustainable society. However, the inability to sustainably generate large amounts of renewable energy has become a problem. It is necessary to stabilize the renewable energy supply by increasing and diversifying options other than solar and wind power, which are currently used as the primary renewable energy sources. On the other hand, driven by global warming, disasters caused by typhoons are dramatically increasing in intensity. Japan's national and local governments have worked out a wide range of typhoon preparedness and damage-mitigation measures, yet typhoons remain as grave a threat as ever. However, if that enormous natural energy could be harnessed as an energy resource, it could provide a renewable energy source, contributing to a carbon-neutral society.

To realize this ultimate goal, our group has proposed a future marine movable power generation, storage, and transmission system utilizing typhoon mechanisms and high-accuracy prediction of typhoons. Specifically, we will develop a sailing ship with movable power generation and storage functions that utilize the strong winds of typhoons. Sails catch crosswinds within a typhoon's navigable semicircle and follow the typhoon track. Electric power is generated and stored in the sailing ship by turning a screw propeller underwater. The stored electricity is then transmitted to land by ship. High-precision typhoon forecasting provides high-precision estimates of power generation and risk in advance. Terao (2010) proposed Wind Hunter, one embodiment example of a typhoon power generation ship. Horinouchi and Mitsuyuki (2023) quantified the dynamic effects of large sailing vessels on typhoons. This paper showed that deploying numerous large sailing vessels for hydrogen production, proposed by Ouchi and Henzie (2017), near a typhoon and following it by operating their sails could

significantly affect the intensity of the target typhoon. Specifically, in one example, assuming a large sailing ship with a sail area of 25,600 m<sup>2</sup> per ship, the intensity of a typhoon could be reduced by 10 % by deploying 200 large-size sailing ships in a 100 km square around the center of the typhoon and having them follow the target typhoon.

The concept of a typhoon power generation ship has great potential for realizing a sustainable society. However, quantitative assessments with specific operational assumptions must be carried out to make this concept a reality. For example, we should examine whether a typhoon power generation ship can conduct physical operations as assumed in a typhoon. At the same time, we should accurately estimate in advance what kind of operations the typhoon power generation ship should perform, the amount of power generation that can be expected if operations are carried out as assumed, and the appropriate size of the typhoon power generation ship. These issues belong to the problem of designing the concept of a typhoon power generation ship. This paper develops a system simulator for quantitatively evaluating the operation concept of a typhoon power generation ship using typhoon track history data. By using the developed system simulator, this paper examines the appropriate size of the typhoon power generation ship.

### PROPOSED METHOD

In this paper, a typhoon power generation ship is called a TPG ship. The operational concept, operation method, and necessary specifications of a typhoon power generation ship are collectively called the TPG ship concept model. The conceptual design and basic plan of the TPG ship are developed by defining its concept and quantitatively evaluating the defined TPG ship concept using a system simulator. Figure 1 shows the proposal to evaluate the TPG ship concept using a developed TPG ship operation simulator.

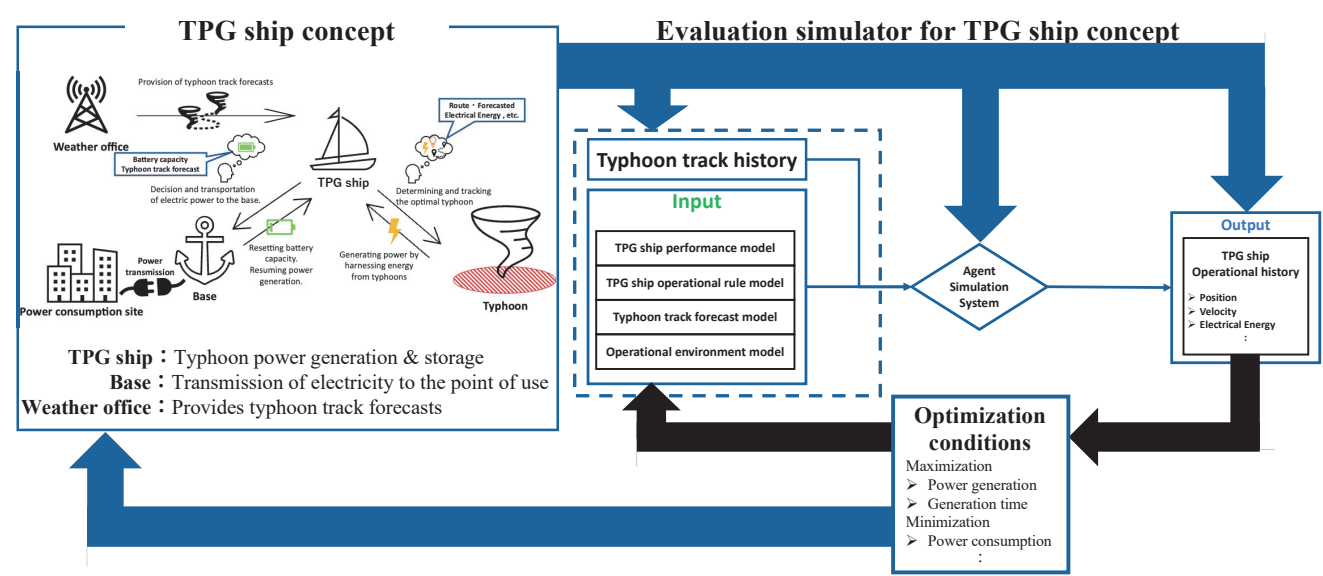

Figure 1: Overview of the proposed method

The TPG ship operation simulator must be able to reflect not only the ship body but also related technologies for power generation and storage and weather information as parameters. It also needs to be able to evaluate the impact of parameter changes on the TPG ship. An optimized TPG ship model is explored by continuously selecting and evaluating the TPG ship model based on the optimization conditions established, such as the maximization of power generation. We can quantitatively evaluate the TPG ship concept based on the required power generation targets and other issues.

## TPG ship concept model

The TPG ship concept model consists of the operational concept, operation method, and necessary specifications of a target TPG ship. Figure 2 shows the operational concept of the TPG ship. In the proposed model, TPG ships can operate stably under typhoon conditions, generating and storing electricity. When sailing under typhoons, the TPG ship is propelled only by wind propulsion. When sailing in other conditions, the TPG ship is propelled using both wind and electricity propulsion stored on board. When sailing during power generation, even if the typhoon speed is slower than the TPG ship, this ship can keep the ship service speed by zigzag maneuvering under the typhoon. TPG ships can obtain accurate real-time typhoon track forecast information from the weather office. During periods when there are no typhoons in the surrounding area, the TPG ship waits in a predefined area. A base for accumulating the energy acquired by the TPG ship shall already be in place, and the base shall transport the energy to the use site by a different method from that of the TPG ship. The TPG ship must call at its base and manage its capacity before its storage capacity is full. The modeling of the TPG ship concept focuses only on the power generation from typhoons. Therefore, the entire supply chain, including transportation to the utilization sites, is not considered. The scope of the proposed model is limited to the transportation to the base, whose place is pre-determined.

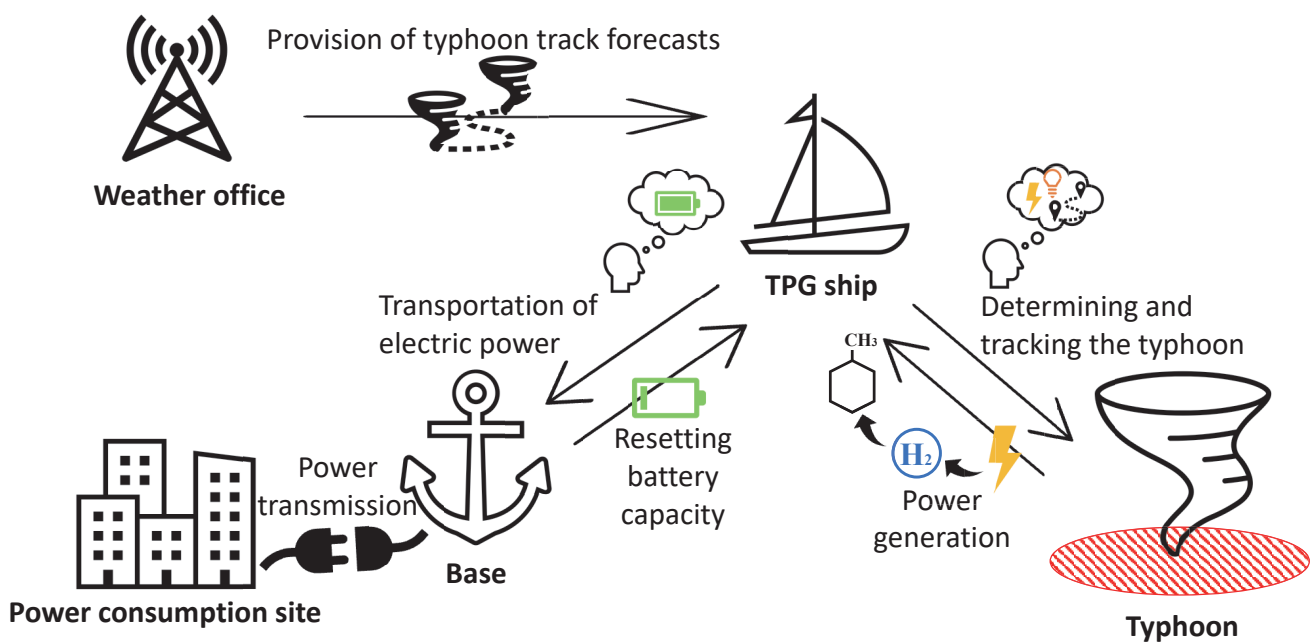

Figure 2: TPG ship operation concept

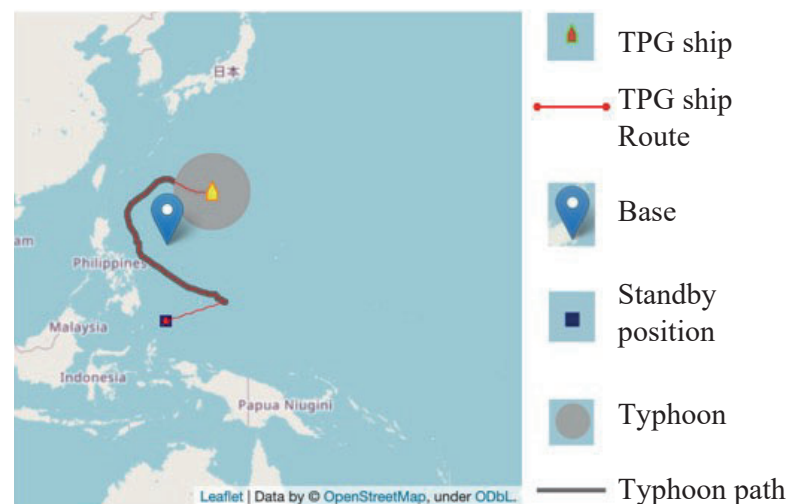

## Developed TPG ship operation simulator

This paper has developed the TPG ship operation simulator as an agent-simulation system. The inputs consist of four models: the TPG ship performance model, the TPG ship operational rule model, the typhoon forecast model, and the operation environment model. This simulator conducts the agent simulation using these inputs and typhoon track history.

The TPG ship performance model defines the specification of functions, including power generation, power storage, wind propulsion, and electricity propulsion. The power generation function generates electricity when the TPG ship is propelled under typhoons. The power storage function stores the generated electricity or hydrogen converted from the generated electricity. The wind propulsion function uses winds to propel the TPG ship. The electricity propulsion function is a function in which the TPG ship is propelled by using the electric power stored on board. The TPG ship operational rule model reflects

how the TPG ship operates, corresponding to the environment. The TPG ship operational rule model is defined as an agent rule in the developed simulator. The typhoon forecast model defines the period and accuracy of typhoon track forecast. The operation environment model defines the position of the base and standby of the TPG ship.

The output of the TPG ship operation simulator includes the position, speed, power generation amount, and power generation time of the TPG ship at each time. Figure 3 shows one of the examples of the developed interface for visualizing the output of the TPG ship operation simulator. Figure 3 depicts a typhoon ship departing from a standby position to track, capture, and generate power from a typhoon. By specifying the period to be visualized, the behavior of the TPG ship in the simulator can be understood in detail and intuitively.

**Figure 3: Interface for visualizing the result of TPG ship operation simulator**

## CASE STUDY

A primary design study of a TPG ship was conducted using the proposed method. Specifically, we performed sensitivity analysis on a simplified performance model of a TPG ship in which the specifications of the power generation function were set as fixed, and other performance functions of the TPG ship were automatically defined according to the storage capacity settings. This paper analyzed how the annual power generation of the typhoon power generation ship changes when the storage capacity setting is changed.

### Problem setting

#### *TPG Ship performance model*

The TPG ship performance model defines the specification of functions, including power generation, power storage, wind propulsion, and electricity propulsion. In this case study, the specifications for the power generation function were fixed, and the specifications for the power storage function were adopted as the parameters for sensitivity analysis. The specifications of the wind propulsion and electric propulsion functions were calculated automatically from the power storage function's specifications by adopting a simple TPG specification model.

The specifications of the power generation function were set based on the studies conducted during the conceptual phase of

this research. Specifically, the rated output of a TPG ship under a typhoon  $P_{output}$  is set to 0.138 GW, and this specification is assumed to remain fixed as long as the ship is within 100km of the typhoon's center. It is assumed that the TPG ship cannot generate power outside the typhoon area. The specification of the power storage function can be entered into the developed simulator in units of 1 GWh. This case study will employ the organic hydride method to model the power storage function. The organic hydride method is a method in which electricity is converted to hydrogen and then added to toluene, an organic compound, for storage. The efficiency of converting the energy of the hydrogen produced by this method into electricity was set to 80 % by adopting the direct MCH method (Matsuoka et al. (2018), Kobayashi et al. (2021)) and in anticipation of future technological innovation. In other words, a 0.138GW TPG ship can store 0.110 GWh of electricity as MCH for one hour of power generation. The wind and electric propulsion function specifications are defined according to the deadweight ton (DWT). This case study uses a simple TPG specification model that transforms the deadweight ton to 379 tons per one GWh of power storage capacity, considering the physical properties of toluene, MCH and a ship hull similar to a tanker. Equation (1) shows the formula for calculating the energy output required for a deadweight ton of TPG ship hull to sail at speed  $V$ , which was adopted in this case study. This case study adopts  $K = 2.2$ , considering that the hull form of a TPG ship is similar to that of a tanker. Since the TPG ship is assumed to be a catamaran, Equation (1) divides the deadweight ton by two and multiplies by two at the end to calculate the energy output for two ship hulls that each ship hull has half deadweight ton.

$$P_{hull} = K \times \left( \frac{DWT}{2} \right)^{\frac{2}{3}} \times V^3 \times 2 \quad (1)$$

The required energy output for the additional items other than the ship hull is calculated using Equation (2). For this simplified study,  $P_{add}$  is calculated as the energy output equivalent to 1 % of the rated output  $P_{output}$  at the service speed  $V_{service}$  of the TPG ship. The required energy output for wind propulsion  $P_{wind}$  for speed  $V$  is always assumed to be 10 % of  $P_{hull}$  at service speed  $V_{service}$ . The energy output required for electric propulsion  $P_e$  is calculated from these three elements, as shown in Equation (3). Note that when the TPG ship generates electricity under a typhoon, it is assumed that  $P_e = 0$ , i.e., the TPG ship can sail at assumed service speed  $V_{service}$  with wind power alone without power consumption.

$$P_{add} = 0.01 \times P_{output} \times \left( \frac{V}{V_{service}} \right)^3 \quad (2)$$

$$P_e = P_{hull} + P_{add} - P_{wind} \quad (3)$$

### ***TPG ship operational rule model***

The TPG ship operational rule model is a model that describes how a TPG ship makes decisions and acts according to the situation. The amount of power a TPG ship generates may vary depending on the operational rules for judging the situation. This case study implements the TPG ship operational rule model as an agent model. Figure 6 shows the overview of the adopted TPG ship operational rule model. We have implemented this TPG ship operational rule model to prevent the TPG ship's inefficient actions, such as tracking typhoons that the TPG ship cannot catch. In addition, we adopted a rule that the TPG ship's power generation output is frequently handed over to the base. This rule eliminates the need for massive power storage capacities and, thus, the need to adopt a huge TPG ship design proposal. As for the specific decision-making process in Figure 6, first, the system selects typhoons that can arrive and decides to call at the base when it is possible to do so via the base. Next, the destination is determined based on whether the TPG ship has stored at least 25 % of its storage capacity; if the TPG ship has arrived, it waits; otherwise, it takes action to move toward the destination. The developed simulator applies this operational rule at every time step in the simulation run.

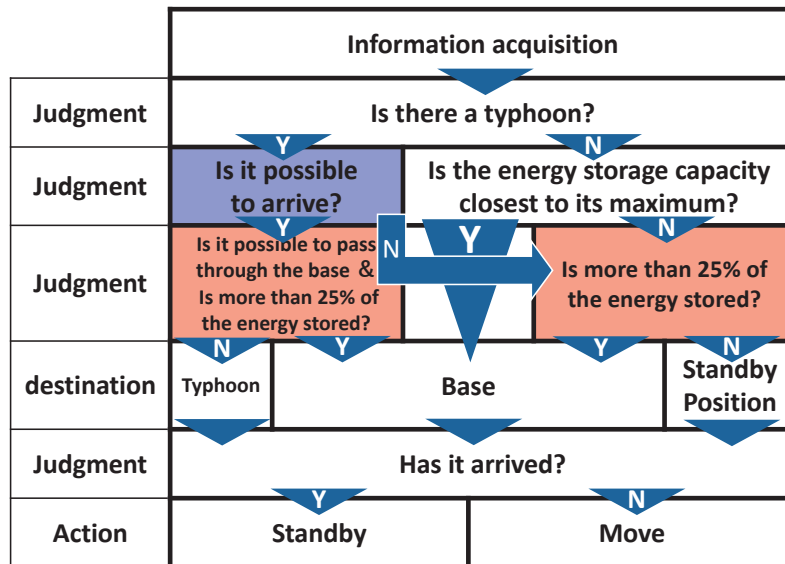

Figure 4: Overview of the TPG ship operational rule model

### *Typhoon forecast model*

The developed typhoon forecast model focused only on the track and consisted of forecast period and accuracy. In this case study, the forecast period of the target typhoon track was set to five days from the time of the forecast, and the forecast accuracy of the track was set to 100 %. Although 100 % accuracy in typhoon track forecasting is unrealistic, the accuracy of typhoon track forecasting has been dramatically improved in recent years compared to typhoon intensity forecasting, and there is no significant difference in the judgment of TPG ship operations unless a typhoon makes landfall. Since the purpose of this case study is the primary design of a TPG ship, the above settings were adopted because they are expected to generate a considerable amount of power. In addition, the TPG ship can freely generate power outside the exclusive economic zone.

### *Operation environment model*

The TPG ship is to be operated in Japan, and its base position is 24 degrees north latitude and 153 degrees east longitude, assuming MINAMITORISHIMA island. The standby position is where a TPG ship anchors at sea to capture typhoons efficiently. The TPG ship is assumed to be completely stationary in the standby position and does not generate power. Land and sea locations were roughly set up on the simulator from map data so that the TPG ship could only operate at sea locations. In addition, track information for each typhoon in the developed simulation was produced using the track history data of typhoons that passed near Japan from 2017 to 2022.

## **Results**

By using the above settings, the annual power generation was calculated by varying the power storage capacity specification of the TPG ship performance model from 5 GWh to 150 GWh in 5 GWh increments. Figure 5 shows the annual power generation of the TPG ship for each power storage capacity specification. The horizontal axis represents the power storage capacity setting in the TPG ship performance model. The vertical axis represents the annual power generation resulting from the simulation. Each line shows the simulation results for each year. This figure shows that improving the power

storage capacity in any year becomes ineffective against annual power generation above a certain level. Table 1 shows the number of typhoons has occurred and past near Japan each year. From Table 1 and Figure 5, we can see that the amount of electricity generated tends to saturate and become constant earlier when the number of typhoons is small, in contrast to the improvement in storage capacity. It can also be read that the amount of electricity generated by the TPG ship is positively correlated with the number of typhoons and that the amount of electricity generated by the TPG ship is not simply proportional to the number of typhoons. A more detailed analysis of the simulation results shows that the amount of electricity generated is correlated with the number of typhoons. The time of occurrence or landfall also significantly affects the amount of electricity the TPG ship generates. Based on these results, it can be concluded that an power storage capacity of 50 GWh to 60 GWh is appropriate for the TPG ship in this problem setting.

Figure 5: Annual power generation of TPG ship

Table 1: Number of typhoons has occurred and past near Japan each year

YEAR	NUMBER OF TYPHOONS
2017	27
2018	29
2019	29
2020	23
2021	22
2022	25

### Sensitivity analysis

A sensitivity analysis was performed to see how the annual power generation would change if the standby position were moved slightly from this problem setting. Simulations were conducted by changing the standby location using the TPG

ship performance model setting of this case study when the power storage capacity specification was set to 60 GWh. In the case study, the standby position was set to MIMAMITORISHIMA island. However, this sensitivity analysis conducted four additional simulations with the center of MIMAMITORISHIMA island shifted ten degrees in latitude or longitude (about 1000 km) to the east, west, south, or north. Figure 6 shows the simulation results for each case from 2017 to 2022. From Figure 6, we can see that the annual power generation difference between each standby position setting is at most 5 % or less under the current conditions. The above results indicate that the effect of changing the standby location is small under this problem setting and simulation assumptions used in this study.

Figure 6: Annual power generation for standby position of TPG ship

## DISCUSSION

This paper estimates the appropriate specifications of a TPG ship using a developed TPG ship operation simulator and simplified models. However, to provide a stable power supply, a TPG ship will be necessary to generate power not only from typhoons but also from ordinary ocean winds. This is because typhoons tend to occur more frequently in the summer, and typhoon power generation cannot occur during winter. On the other hand, the optimal decision on the extent to which typhoon power generation should be conducted and the extent to which power generation should be conducted using ordinary ocean winds is expected to vary depending on the specifications of a TPG ship. In this paper, simulations were conducted under the assumption that a TPG ship can operate as required, even in a typhoon environment. However, it is necessary to quantitatively estimate the extent to which operation is possible under a typhoon environment, reflect the results in the TPG ship operation simulator, and then develop the agent rule settings.

## CONCLUSIONS

This paper proposes a typhoon power generation ship concept. The TPG ship concept model consists of the operational concept, operation method, and necessary specifications of a target TPG ship. For designing a preliminary concept of typhoon power generation ship, this paper developed a system simulator for evaluating the operation concept of a typhoon power generation ship using typhoon track history. Developed simulator was applied to the case study for designing a TPG ship which is operated near Japan. The case study showed that the annual power generation of the TPG ship tends to saturate and become constant earlier when the number of typhoons is small, in contrast to the improvement of power storage capacity. It can also be read that the amount of electricity generated by the TPG ship is positively correlated with the number of typhoons and that the amount of electricity generated by the TPG ship is not simply proportional to the number of typhoons. A more detailed analysis of the simulation results shows that the amount of electricity generated is correlated with the number of typhoons. The time of occurrence or landfall also significantly affects the amount of electricity the TPG ship generates. Based on these results, it can be concluded that a power storage capacity of 50 GWh to 60 GWh is appropriate for the TPG ship in this problem setting. This result indicates that appropriate size of TPG ship has existed in the current technology level. However, to provide a stable power supply, a TPG ship will be necessary to generate power not only from typhoons but also from ordinary ocean winds. In addition, it is necessary to quantitatively estimate the extent to which operation is possible under a typhoon environment, reflect the results in the TPG ship operation simulator, and then develop the agent rule settings.

# Conceptual design of shore station for an innovative waste collecting vessel

Niklas K.<sup>1,\*</sup>, Pruszek H.<sup>2</sup>, Reichel M.<sup>3</sup>, Jaworska J.<sup>4</sup>, Marcinkiewicz E.<sup>5</sup>

## ABSTRACT

*Marine environment protection legislation in the EU requires ships to return waste they generate on voyages to waste-reception facilities in ports. In many harbors there is a need to expand the port infrastructure to enable the operation of Waste Collecting Vessels (WCVs). In addition, these vessels can perform new functions of cleaning port basins and adjacent waterways. A novelty in the presented research on the conceptual design of the shore station is the inclusion of new requirements for an autonomy and modularization of the vessel. The shore station was designed in the form of a floating pontoon, taking into account the various functional requirements addressed in the ship's conceptual design stage. The pontoon consists of modules corresponding to the ship segments moored in them. The conceptual design was intentionally defined in a generalized form to allow for further development and adaptation to local requirements at individual ports.*

## NOMENCLATURE

MARPOL - International Convention for the Prevention of Pollution from Ships

PRF - Port Reception Facilities

WCV – Waste Collecting Vessel

## INTRODUCTION

At the international level, marine environment protection is addressed by the MARPOL Convention, which has been consistently extended to new areas including oil pollution (Annex I), sewage (Annex IV) and garbage (Annex V), air pollution (Annex VI). The most demanding environmental protection rules apply in so-called "special areas" which include the North Sea, the Baltic Sea, the Mediterranean, the Black Sea, the Red Sea and other basins that include a globally significant number of seaports. In European Union countries, the law is implemented on the basis of the relevant directives into national regulations. Recently, a directive was introduced on port reception facilities for the delivery of waste from ships (The European Parliament & Council of the European Union, 2019). The directive is a part of the circular economy policy (European

Commission, 2018) and the plastics strategy (European Commission, 2020) of the European Commission. Under the requirements, ports are required to collect sewage and garbage from ships using land-based Port Reception Facilities (PRF). In practice, these are the most often adapted sections of existing port infrastructure. Garbage collection is particularly problematic, due to the fact that waste is segregated differently in various countries, and the way it is disposed of has not been standardized internationally. Thus, a ship returning garbage at each port can expect different formal rules and different collection methods, as well as different fees.

Port waters are at particular risk of pollution due to their high exposure to the negative effects of various human activities. It is port basins that often have the highest density of ship traffic in relation to water volume. It should be noted that these areas are often characterized by very limited exchange with the waters of the seas and further with the world ocean. Pollution is concentrated in port basins and is a growing challenge that should be addressed for environmental protection. It is worth noting that ships themselves and their traffic may account for only a fraction of a percentage of the various sources of pollution in many ports. In addition to ship traffic, port basins are exposed to impacts from various industrial companies, such as chemicals, heavy industry, ship repair yards, and cargo reloading companies. Particularly the latter in some locations pose a problem of heavy dusting of loose coal cargo, which, blown by the wind, partly ends up in the water and partly in nearby land areas. In many locations, harbor waters also experience pollution from various types of garbage, which, unlike that on land, is much more difficult and costly to remove, mainly because of the difficulties involved in finding, identifying, collecting, separating, transporting and disposing. Water pollution has been identified in many places as the most important environmental problem according to port authorities (Roberts et al., 2023). The survey was conducted among port authorities in 26 countries and city authorities in 13 countries. Air pollution and waste were identified as equally important aspects of environmental protection, where significant improvement measures are planned in the coming years. Currently, about half of the ports surveyed have facilities for re-use and recycling. This creates a lot of room for change with the growing awareness and ability to incorporate ports into circular economy (Roberts et al., 2021). For example, organic waste from ships can be used to produce feed for aquaculture (Strazza, Magrassi, Gallo, & Del Borghi, 2015). With the rapid development of many port cities and their revitalization, there is a need to address the challenge of cleaning port basins through special vessels, which are called Waste Collecting Vessels (WCV). It should be noted that they can have a variety of functionalities and range from picking up trash from commercial vessels, collecting trash from the water surface, to neutralizing small oil spills. The inadequate port infrastructure also poses a significant practical challenge to the operation of such vessels. In most port basins, the need for a systemic solution to the water treatment problem has not yet been addressed. Most port basins do not have a specially designed section dedicated to WCV and other environmental vessels. Garbage collection in ports is generally carried out in adapted portions of wharves, which have significant functional limitations. These are generally makeshift solutions that have been organized by local port authorities to comply with increasingly demanding environmental regulations. It should also be noted that a problem in vast port basins is also the presence of multiple stakeholders who use a common basin but are involved to varying degrees in its proper maintenance. Meanwhile, thinking ahead, in most port basins, since they are owned by a public entity, a systemic solution can be applied in the form of special municipal water services co-financed by all stakeholders. The next chapter presents the design assumptions for the selected conceptual design of a WCV-type vessel. This is followed by a description of the conceptual design of the shore station serving this new type of vessel. The conceptual design was made in the form of a universal modular concept adaptable to a variety of ports.

## **FUNTIONAL DESIGN ASSUMPTIONS OF THE WASTE COLLECTING VESSEL**

The main functional design principles for the next-generation WCV vessel will be presented here. This is a conceptual design for a vessel with autonomous operation capability being developed through a consortium of an ongoing research and development project titled 'Zero Emission Waste Collecting Vessel to Use in Ports and Close-to-Shore Areas' carried out by a Polish-Taiwanese consortium. This description is intended to present a broader context on the various functionalities of the innovative vessel and the resulting requirements for the shore station. Various vessels of this type are currently being developed by design firms as conceptual designs in response to new demand from the niche sector of debris removal from port areas. It should also be added that the vessels currently operating in various ports are mainly the simplest solutions adapted from existing other vessels. A good example would be a towed transport barge with a container on board for collecting or picking up garbage by hand. Admittedly, this can be a quick and cheap temporary solution that works well in some places. At the same time, the large scale of needs and increasing environmental requirements are prompting the design of a dedicated special vessel that can safely and economically realize new functions. Functionally, a WCV vessel is envisioned for both collecting garbage from the water and areas near ports. In some cases, the functionality to pick up garbage directly from ships from the harbor roadstead is also required. An important task of this vessel is also to clean the harbor waters of trash, seaweed and minor oil spills. It is worth noting that statistically, as much as 80% of oil spills occur in ports and involve the normal operation of ships and port operations (Miola, Paccagnan, Massarutto, Perujo, & Turvani, 2009). These are unitary relatively small spills. However, their

negative effects accumulate over time in small volumes of port water. In summary, the following main functions were selected for the designed universal WCV vessel:

- collecting and removal of garbage floating on the surface of port waters,
- picking up of garbage containers from ships and yachts at anchorage,
- removal of minor oil spills from port waters,
- collecting seaweed from the water surface.

Since the required functionality may be different in different ports, the ship project was developed in the form of modules, which are connected according to the needs and tasks performed. The following modules of the WCV ship were defined:

- Module 1 (bow) occurs in different variants depending on the intended functions of collecting small oil spills. In Figure 1 the option of oil skimmer is shown.
- Module 2 (middle) which is the propulsion module of the vessel to which modules 1 and/or 3 are attached as required. The propulsion has been considered in two variants: the azimuth thrusters, or special water jets. This module also has consoles for optional manual control and suitable working conditions for a one-man crew. This module is equipped with tools for collecting trash from the water, a transport belt and containers for collecting waste.
- Module 3 (aft) provides additional transport volume for collected garbage. Optionally, this module can also have a transport belt.

Thanks to the hull's modularization, the ship can operate as a full three-module set or as a set consisting only of two modules, or as just the middle module as an independent unit. Modularization of the unit will ensure that it is multifunctional, allowing it to be used to its fullest potential, with the ability to select multiple modes of operation as needed. The vessel will be able to perform tasks in three operation modes: as a fully autonomous unit with pre-programmed operation mode, as a remotely controlled vessel and as a manned vessel controlled from aboard. In the last case, control will take place from a control panel located in the superstructure of the middle module. The use of Artificial Intelligence (AI) can also be considered in the autonomization of a ship of this type. In particular, to increase the operational energy efficiency and effectivities learned by the algorithms based on site-specific data. The conceptual design of a WCV-type vessel is analogous to that of other ship types and includes the design of the hull, propulsion and other equipment. At the same time, relatively more attention needs to be paid to maneuverability due to the functions performed and the often-tight area of operation. The initial design process shall include the selection of hull type between i.e. monohull and catamaran. The main dimensions are mainly driven by the desired functionalities. A key component of the project is the propulsion. Also in terms of its damage safety and operability in shallow waters. Overall, due to the multifunctionality and the required small hull size, the design process of a WCV-type vessel may be quite complex and demanding. A description of the innovative design approach for the new type of small special vessels like the WCV's is planned as the subject of a separate article. A visualization of the selected conceptual design of the WCV vessel in a catamaran version with an overall hull length of LOA=14 m is shown in Fig.1.

**Figure 1: Conceptual design of the modular Waste Collecting Vessel**

## CONCEPT DESIGN OF THE SHORE STATION

The implementation of legislation on port reception facilities for the delivery of waste from ships assume fulfilling the following general requirements (The European Parliament & Council of the European Union, 2019). The main indication is that the port infrastructure shall be adequate to receive the types and quantities of waste from ships normally using that port. This needs to be done avoiding delays and without charging excessive fees. Also, ship waste needs to be managed in an environmentally appropriate way in accordance with the directive (European Parliament, 2008) and other EU legislation on waste. However, as the study shows, the current waste management at the vast majority of ports is insufficient (Özkaynak & İçemer, 2024). In large part, this may be due to the lack of proper port infrastructure, which was built when current environmental requirements did not apply. Effective logistics and management without a systemic solution of utilities is practically unfeasible. Thus, here the authors propose the modern idea of a shore station for Waste Collecting Vessels. The following functional assumptions are defined for the port quay:

- a) The possibility of mooring a WCV-type vessel, which can operate in different modular configurations: as a single module designated as "2", as module "2" with attached modules "1" and "3". At the same time, module "1" comes in three variants depending on the function performed. In addition, the modularity of the ship and its multifunctionality is tailored to the individual needs of the specific area on which it is to operate and the selection of functionality with which it is to be equipped. No less, there is always at least module "2", which is also the propulsion module of the vessel. All modules should allow mooring in a position suitable for the connection and/or departure of the vessel. That is, bow modules marked "1" should be moored bow to quay, and stern modules marked "3" should be moored stern to quay. Module "2" should be moored with the stern to the quay, due to the easier transfer of containers with collected garbage to land. This positioning of module "2" influences the preferential location of the connection connectors for charging the electric drive batteries on the stern side of module "2". It is possible to use a different configuration of charging connections if there are other reasons for this. The functional diagram of the mooring of the modules of the WCV ship is shown in Fig.2. The arrows in the diagram indicate the direction in which the modules will sail when connected to each other.

**Figure 2: Functional diagram of the mooring of WCV ship modules to the shore**

- b) Mooring capability with different levels of autonomy of the WCV vessel. This functionality creates the need for an automatic mooring system. For a small vessel, it is possible to develop an automatic mooring system using suction pads and hydraulic actuator systems. Such solutions have already been developed commercially for larger vessels and their adaptation is relatively easy.
- c) Capability of automated charging of electric propulsion batteries.
- d) Ability to return collected waste to land. Each module is designed to collect waste of a different type. The quay at the docking point of module "1" should allow for the return of oil pollutants to land. This is usually done by pumping out the oily water to a vehicle (tanker) receiving the waste ashore. For this function, it is possible to automate the pump-out process (connecting, pumping, disconnecting). The second module is designed to drive the vessel and collect garbage and plants from the water surface has containers in the rear for collecting them on board the vessel. Again, it is possible to automate the replacement of containers. Replacement of the containers with empty ones, their cleaning is carried out by the city's municipal services. The third module is designed, like module "2", to store garbage and seaweed collected from the water. In addition, this module can receive garbage from ships, and this can be done similarly to module "2" using standardized site-specific containers. In all of the above cases, access to the quay and moored modules should be made available to vehicles dedicated to collecting each of the listed types of waste. Usually there will be special municipal vehicles – i.e. garbage trucks, cisterns, trucks with transport containers.

- e) Ability to moor in defined weather conditions. Safety associated with mooring also in difficult weather conditions (e.g., strong wind, ice).
- f) Ability to moor in tidal areas without restrictions (in practice, it is 15 m). For this purpose, the charging station was designed in the form of a floating modular pontoon. The movement of the station in relation to the quay can be carried out using guides attached to the quay, or by means of piles driven into the bottom of the basin. Depending on the expected loads from sea waves, the tidal guides and piles can have an additional function of stabilizing whole pontoon.
- g) Safety capability. Selective access, the ability to access the modules for inspection.
- h) Ability to disconnect modules and access each module for the purpose of performing maintenance work, and major repair work if needed.

Different variants of possible technical solutions have been analyzed in terms of the design assumptions set above. There are no dedicated design regulations for this type of facility. Therefore, design can take place based on i.e. the individual evaluation of the selected classification society. Design requirements for this type of object strongly depend on the choice of material to be used. For the design of a barge made of steel, the regulatory requirements for standard barges can be used directly. On the other hand, if one would like to use different material, the specific requirements must be agreed with the regulatory body. It should be noted that due to local regulations, in some countries it may be advantageous to classify the docking station as a hydro-engineering structure, and in others as a floating barge. This requires recognition in the country of intended use and is important because of differences in the costs of maintenance. The main design criteria concern structural strength and stability. When it comes to structural strength, the dominant load is dead weight and water hydrostatic pressure. In addition, there is a need to take into account the hydrodynamic pressure from wave action caused by passing ships. Particularly vulnerable elements at that time are the connections between modules and the junction area between the barge and the quay. Consideration needs to be given to both the loads from short waves hitting the side surfaces of the docking station and long waves that can induce additional bending moments on the entire hull of the barge. When designing a new type of docking station, stability requirements shall also be taken into account. This is not obvious, after all, the station is ultimately connected by movement to the guides or piles of the quay. At the same time, the transport of modules separately or combined to the site of use may include towing. The docking station does not have its own drive, which greatly simplifies the design process. On the other hand, the docking station is equipped with electric charging stations which introduces additional requirements specific to electric devices. However, from a practical point of view, the main determinant of the project concept presented below was economic criteria while allowing the design to be used in various ports around the world. Implementation in existing ports precisely for economic reasons is possible almost exclusively through the adaptation of existing port berths. A major challenge in most locations is ensuring the safety of the ship's mooring due to possible high wave loads, i.e. from passing vessels. Therefore, the individual modules of the WCV unit are docked in such a way that they do not protrude beyond the outline of the pontoon. A key aspect that improves the economics and flexibility of the proposed solution is the modularity of the shore station to match the modularity of the WCV. Each module reflects functional requirements of a particular vessel module. This means that the shore station will consist of such modules for which the need for mooring in a particular port is foreseen. Due to the optional different levels of autonomy of the WCV, all modules are suitable for both traditional human-operated mooring and different levels of autonomy. The design assumes applying universal connectors that allow different configurations of shore station modules. A visualization of the shore station conceptual design is shown in Figure 3. The stern and bow modules are to be moored in a way that enables their automatic connection with the middle propulsion module without the need to move or rotate and without human intervention. This means that the stern module will be moored aft, while the bow modules will have the bow facing the quay. Automatic mooring of all modules can be carried out using a dedicated pneumatic mooring system. After mooring, the module needs to be additionally secured by an automatically released mechanical holder. The reason for this is the need to reduce energy consumption during downtime. The charging of the middle module can be realized by dedicated automatic connector from the shore. At this stage of conceptual design technical details both for the pneumatic mooring system and the automatic charging connector were not analyzed. However, a review of the literature indicates that products with the required features could be available on the market very soon, if only they are desired. However, the implementation of the presented project to the technical design phase requires adequate research work for the components and the entire system. This may be the subject of further research work.

**Figure 3: Conceptual design of the shore station for WCV vessel**

## SUMMARY

Progressive environmental regulations, especially in the port zones of SOLAS special areas, are forcing the development of port infrastructure and vessels related to the collection of waste from ships. On many basins, it is also important to clean port waters of various types of pollution - such as minor oil spills, garbage floating on the water surface and others. The problem, although it affects many ports and various locations, is particularly evident in developing countries where, for various reasons, waste management has not yet been properly addressed. It should be noted that the key challenges are the unification of solutions used in different ports, the application of affordable fees and the time of waste collection from ships.

The proposed conceptual design of shore station can be part of a key infrastructure for receiving waste from ships and pollution collected from the surface of port waters. The project uses a modern design approach based on modularity and versatility of various functionalities that can be tailored to the individual needs of a given port. They can also be changed or expanded relatively easily as the port grows. The presented shore station included new requirements for autonomy and modularization of a Waste Collecting Vessel. Finally, the form of modularized pontoon takes advantage of cost efficiency both for new and existing berths. Mooring the pontoon on piles or guides allows the station to be used in tidal areas. Also crucial for the mooring of small WCV-type vessels is their protection from waves, which has been achieved by the special shape of the station modules matching those of the ship. The presented conceptual design was made intentionally in a generalized form to allow for further development and adaptation to local requirements at individual ports. The project is under development being in line with the circular economy and industry 4.0 trends.

# From Functional Arrangement to Vulnerability Assessment: Automating Naval Ship Design for Enhanced Survivability Analysis

H.J. den Ouden<sup>1,\*</sup> and R. van der Wal<sup>1</sup>

## ABSTRACT

A novel method has been developed to rapidly assess vulnerability of a new platform which has been generated through a packing approach. This method quickly transforms a volumetric packing model into a surface model that includes ship structure including doors and hatches, mission critical systems and the crew. A weapon model was developed taking into account the unpredictability of a threat by generating multiple scenarios with the Monte Carlo method. Based on this set of simulations vulnerability measures can be introduced in a weight efficient manner. This in turn will allow the naval architects to design safer naval ships in balance with other requirements. This paper describes the process of vulnerability analysis in early ship designs and the feedback loop of conclusions to the designers

## KEY WORDS

Design; Vulnerability assessment; Naval ship; Internal Explosion; Fragmentation; Early ship design; Survivability.

## INTRODUCTION

Command Materiel and IT (COMMIT) is responsible for the procurement and sustainment of the navy ships (van Oers et al. (2018)). The FIDES tool has been developed by COMMIT to facilitate the process of procurement, in which initial optimizations are performed with respect to layout and weight (Takken (2008)). Once a set of concept designs have been deemed acceptable, it becomes more important to test these designs on the aspect of ship vulnerability with the potential threats which this new navy ship can face. This analysis is directly performed after the initial early design process and should give insight on the ship design when it is still possible to alter the layout and component placement. The purpose of the paper is to demonstrate tooling and methodology in which TNO supports COMMIT with ship vulnerability assessment against damage from threat weapons. The tool entails the process of transforming the volumetric FIDES model that COMMIT produces into a model suitable for TNO's software RESIST (RESilience of Ship Targets), as well as the tooling used for developing the threat information and threat detonation locations. The tooling will be demonstrated in the following order: the model transformation of a volumetric model to surface model process by means of ShipMATE (Ship Modelling through Automated Technology) is demonstrated. Manual steps are performed to rapidly setup a RESIST model which includes both structural and systems information. Secondly the fragment distribution model of the threat weapon is explained. In-house developed tooling is used for determining the threat detonation locations. Lastly the RESIST tool is showcased in which the weapon effects are made visible for a specific case study. In this case study an initial ship layout is used with

specific conservative demands through which vulnerability improvements can be showcased. Various vulnerability reduction measures are applied to the ship and their effectiveness is determined based on the ship system state, after which a set of combined vulnerability measures are synthesized. These results are then communicated with the naval architects which concludes the vulnerability analysis process.

## SHIP MODEL DEVELOPMENT PROCESS

As mentioned in van Oers et al. (2018) the Netherlands Defence Material Organisation (present day COMMIT) is responsible for the procurement of new navy ships. This includes the exploration of the naval ship design during the early stages of such a procurement process. During the exploration of the initial ship design, several different volumetric functional arrangement models are built with the tool FIDES (Functional Integrated Design Exploration of Ships), see Takken (2008). With the help of this tool various design routes are explored in which each route undergoes their own design loop in which stability, weight, costs and other requirements are assessed. Once such a design seems feasible, the model is shared so that more detailed analysis can be performed. Vulnerability requires more detail since it is influenced by a broad set of parameters: the ship structure, the placement and robustness of components, the routing of cables and pipes and the location of crew members. The threat definition based on the ship's mission is important for the assessment of vulnerability, which requires a different type of modelling effort. To quickly deliver a vulnerability assessment, the model building process from Figure 1 should be automated as much as possible.

**Figure 1:** The process of model development through ShipMATe

During the early design stages, designers at COMMIT require an evaluation of design iterations within weeks. Next to the development of the initial arrangement, the designers also develop an initial plan of the routing and make an initial estimate of the primary component placement, see van Diessen et al. (2022). ShipMATe (Ship Modelling through Automated Tech-

nology) was developed to quickly prepare these initial ship arrangements into a model suitable for vulnerability assessment. The process is illustrated in Figure 1 and works in three distinct steps; The first step transforms the volume based FIDES model, portrayed in Figure 1a, into a surface model, shown in Figure 1b. The FIDES model that has been used for this paper is the same as the one developed for the automatic routing paper of COMMIT (Duchateau et al. (2018)). The reason for this surface model creation step is that most of the vulnerability analyses uses either a quadrangular surface with a specific thickness or shell elements in the case of FEM (Finite Element Method) model. This process is nearly completely automated while it allows the naval architect to make changes in the layout during the transformation process.

The second step in the process is to turn this surface model into a simplified surface model that only consists of quadrangular surfaces which is portrayed in Figure 1c. The reason for this simplification is that the current blast response model within RESIST requires a panel with two distinctive bending directions. This simplification affects the ship hull and panels that are in connection with the hull. These include: watertight bulkheads, transverse bulkheads and the hull panels. After this process is finished, the following steps will focus on including the structural data of the ship. Structural data is allocated to the various panels with the help of a 'scantling sheet'. This sheet appends the longitudinal and transverse stiffeners to various panels based on their type (deck, hull, longitudinal, watertight bulkheads and regular bulkheads) and their location (zonal position and deck level). The values for each of these properties are discussed with a naval architect specialised in the field of structural engineering. The inclusion of structural properties are essential for this type of vulnerability analysis since a more realistic approach for damage is used in this stage, which is where the analysis differs from other early design studies (Goodfriend and Brown (2018); Cramer et al. (2011)). The final structural properties of the panels can be modified if required. This allows the naval architect to add the necessary details to compartments which differ greatly in structural properties compared to the standard ship layout such as the ammunition storage rooms, the helicopter deck and the diesel generator room.

Once the structural model of the ship is completed, the systems on board of the ship can be created. Systems are included in a simplified manner because only limited information is available during the early design stages. Firstly the major components are approximated as filled bars, which include a skin material, skin thickness an internal material and a filling grade. This methodology is applicable to components ranging from small sensors to large components like diesel generators. The second step is to make an initial routing between the major components. Cable or pipe routing is often the more vulnerable part of the overall system. This process is currently performed manually, however tooling is in development to automate this process. The final step, see Figure 1d, in this process is to add the system logic to the model. The primary system logic is represented in a directed-graph, the requirements which check the ship state are represented in a tree structure. With all the necessary elements of the ship prepared an xml is generated by ShipMATE which allows for a direct transfer of the model into the RESIST software.

The ship has the following systems on board:

- The ship has a CODLAD (Combined diesel-electric and diesel) propulsion system
- The ship has a single anti surface weapon system and a single anti air system
- The ship has a single radar mast
- The ship includes for this study only the chilled water distribution and electrical distribution as auxiliary systems

## THREAT MODEL

Where system studies commonly simplify the damage extend to compartment based rules , see (Duchateau et al. (2018); Jansen et al. (2020)), the damage extend for this systems study is based on physics-based model in which the threat consists of a blast and fragmenting warhead. A missile carries the warhead to the target and the fuse mechanism determines the detonation location, which could be either inside or outside the ship. The warhead is commonly a high explosive contained in a metal casing. The metal casing can be smooth resulting in natural breakup of the casing in fragments, or the casing can

contain pre-formed fragments of most any shape. In this paper we have assumed an anti-ship missile with a naturally fragmenting casing. There are several models available to describe the fragment distribution from such casings, one of which is given in ANEP43 (NATO Standardisation Office (NSO) (2014)). This describes a generic approach based on the warhead geometry and a mathematical mass distribution. For the current study, we have made use of the SPLIT-X tool from Numerics GmbH. SPLIT-X includes an elegant approach to natural fragmentation where the Hoop strain of the expanding metal is compared to the material tensile strength. SPLIT-X results in a spatial distribution and mass distribution of fragments. These stochastic distributions have a certain level of randomness, which is also witnessed in testing of shells or warheads. The break up process results in a unique distribution for each and every test. This requires a probabilistic approach when dealing with natural fragmentation, every run will yield in different fragment loading on the construction (although RESIST includes the option to fix the random seed, so that identical runs can be performed). Ejection velocities of the fragments are based on the Gurney velocity (Gurney (1943)).

The blast module in RESIST is deterministic in its approach. Every run of the same scenario will yield the same blast loading results on the structure. Reflected blast waves are determined using the mirror approach; the detonation charge is mirrored with identical charges in the plane where the reflection takes place. A target panel is divided in discrete loading areas and reflections up to first or second order from all other panels in the compartment are taken into account. Quasi-static pressure level is determined using a TNO-developed model for the rise time. Isentropic venting is based on leakage through failed decks, panels and doors. The response of the blast loaded panel is based on an advanced Single Degree of Freedom (SDOF) model (van Erkel (1992)) that is solved by time step integration. Failure is based on empirical strain values at the rim of the panels. RESIST combines the effects of fragments and blast: panels are weakened when fragments perforate before the blast wave arrives.

## **Threat physics definition**

The threat considered in this case study is a sea skimming anti-ship missile. Sea-skimmers approach the ship a few meters above sea-level. Sea-skimmers have a circular error probability (CEP Webb (2012)) that is significantly smaller than the ships dimensions, and therefore can hit the ship at a specific spot. Weapon system ballistic performance is often expressed in CEP. In statistics the standard deviation is often used for expressing Gaussian distributions.

Here the assumption is made that the aim-point of the missile is selected near the bridge of the ship. This likely improves weapon effectiveness, because the centre of the ship contains more valuable compartments than the bow and the stern. The current model assumes no special manoeuvres. For optimal probability of hitting a target, a sea skimmer should hit the target from the side, with enough margin to miss the water, and low enough to not miss the freeboard. For users of the derived detonation point clouds it is recommended to check if the aim-point aligns well with the ship most important compartments. The model assumes an average impact altitude above sea-level, with a standard deviation. A dive angle is drawn from a uniform distribution, which corresponds to a slight dive in the terminal trajectory. Although not fully representative, the relative bearing of the missile with respect to the ship is chosen with a uniform distribution. For the fusing mechanism an impact delay fuse is chosen, with a delay that aims for a detonation near the centreline of the ship.

## **Uncertainty of the detonation location**

The impact location of a threat on a naval vessel depends on a number of parameters in the flight trajectory of the missile, the seeker head, the fuse mechanism and the signature of the vessel. Therefore, a Monte Carlo Method is used to account for multiple scenarios. The Monte Carlo method that is used for the points distribution operates in the following manner: the impact location of the warhead on the ship is determined which can be achieved by either pulling a location from an uniform distribution (mostly applied for shells) or by using a Gaussian distribution. Limitations can be applied for the impact locations for threat, for instance the height range is limited for the sea-skimmer whereas the impact locations of the grenade threat is limited to impacts on the decks.

The other properties of the threat that are determined with a Monte-Carlo method are the elevation and azimuth angle. The

**Figure 2:** The impact and detonation points generated by the Monte Carlo detonation generator

velocity of the threat is fixed in this set of simulations since no distance based assumption is included for the determination of the threat properties. Finally the detonation mechanism of the threat needs to be defined, this can either be a deck counter or a proximity (delay) timer. With all these properties included a set of detonation locations are determined, similar to the example in Figure 2. The number of impact locations that is required for the analysis is dependent on both the type of analysis and the required confidence interval. As an example when we investigate the binary state of the ship with a confidence interval of 95% then about 1200 simulations are required to limit the error band to 5.7% (Clopper and Pearson (1934)).

## CASE STUDY

With the ship model prepared and the threat impact points generated a set of Monte Carlo runs can be performed. The first results are the indicator to find improvements in the design. This ship model has been made so that it is not fully optimized with respect to vulnerability a priori. By performing an initial run of the Monte Carlo simulations on this baseline ship, the effectiveness of measures are demonstrated. The vulnerability is tested on the baseline ship by checking if the "Mission Capability" state of the ship is still met. The "Mission Capability" state is defined by the following conditions:

- Power must be available in each of the zones of the ship
- The SeWaCo (Sensor Weapons Communication) system must be active
  - The mast must available
  - Chilled Water must be available
  - 2 out of the 3 servers must be available and cooled
  - Either the anti-air or anti-surface weapon system must be available
- The ship must remain mobile
  - One of the propulsion lines must be operational
  - One of the propulsion machinery (diesel-electric or diesel) must be available
  - One of the steering gears must be available

The vulnerability of the ship can be minimized by intelligently combining the different measures. The second step of proposing effective vulnerability measures is to assess how effective various vulnerability measures are. To assess the effective-

ness of the vulnerability measures three variations of the ship have been made. Once a model is setup, it becomes easy to update the model with new additions to the design.

The first modified ship model has all its transverse bulkheads upgraded to blast and fragment resistant bulkheads (HARNES bulkheads in this case, see van der Wal et al. (2018)). The outcomes of the simulations, visualized in Figure 3b demonstrate two areas in which the HARNES bulkheads prove to be particularly effective when compared to the unprotected state. The first point is allocated at deck C underneath the bridge and close to a chilled water riser and a server room. The original 40 runs that take place in this compartment are rendered harmless due to the bulkhead taking more dynamic load of the blast wave and while also reducing the amount of fragments that would normally hit the servers. Similar effects are seen at deck D at the compartment second left to the furthest right bulkhead of the main superstructure. In this case a chilled water riser is protected significantly increasing the survivability of the local systems that require cooling like the server and the distribution board nearby.

The second vulnerability measure that is explored is increasing system redundancy. The ship design was improved with the redundancy of the electrical system of the ship, whereas the chilled water system remained unchanged. The chilled water system was not altered in this model since it required to add piping, whereas the electrical system does not require extra cable trays. The redundancy is increased by linking a load centre to two different distribution boards. The difference between the regular layout (Figure 4a) and redundant layout (Figure 4b) is the interconnection of the main switch board and that each load center is linked to two distribution boards.

Aside from the Monte-Carlo distribution, which is shown in Figure 3c, the actual performance of the systems can also deliver insight which parts of the systems benefit from the redundancy. For this case-study the system based comparison are made for the “Power to all zones” requirement of the ship and to investigate the performance of the mast which is a single point of failure within this ship design. Figure 5 shows how the overall “Power to all zones” criteria is met in more cases. It should be mentioned that the increased redundancy measure seems to be having the most effect in zone 3, whereas for example improving zone 2 does not increase the performance by much. The mast increases in survivability significantly as well, as shown in Figure 6. The load centre of the mast is in zone 3, meaning that increasing redundancy is a worthwhile effort.

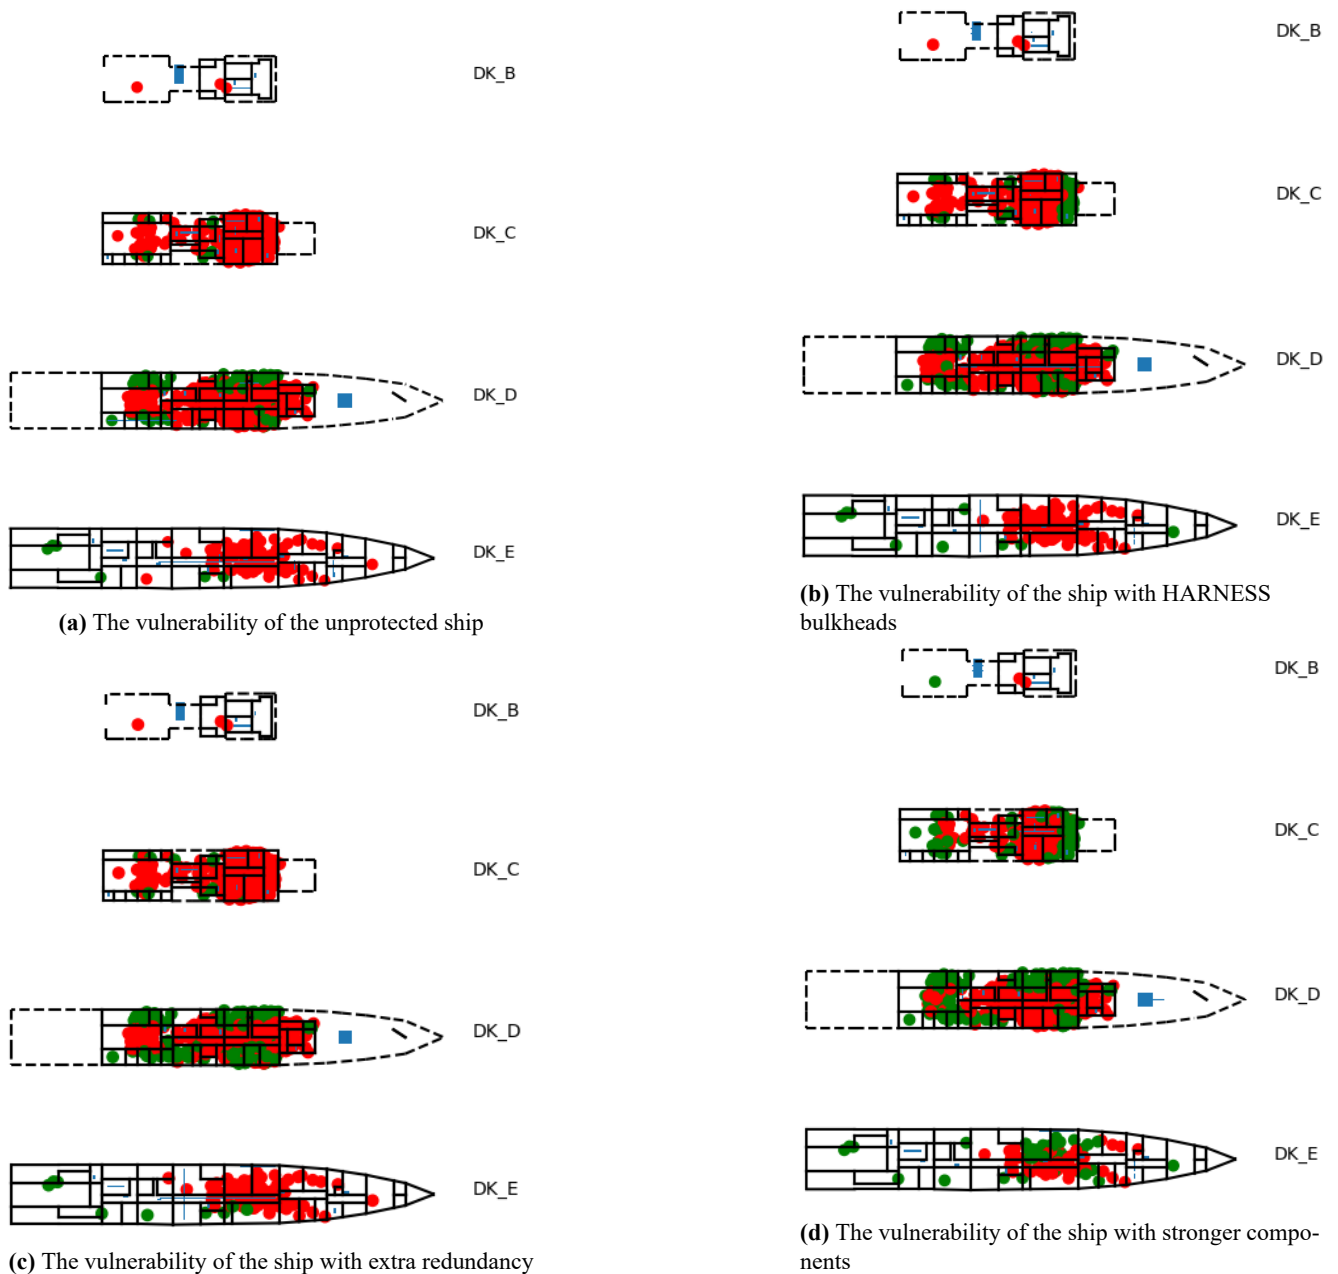

The third vulnerability measure that has been investigated is that of hardening the components within ship. The ship model has been altered in such a manner that all the kill criteria of the components have been tripled. The kill criteria include the maximum pressure and maximum amount of kinetic energy that a component can withstand. Based on the results of this set of simulations, illustrated by Figure 3d it can be concluded that increasing the strength of the components is the most effective solutions. An analysis tool is used to see which hardened components improve the resilience the ship the most. This is done by correlating the increased “Mission Capable” states and see which components did not fail in these specific runs. The conclusion of this analysis is to harden the components that are close to the single points of failure like the chilled water piping close to the mast and the cables to the load centre of the mast.

By combining the lessons of the three sets simulations with different vulnerability measures, the following adaptations have been made to a final model:

- The HARNES bulkheads will be placed in the areas where they caused reduction in vulnerability, this is highlighted in blue in the results
- Zone 3 and zone 4 will have redundant cables to significantly increase performance of the zonal power requirement
- The components with respect to the single point of failure (the mast and its subsystems) will be hardened

Each of these measures have been selectively chosen and the weight of the ship is only marginally increased by the adjustments:

- The cables and piping that have been strengthened has been limited to 100 meters. This is realised with an armoured

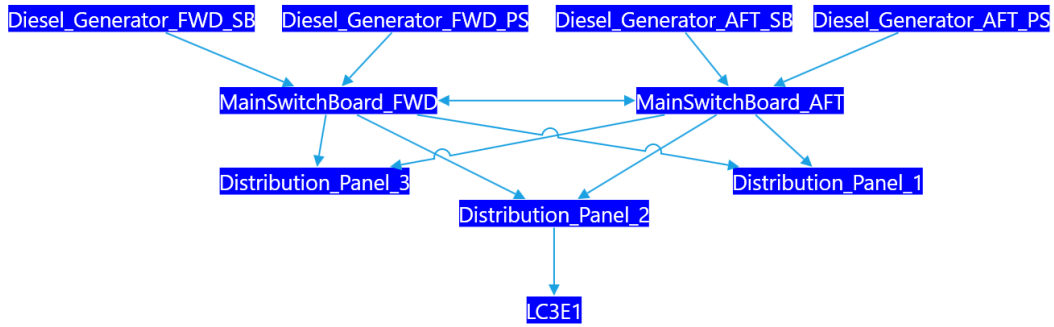

**Figure 3:** Monte Carlo results with a sea-skimmer threat, showing when the ship is "Mission Capable" in the colour green after impact

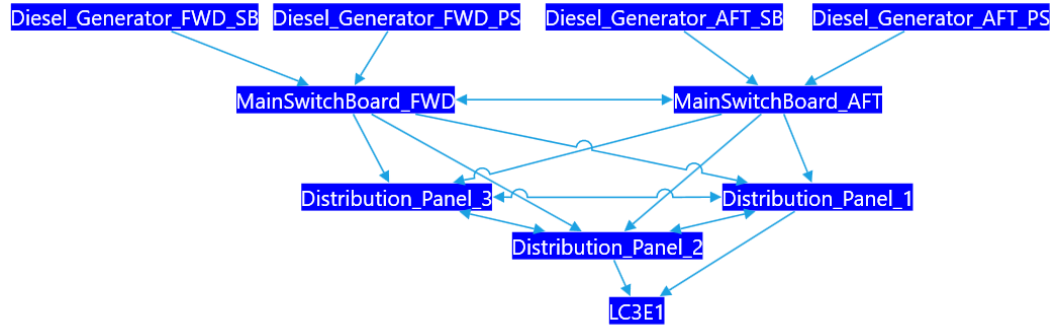

tray of about 0.1 m tall and 0.4 m wide, in which both cables and pipes can be protected. This would result in a weight increase of about 3 tonne

- The area of panels that have been turned into HARNESS bulkheads is about 100 square metre which results in a weight increase of about 9 tonne
- The increased weight increase of the redundancy is hard to estimate since the cable trays were already in the model. Extra cables would have to be introduced but this is more complicated to give insight in.

By performing a new set of Monte Carlo calculations there is a clear decrease in vulnerability as shown in Figure 7. The to-

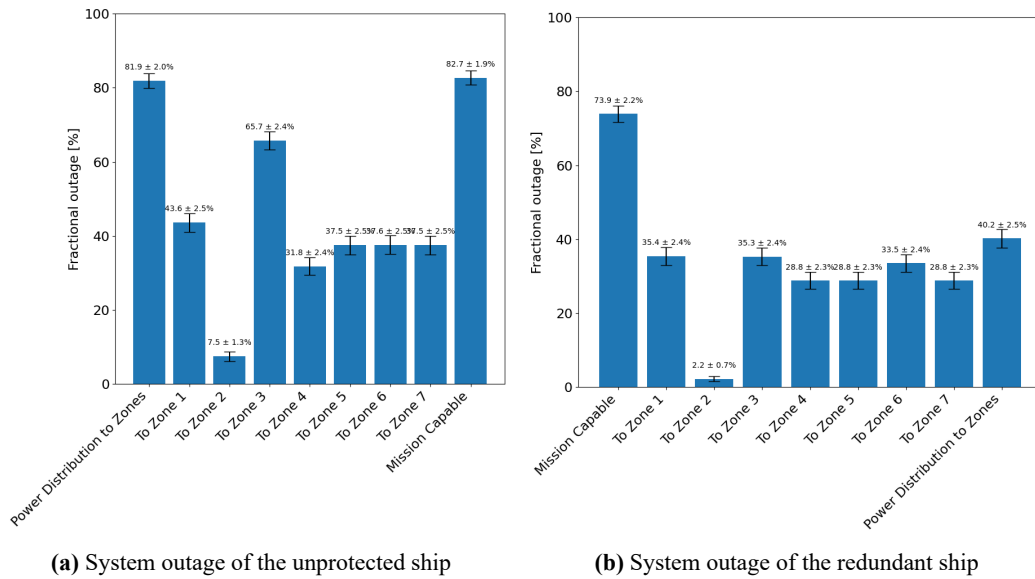

(a) Regular layout electrical system to a single load center

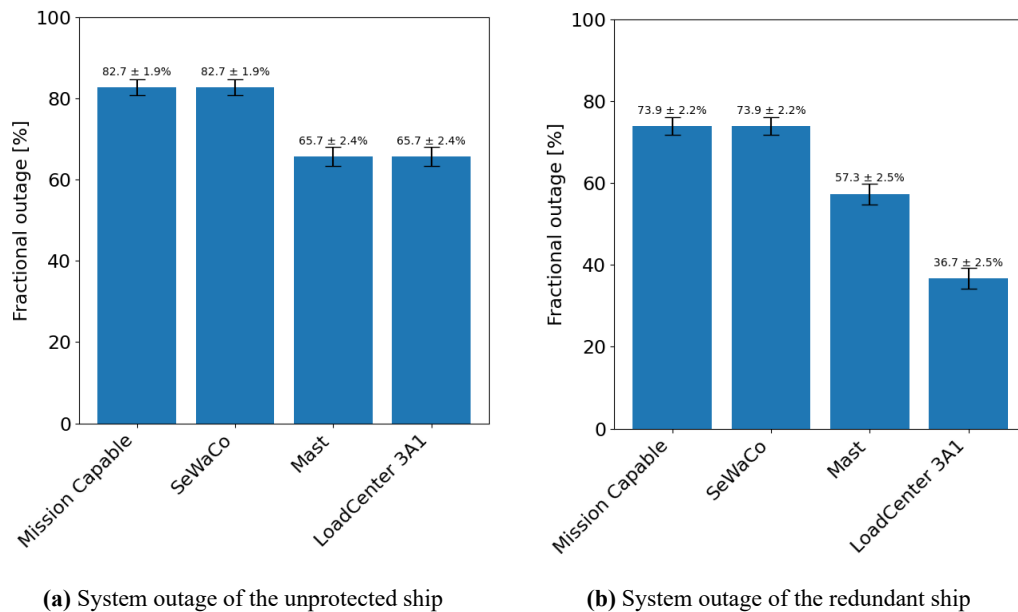

(b) Redundant layout electrical system to a single load center

**Figure 4:** Comparison of the system layout between the regular and redundant system

**Figure 5:** "Power to each of zones" requirement in relation to the "Mission Capable" state of the ship

tal availability, that is the 100% minus the percentage outage, of the mast increases from 34% to 43%, the availability of the power in zones from 18% to 60% and the overall "Mission Capability" has been met from 18% to 33%. It does demonstrate that a ship with a lot of single points of failure it is impossible to retain the "Mission Capability" state for all the impacts. However, using a smart selection of measures a great deal of vulnerability can be reduced. These upgrades to the ship de-

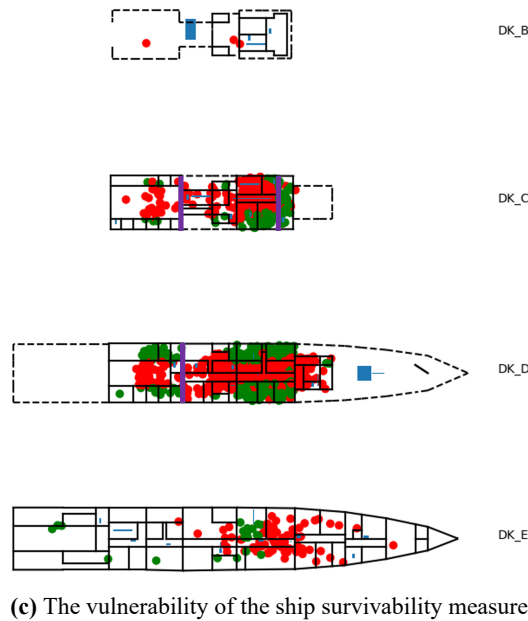

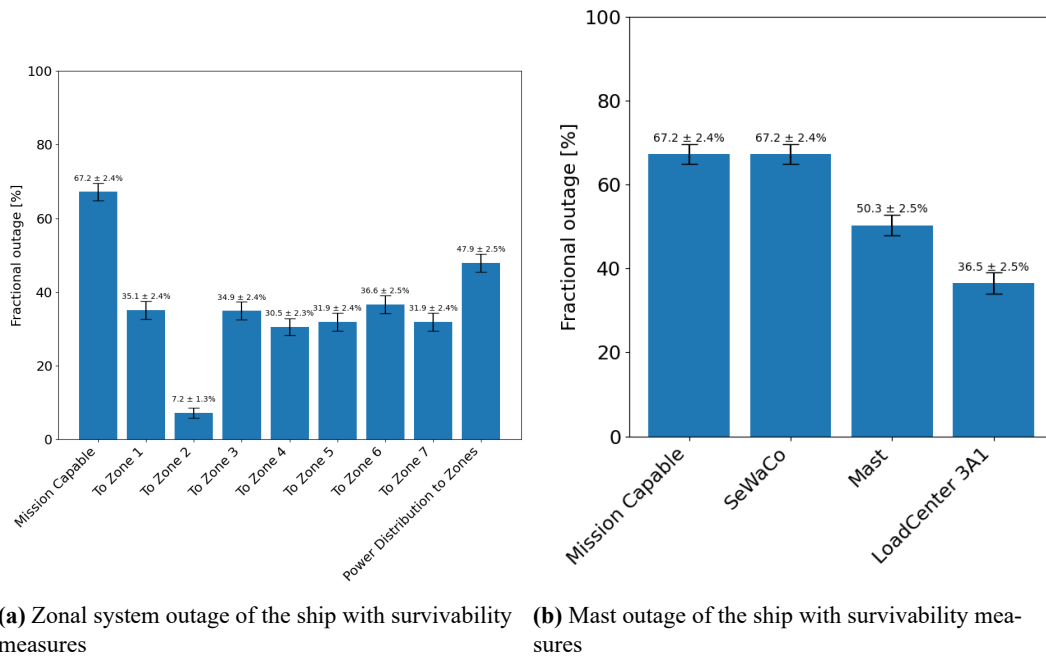

**Figure 6:** Mast availability requirement in relation to the "Mission Capable" state of the ship

sign were verified and could be advised to the naval architects in the design department of COMMIT to include in the next iteration of the design. The naval architects review whether the vulnerability reducing measures can be accommodated taking into account volume, weight, estimated cost and other requirements. This review is based on a balance between the penalty on a specific requirement and the gain in survivability of the ship.

## CONCLUSIONS

Through an automated process of model conversion it is now possible to evaluate an early stage ship design with respect to vulnerability. While the process requires the knowledge of a naval architect with respect to the structure and the component placement, quick simulation can aid the further improve the arrangement design. The threat modelling methodology demonstrates the need for the inclusion of both fragmentation and blast damage. Following from the probabilistic and non-uniform behaviour of the fragmentation model it is necessary to determine the detonation locations in a probabilistic manner. The detonation location tooling is based on specifics of a missile, such as the final flight trajectory, seeker head and fuse mechanism. When accounting for the variability of both the threat and threat detonation location a baseline for the assessment of the ship can be produced and weak points of the ship arrangement can be identified.

Based on the ship design variations the effectiveness of the vulnerability reduction measures could be determined and a smart selection of measures was made. This complete process shows how rapidly vulnerability of primary damage can be reduced, however for the inclusion of secondary damage and damage control, further model development and tooling should be developed. TNO and COMMIT continue to work closely together to further shorten the feedback loop of consequences by design choices on the vessel's vulnerability. This allows for participation in concurrent design sessions, in which several disciplines work together on the design of a new vessel. Such sessions require on the spot answers to questions relating to vulnerability, or at least within weeks between subsequent sessions. Based on the work described in this paper COMMIT and TNO are able to iterate early ship designs to achieve a "first time right" design that is compliant with the vulnerability requirements.

**Figure 7:** Mast availability requirement in relation to the "Mission Capable" state of the ship

## FUTURE WORK

Further work focusses on combining the disciplines of susceptibility and recoverability, so that the entire chain of survivability of a naval vessel is covered. Vulnerability experts and experts on signatures (susceptibility) can for example work on technologies to predict and manipulate hit locations of particular missiles. When all countermeasures fail, the hit location may be steered to a spot with minimal crew attendance at that particular moment or to a spot with minimal consequences on operational availability of systems. A priori RESIST simulations can populate lists of such locations for a number of threats.

The future work could also aim to combine the routing optimisation that is performed by the designers with the a better definition of the damage extend that is defined by the analysts. This would bring the topic of vulnerability in a more realistic manner earlier into the design process.

## CONTRIBUTION STATEMENT

**H.J. den Ouden:** Conceptualization, methodology investigation; writing – original draft. **R. van der Wal:** supervision; writing – review and editing.

## ACKNOWLEDGEMENTS

We would like to acknowledge Rachiel de Boer for the development of the Graphic User Interface that helped us analysis the Monte-Carlo results. Furthermore we would like to acknowledge Mark Zijlstra for his input regarding the detonation location determination, Andre van Erkel for his input for the blast model and Noud Altinga for giving general input and creating the ship render.

# Special ship design and ocean space multi-use synergies

Sigurd S. Pettersen<sup>1,\*</sup> and Arnstein Eknes<sup>2</sup>

## ABSTRACT

*This paper introduces the concept of synergistic multi-use between offshore wind and other sectors in the ocean space, to the ship design audience. We study the opportunities that arise when using special ships to service several ocean sectors, thereby realizing some of the synergies for multi-use. Multi-use of the ocean space becomes desirable due to the increasing demand for marine area by growth sectors like offshore wind and offshore aquaculture. We find that the primary opportunities to realizing multi-use synergies from vessels lie in the operational phase. Logistical support, crew transfer, emergency response, accommodation, and some inspection and repair tasks are sufficiently similar across offshore wind and fish farming that multi-use should be considered. The application of the synergistic multi-use concept also extends to other special ship types, such as offshore support vessels serving oil and gas production.*

## KEY WORDS

Special ships; Blue Economy; Ocean Space; Multi-use; Shared logistics

## INTRODUCTION

The ocean is at the forefront of solutions to many of the world's most pressing problems, including the transition to green energy and more sustainable protein, for instance from seafood. Addressing the fight against climate change, the *High Level Panel for a Sustainable Ocean Economy* (Hoegh-Guldberg et al., 2023) recently suggested a number of mitigation opportunities across seven ocean-based sectors. Policy and market dynamics in key sectors that shape the blue economy suggest that buildout of renewable energy and food production in the ocean space will be highly geographically centralized. Locations with desirable ocean conditions will be highly sought after by several actors, meaning that there are opportunities for cross-sectoral collaboration and synergies, as well as a risk of competition for space (DNV, 2023d).

In Europe, the EU ambitions for offshore renewables have been reaffirmed by the countries surrounding the North Sea. The Ostend Declaration of April 2023 aims to grow offshore wind in the North Sea to 300 GW by 2050, signed by nine countries. Addressing the heightened concerns about use of marine space, the EU Maritime Spatial Planning Directive now requires all EU countries with a coastline to develop and implement a maritime spatial plan, to align energy production with other societal objectives depending on the ocean space. Following the introduction of MSP in the EU, a plethora of research projects have investigated multi-use as a solution where ocean industries make use of the same core or peripheral infrastructure (Schupp et al., 2019).

At DNV, multi-use challenges and opportunities are currently explored by the Ocean Space research programme. The *Ocean's Future to 2050* suite of reports provide forecasts of the Blue Economy on a global scale (DNV, 2021; DNV, 2023d), following the system dynamics methodology also applied in DNV's *Energy Transition Outlook* (DNV, 2023a). In 2023 we published our *Spatial Competition Forecast* (DNV, 2023d), showing that offshore wind area use will instigate competition for space among industries operating in the ocean. Later in 2023, we initialized a new project MARCO (*MARine CO-existence scenario building*), which investigates co-existence through a range of solutions turning the area conflict into a range of opportunities,

among them industry multi-use interlinkages (DNV, 2022c). Special ships are among several enabling infrastructures for multi-use, and already employed in service of many offshore industries, like offshore O&G, wind, and aquaculture.

The main purpose of this paper is to explore the challenges and opportunities for special ship design that targets multi-use synergies, which could exist when several ocean industries operate in close proximity of each other. How much of the vessel logistics involved in the operation of an offshore wind farm can be shared with an offshore fish farm? Which functionality is needed, and to what extent do the required vessel functions overlap? Can offshore charging systems near wind farms make battery-powered service vessels a reality? Can the chartering of service vessels with relevant functionality be shared between wind operators and fish farmers? How much would this reduce the OPEX of fish farmers and offshore wind operators?

Experiences from offshore support segments ten years back suggests that stakeholders in the wind and aquaculture sectors should take a cautious approach to designing in multi-functionality. Back then, ship design practice adapted to a “more is better” approach where more demanding operations, new rules and regulations, and a need for market differentiation allowed more costly vessels to be built, supported by high oil prices and chartering rates (Garcia et al., 2016). If multi-use opportunities for special ships are to materialize in an economically sustainable fashion in the emerging blue economy sectors, ship design needs to take a broad systems approach, and be conducted in smarter way, with respect to multi-functionality.

The paper is structured as follows: First, we review the relevant literature on marine multi-use and special ships. Second, we assess the primary drivers of multi-use between ocean industries. Third, we review the special ship types servicing offshore wind and aquaculture, through typical project lifecycles. Fourth, we assess the opportunities and challenges associated with multi-use that arises for special ships. Finally, we conclude.

## LITERATURE REVIEW

We provide a brief literature review on key research across three distinct, but related domains. First, most advances related to the concept of multi-use recently has seen this in relation to the process of marine spatial planning, and hence has gained a lot of interest not only among engineers, but also from policymakers and marine science communities. Second, parts of the literature on design of special vessels that has ventured into concepts like multi-functionality, modularity, and future uncertainty, is highly relevant. Third, special ships are always part of a wider logistics system and it is difficult to understate the impact of the logistics system design on the capabilities needed in each ship.

**Figure 1: The main idea of the paper and topics addressed in the literature review.**

## Synergistic multi-use in marine spatial planning

Marine Spatial Planning is defined as “the public process of analysing and allocating the spatial and temporal distribution of human activities in marine areas to achieve ecological, economic and social objectives that have been specified through a political process” (Ehler & Douvère, 2007). In the EU, the Maritime Spatial Planning directive mandates every member state to introduce the concept into national legislation. On a global level, more than 75 states worldwide have some type of MSP process in place (Ehler, 2021).

Introducing MSP provides agency to stakeholders across ocean domains. However, in a world with rapidly evolving ambitions to build out offshore wind, the existence of trade-offs between societal objectives like energy production, seafood production and nature protection, could still lead to situations where some stakeholders remain unsatisfied. For instance, this has been seen between fishermen and the offshore wind sector over concerns that offshore wind will limit access to fishing grounds, when policymakers decide to prioritize renewable energy production. In some cases, considering synergies between sectors can reduce risk of conflict, and lead to identification of win-win opportunities.

Several large research projects have received funding from the EU to study the potential for multi-use of the ocean space, in order to reduce the potential for stakeholder conflicts, and to realize synergies. *MUSES (Multi-Use in European Seas)* developed seven multi-use case studies with a specific combination of production systems at a specific geographic location. Combinations with relevance to the food and energy sectors included offshore wind-wave energy, offshore wave energy-aquaculture, offshore wind-fisheries, offshore wind-aquaculture, and offshore O&G decommissioning with repurposing (Bocci et al., 2018). *MARIBE (Marine Investment for the Blue Economy)* investigated 24 sectoral combinations offshore, with more in depth demonstration of the most promising concepts (Dalton et al., 2019). Ongoing projects like OLAMUR (*Offshore Low-trophic Aquaculture in Multi-Use scenario Realization*) introduce pilot test sites for low-trophic aquaculture (e.g. mollusc and seaweed farming) inside existing wind farms (OLAMUR, 2024). Similar to the multi-use term, the concept of *Marine business parks* has been proposed by the *Center for the Ocean and Arctic* at the Arctic University of Norway, in a collaborative project involving stakeholders across the Norwegian offshore energy, seafood, shipping, non-governmental organization, and research sectors (Hersoug & Mikkelsen, 2022). Very little research has been done on the opportunities for designing special ships for this context.

In summarizing the results of the EU project *MUSES*, Schupp et al. (2019) provide a typology for multi-use, stretching from multi-purpose platforms to repurposing of offshore infrastructure, classified along four criteria; spatial, temporal, provisional, and functional. Table 1 introduces the typology proposed by Schupp, with examples prepared by Pettersen et al. (2023). In this paper, we build further on the concept with the second highest level of integration, called *symbiotic multi-use*. However, we will use the term *synergistic multi-use*, to emphasize more strongly the joint efforts by two actors to create an improved outcome for both, rather than to presume that a *symbiosis* emerges from the actor's mutual dependence. Under the concept of *synergistic multi-use*, offshore production systems may depend on the same logistics support and are located within proximity of each other. Hence, the two production systems make use of the *same space*, at the *same time*, and sharing *peripheral* infrastructure and services. Among several examples of multi-use, Pettersen et al. (2023) identify examples of potential for synergistic multi-use that includes special ships, highlighted in bold in Table 1.

As opposed to synergistic multi-use, multi-purpose platforms would reflect a fully integrated structure where a single infrastructure accommodates two or more distinct ocean uses. This means that multi-purpose platforms are also tightly functionally connected. Fully integrated multi-purpose structures face numerous barriers, both technically, economically, and regulatory (Van Den Burg et al., 2020). Naturally, they face difficulty meeting key design principles like functional independence (Braha and Maimon, 1998). Reporting on the results of the *MARIBE* project, Dalton et al. (2019) found that very few concepts for large-scale multi-use platforms were economically viable, according to a generalized “levelized cost of output” metric developed to compare unit costs for different production systems combined on a single marine platform. Other difficulties for scaling multi-use at sea are discussed by Van Den Burg et al. (2020) who, through a synthesis of the *MUSES* and *MARIBE* results, and other research on the topic, present an overview of the key barriers to multi-use, including economic, technical, social, administrative, legal, and environmental ones. Differing perspectives on risk among the stakeholders involved in multi-use will also influence the opportunity space, with distinct sector-specific frameworks dominating the sectors that will be involved in a multi-use concept (Van Hoof et al., 2020).

**Table 1: Typology of multi-use concepts by level of system integration (Pettersen et al., 2023), based on Schupp et al. (2019). Examples in bold are particularly relevant for special ships.**

Typology	Spatial	Temporal	Provisional	Functional	Description
<b>Multi-purpose</b>	X	X	X	X	Same area, same time, sharing core infrastructure and services
Examples	Combined floating offshore wind structure and finfish cage aquaculture Floating desalination plant powered by wave power Energy islands acting as hubs for grid connection and green hydrogen production plants				
<b>Synergistic use</b>	X	X	X		Same area, same time, sharing peripheral infrastructure and services
Examples	<b>Shared logistics systems and service vessels for offshore wind and aquaculture operations in the same area</b> Electricity from offshore wind to replace gas turbines on offshore oil and gas installations <b>Offshore wind farms to act as charging stations for electric ships</b> Floating solar photovoltaics replacing diesel generators at fish farms Integrated multi-trophic aquaculture: Fish farming combined with farming of low-trophic species like molluscs and seaweed				
<b>Co-location</b>	X	X			Same area, same time
Examples	Adoption of passive fishing gear to reduce risk of gear interference with offshore wind structures Requirements to reduce risk for trawling over pipelines and subsea structures				
<b>Repurposing</b>	X				Same area, subsequently
Examples	Ships and offshore structures decommissioned to become artificial reefs Area traditionally used as fishing grounds repurposed to fixed offshore wind farms				

## Synergistic multi-use and research on design of special ships

Synergistic multi-use as described above will rely heavily on sharing of provisional functions, primarily provided by special ships that “go to sea to do something” (Andrews, 2018), besides transportation.

At the previous IMDC, Erikstad & Lagemann (2022) reviewed the state-of-art on ship design methodology, identifying four primary design strategies taking a hold, beyond the traditional design spiral approach; optimization-based, set-based, system-based, and configuration-based design. They argued that most design practice combines the four, but for practical purposes, the system-based approach (Erikstad & Levander, 2012) based on a “needs-function-form” mapping process, provides a useful starting point for understanding the role of special ships in synergistic multi-use. System-based ship design is a mission-centric approach where a good understanding of the market conditions and the main operational needs enables “right-sizing” of the vessel before concept exploration and design iterations take place. “Right-sizing” is becoming an essential aspect of teaching vessel owners in offshore wind service to specify requirements that correspond to the intended operational needs, rather than adding additional capabilities “just in case” (The Naval Architect, 2024).

Designing vessels for synergistic multi-use, considering the distinct needs of offshore wind and aquaculture markets, will require a deflection from previous run ins with concepts like multi-functionality in offshore support vessels. Up until nearly 10 years ago, offshore support vessels were increasingly designed for multi-functionality under the guise of high chartering rates due to high oil prices. Due to their high operating costs, some of these highly functional vessels turned “multi-useless” (Gaspar et al., 2015), as they could not find profitable work in a context with day rates dropping when the oil price collapsed (Garcia et al., 2016). The next generation of special ships, whether serving offshore wind, aquaculture, or the two sectors in combination, should adopt smarter design practices, aimed for instance at enabling future changes in configuration and mission-related equipment at a lower cost.

The EU-funded *NEXUS* project (*Next generation support vessels providing safe and more efficient offshore wind farm services*) investigated possible conditions for game-changing service operation vessels, with the objective of reducing maritime logistics

costs for offshore wind maintenance by 20%. Puisa et al. (2021) analyze the safety of SOV operations at a wind farm by introducing the concept of system variability as a proxy for the likelihood of incidents, finding that the most safety-critical interface during operations is between SOV gangway and the turbine. Also as part of the NEXUS project, the benefits of variable speed engines for fuel saving on vessels that spend a significant proportion of their operating profile in dynamic positioning (DP) were investigated (Holmefjord et al., 2020). Holmefjord et al. (2020) find a 20% fuel saving on an analysis of the Service Operation Vessel (SOV) *Edda Passat*. Similarly, in an earlier study by Lindstad et al. (2017), batteries were evaluated as a solution to hybridize offshore support vessels, thereby reducing the need for running redundant combustion engines at low loads when operating in DP mode.

Approaches to handle future uncertainty at the design stage will be needed to address new ocean sectors, exploit synergies in logistics support, new fuel types, and emerging mission-related requirements. To avoid overdesign, modularity and flexibility is desirable, and fits well with a “design for sustainability” perspective, where ship design considers long-term economic, environmental, and social objectives (Erikstad & Lagemann, 2022). Core design principles like modularity and flexibility are increasingly well-addressed in industry practice as a means to adapt to the energy transition (Willumsen et al., 2023). “Prepared for X” class notations exemplify the willingness of ship owners to pay a premium to prepare the vessel for future functionality, particularly in relation to upcoming fuel types (DNV, 2022b), exemplifying the designing of real options “into” ships. A number of recent vessel conversions of platform supply vessels to service operation vessels also illustrate that the industry sees retrofit as a more cost-efficient and sustainable option than newbuilding (Ulstein, 2022), particularly when the underlying marine platform is sufficiently versatile. Various methods have been developed to support offshore ship design viewed as decision-making under uncertainty with the goal of enabling flexibility through the lifecycle (Gaspar et al., 2015; Pettersen et al., 2020; Rehn et al., 2019; Zwaginga et al., 2021; van Lynden et al., 2022). In the offshore wind sector, Zwaginga et al. (2021) consider the uncertainty in future design requirements for installation vessels in offshore wind, for instance related handling turbines with increasing size and capacity. Similarly, van Lynden et al. (2022) apply epoch-era analysis (see for instance Gaspar et al. (2015)) to generation of future market scenarios for offshore wind installation vessels, combining this approach with parametric ship design modelling.

Pettersen et al. (2020) provide examples of latent capabilities existing in complex special vessels, enabling these vessels to perform a range of operations for which they were not originally designed, of particular importance for improving emergency preparedness. Latent capabilities refers to functional attributes vessels were not intentionally designed for. The idea of latent capabilities can be a powerful one in a context where possibly stranded assets from O&G service segments can be repurposed, possibly without large design changes, to new market segments. In the co-existence between offshore wind and other ocean users, one can consider concepts that use fishing vessels for ocean observation (Van Vranken et al., 2023), for instance providing new knowledge about the environmental impact of offshore wind. The use of fishing vessels for oil spill response or other emergency response tasks are also a prominent example of this (Pettersen et al., 2020).

## Logistics of synergistic multi-use

A big operations research literature exists on use of optimization and simulation methods applied to complex special vessels and their logistics, serving both offshore oil and gas (Fagerholt & Lindstad, 2000), offshore wind (Irawan et al., 2023; Lazakis & Khan, 2021), and marine aquaculture (Slette et al., 2022, 2023). To the knowledge of the authors, very few studies have addressed the logistics of synergistic multi-use as described above, outside of emergency preparedness where e.g. oil spill response systems will address accidents regardless of in which industry they originate. We mention a few interesting examples from recent years, which has addressed logistical aspects relating to new ocean industries.

Lazakis & Khan (2021) propose an operational planning methodology for the optimal short-term route planning and scheduling of SOVs and crew transfer vessels (CTVs) taking into consideration characteristics for the wind farm, turbine failures, and the two vessel types, as well as environmental conditions. They find that the operational window increases when SOVs and CTVs are used together. Similarly, Irawan et al. (2023) construct a two-stage stochastic programming model accounting for weather uncertainty, and find that SOVs improve offshore wind maintenance efficiency, and that using SOVs in combination with a safe transfer boat (daughter craft) minimize the total maintenance costs. For the cases studies, SOV and the safe transfer boat combination are found to reduce maintenance costs by up to 70% over approaches that rely on CTVs.

Within aquaculture, Slette et al. (2023) provide an integrated simulation-optimization framework to evaluate the performance of alternative fleets composed of a combination of specialized vessels or multi-purpose vessels that service a set of fish farms. They find that the performance with respect to utilization of weather windows is generally higher for fleets composed of multi-purpose vessels, as appropriate functionality does not become a limiting factor when routing for the next service mission. Furthermore, they find that letting service vessels serve localities that are not correlated in terms of weather, also improves overall utilization of the fleet. The logistics of fish health emergency response has also been studied in another paper by Slette et al. (2022), focusing on the cost-benefit trade-off of dedicated emergency response vessels in fish farming.

The *North Sea Energy programme* report on *The Potential of Shared Offshore Logistics* analyses key scenarios for sharing of offshore logistics in the future offshore energy system of the southern North Sea (Omrani et al., 2022). The report focuses on logistical needs in the energy sector, considering wind farms and oil and gas platforms that increasingly turn to producing blue hydrogen and capturing carbon. In the scenario of the Dutch “Hub West 1”, which includes the Hollandse Kust Noord wind farm and six O&G platforms close by, they find that 8% of the wind farm OPEX (1.9 MEUR) can be saved by using a shared logistics concept that uses CTVs for personnel transit to the oil and gas installations, without compromising the availability of the offshore wind farm. The effects of reducing PSV usage are not described in detail in the study but gives rise to the suspicion that the PSV functionality to be replaced is not sufficiently accounted for.

On top of sharing costs through multi-use synergies, European shipping will increasingly be forced to report on emissions (DNV, 2023b), meaning there is also an environmental dimension to the sharing of vessel capabilities among actors in the ocean industries.

## KEY DRIVERS FOR MARINE MULTI-USE

DNV's efforts to forecasting the Blue Economy, the *Ocean's Future to 2050*, provide reference modes for developments across the ocean industries, a summary of which is shown in Figure 2. Offshore wind will by far be the fastest growing segment to mid-century and is forecast to see around a 20-fold growth between 2024 and 2050, as shown in blue. The floating offshore wind subsegment is forecast to rise even faster, but from a significant lower starting level than bottom fixed turbines, and is therefore not included in Figure 2. Marine finfish aquaculture, i.e. the farming of high-value fish like salmon in sea-based cages is forecast to triple, as shown in green (DNV, 2023c). Offshore fish farming grows much faster than other marine aquaculture, also growing around 20-fold, albeit from a much lower starting point than offshore wind. The prognoses of key developments within major ocean industries in Figure 2 is based on DNV (2023a), (2023c) and (2023d).

Figure 2: Prognosis for development in key ocean industries

## Offshore wind

Offshore wind is the single, fastest growing sector in the ocean economy, spurred on by the need to decarbonize the energy system. By 2050, DNV (2023a) forecasts the installed capacity in the offshore wind sector to reach around 1,600 GW, which means 100,000 turbines globally if the average turbine rating by then reaches 16 MW. In Europe alone, the installed capacity reaches more than 400 GW, implying approximately 25,000 turbines. If all turbines globally require planned maintenance twice per year, more than 500 turbines need to be serviced every day, before considering unscheduled maintenance and repairs. With this, there will be a large demand for logistical support throughout the field lifecycle.

Geography largely determines the location of offshore wind, with wind speeds and proximity to existing electricity grids and other infrastructure, as some examples. Fixed offshore wind farms are build using monopiles or jackets, which may also be the

technically preferred solution down to around 80-100 m water depth, further limiting the availability of sites. Floating offshore wind is currently developed for deeper waters, with Hywind Tampen a first example of an industrial-scale floating wind farm built to electrify oil and gas production (Equinor, 2023). Future power-to-X solutions like green hydrogen production could alter the dependency of the sector on grid connectivity, but would introduce other logistical challenges, for instance related to hydrogen (DNV, 2023a).

In Europe, the geography of the North Sea basin makes it the most attractive sea basin for developments, with around two-thirds of installed capacity in 2050 (DNV, 2023d). Even if the North Sea will be the main market for European offshore wind, price cannibalization due to weather correlations between offshore wind fields, spatial conflicts at the most attractive sites, etc, will increasingly cause capacity to be developed far from shore and in deeper waters, where floating solutions will be needed.

Offshore wind, as a quickly emerging market segment, has seen rapid declines in cost (levelized cost of electricity (LCOE) over its first twenty years. In the last two years, high costs of raw materials and supply chain bottlenecks (ports, manufacturing, installation vessels) has contributed to large increases in the LCOE, resulting in delay of many investment decisions and poor turn-out in high profile offshore wind auctions (Equinor, 2024; Grønholt-Pedersen, 2023). Nevertheless, most forecasters believe this to mainly be a short-term problem, as many other industries face similar inflationary pressures. Over the longer run, LCOE is forecast to halve for fixed offshore wind between 2020 and 2050 and halve for floating offshore wind between 2030 and 2050 (DNV, 2023a).

Offshore wind is a capital-intensive industry as shown in Figure 3, based on data from the Crowne Estate and ORE Catapult (2019). Purchasing major components like turbines and balance of plant (non-generator supporting infrastructure like foundations, cables, etc.) constitutes around 40%, while installation costs add another 20%. In the operational phase, operations and maintenance costs contribute almost 30%.

**Figure 3: Generic levelized cost of electricity breakdown for offshore wind (based on The Crowne Estate and ORE Catapult, 2019)**

As a relatively new market, Clarkson’s Research (2024) historical time charter rates for key subsegments are available back to 2020 only (see Figure 4). In the three years following, there has been a significant increase in the chartering rates, with rates for e.g., large SOVs with walk-to-work (W2W) functionality and accommodation for more than 40 people have almost tripled from slightly more than 20,000 EUR/day to more than 55,000 EUR/day. In 2023, day rates for these vessels exceeded those of AHTS vessels operating in the North Sea. Smaller W2W vessels and non-W2W SOVs saw lower day rates over this period, owing to less functionality and hence likely lower operability (e.g. lack of gangway limiting time windows with sufficiently small waves). Compared to traditional offshore support segments, offshore wind will likely see lower rates, but likely also less volatility (The Naval Architect, 2024).

**Figure 4: Charter rates for key vessel segments in offshore wind operations (Clarkson’s Research, 2024)**

A key driver for increasing vessel sizing and more advanced capabilities is the fact that offshore wind farms are being installed further from shore and in deeper waters. This is most critically pronounced in the construction phase, where novel solutions that can bring down the cost of installation will be desired. Also in the operating phase, new logistics support solutions may be favorable, due to the increased distance to shore. To great challenge will be for ship designers to advance offshore wind service vessel capabilities without adding excessive costs.

## Offshore fish farming

Offshore fish farming is likely to become a fast-growing subsegment of marine aquaculture. Most current marine fish farming operations take place in benign waters (e.g. Mediterranean seabass and seabream production) or sheltered waters (fjords in Norway, Scotland, Iceland, Canada, or Chile). Over the last ten years, increasingly exposed localities have been tested out, particularly in Norway and the Faroe Islands. Some of the most promising concepts for offshore fish farms were awarded with development licences, with some key characteristics shown in Table 2 (Pettersen, 2022).

A key feature of the development licenses was that they allowed licenses free-of-charge for concepts with a sufficient degree of innovativeness. However, despite the introduction of development licenses several years, the regulatory framework for offshore fish farms is still lacking, causing many investments to be delayed in the short term as the developers see limited opportunity to scale to the increased number of units to trigger sufficient investment cost reductions. Another recent showstopper has been the decision that offshore fish farms will not be liable for a new resource rent tax, a scheme that would have opened for offsetting expenditures on offshore projects against high profits earned in coastal aquaculture.

**Table 2: Some offshore fish farms awarded development licenses in Norway (based on Pettersen, 2022)**

Name	Owner/operator	Concept description	Capacity [tonnes]	Operational year
Ocean Farm 1	SalMar Aker Ocean	Ocean fish cage based on offshore technology	6,000	2017
Havfarm Jostein Albert	Nordlaks	Ship-shaped ocean fish cage	10,000	2020
Arctic Offshore Farming	SalMar Aker Ocean	Semi-submersible fish cage	3,000 x 2	2021
Smart Fish Farm	SalMar Aker Ocean	Semi-submersible ocean fish cage	19,000	Planned 2022 (delayed)
Spidercage	Nova Sea	Heave-compensated, wave breaking, semi-closed ocean fish cage	3,120	Planned 2023 (delayed)

In the longer run, regulatory uncertainties will likely be sorted out, and one can expect other countries to explore offshore aquaculture including multi-use solutions, in Europe and beyond. Outside Europe, progress on offshore fish farming is also happening in China. A first structure called “Deep Blue” was launched in 2018 but saw operational problems and made its first

harvest of Atlantic salmon in 2021 (Pettersen, 2022). Following this, China has developed a variety of concepts for a number of species. The country also has high ambitions for offshore fish farming, e.g. as reported on by Feng (2023). DNV (2023c) finds that the offshore fish farming sector globally achieves a 7% market share by 2050.

A generic production cost breakdown for sheltered aquaculture is provided in Figure x, based on Iversen et al. (2020). Production costs in fish farming is mainly driven by the need for feed, which typically constitutes around 50%, or around 2.2 EUR/kg (Iversen et al., 2020). Investments, reflected through depreciations, constitute a relatively small cost share, but tripled over the period from 2006 to 2018 to 0.3 EUR/kg.

**Figure 5: Generic production cost breakdown for sheltered aquaculture (based on Iversen et al., 2020)**

For offshore fish farms, capital expenditures will make a much larger mark on production costs. Consider for instance a unit with a capacity of producing 3000 tonnes per year with a 25-year lifetime, and costing around 100 million EUR, then this would add around 1 EUR/kg to the production costs. To compete with existing aquaculture, offshore fish farming is therefore dependent on learning and scaling effects to reduce costs (Pettersen, 2022).

Additionally, with offshore locations comes more complex well boats and other specialized ships, which may further add to the costs. There is limited information about current chartering rates for well boats and other special vessels in aquaculture, with these costs often bundled with downstream processing activity in statistics (Iversen et al., 2020). For service vessels used for delousing operations, removal of sea lice, Iversen et al. (2017) cites day rates of up to 130 000 NOK, around 15 000 EUR. Some of the well boats retrofitted from laid off PSVs (AquaShip, 2021), will likely need to command rates similar to that market segment, which could be in the same range or higher.

Even though vessel-related costs constitute a relatively small fraction of costs associated with aquaculture today, more advanced vessels needed to support offshore operations, would require higher chartering rates. With a traditionally very cost-conscious industry (Iversen et al., 2020), and a low degree of willingness to be associated with the splurge associated with the golden-era of offshore support vessels (Garcia et al., 2016), offshore fish farmers might very well see the savings potential embedded in sharing of some logistical services with offshore wind.

## Spatial impacts and benefits of sharing maritime resources

In area terms, 80% of the area reserved for permanent use by ocean industries will be taken up by offshore wind farms, not counting uses that are mobile, like shipping and fisheries, nor unproven offshore renewables (solar PV, tidal, wave power) (DNV, 2023d). Hence, by co-locating offshore wind with all other offshore installations (e.g. offshore oil and gas, marine aquaculture), the full potential of marine multi-use is estimated to reduce mankind's long-term use of marine area with 20%.

Apart from reducing the area footprint of marine use, this multi-use could come with potential synergies. Symbiotic use entails the use of marine space in a manner that exploits synergies, for instance by making use of shared peripheral infrastructures or services (Schupp et al., 2019). For example, there could exist a potential for cost saving when coupling the logistical support requirements of offshore wind with those of offshore aquaculture, if the production systems are in proximity of each other.

From the perspective of the overall production cost in aquaculture, or the levelized cost of electricity in offshore wind, chartering of vessels constitutes a relatively small share, indicating a need for further cost-benefit analyses for shared logistics concepts. Emerging regulatory and financial requirements can result in a stronger business case for the synergistic multi-use of

special ships, as carbon pricing is introduced (DNV, 2023b), and offshore wind tendering increasingly emphasizes co-existence with other ocean stakeholders (DNV, 2023d).

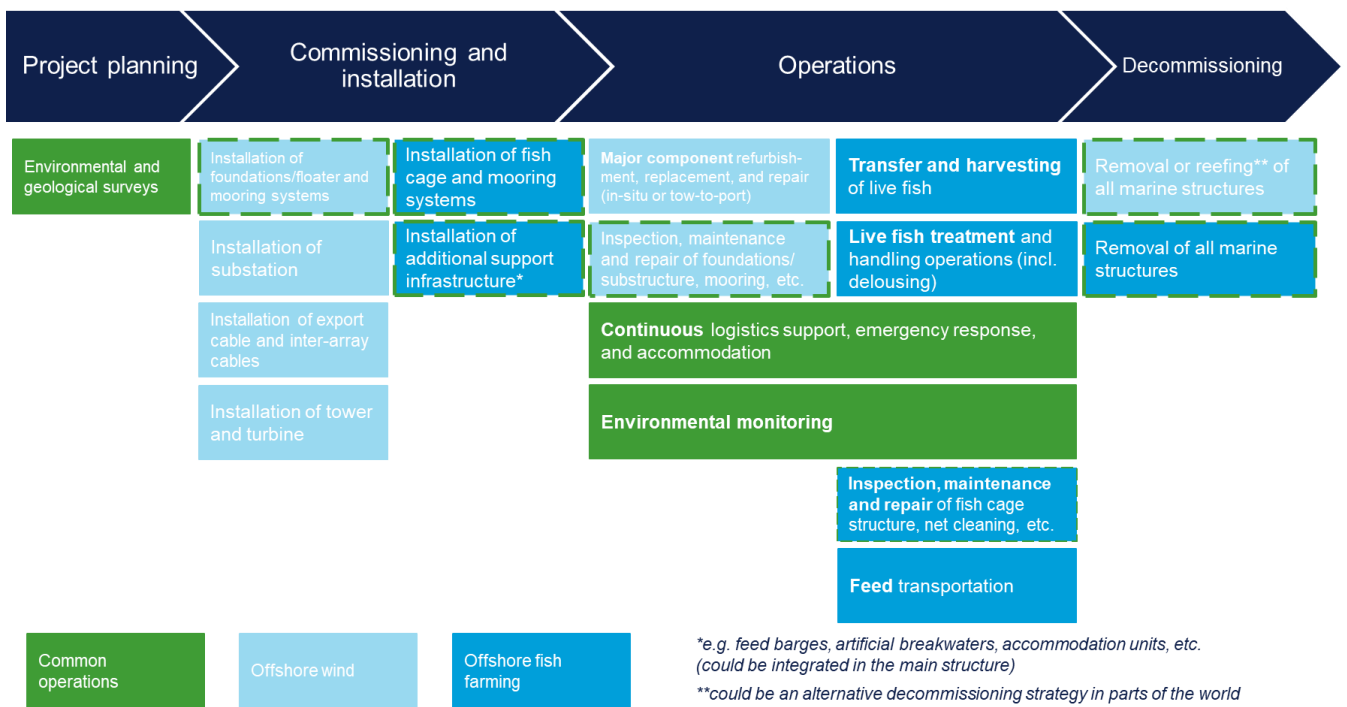

From 2027, offshore ships above 5000 GT will be included in the EU Emission Trading System (ETS), and smaller offshore vessels will also be considered for inclusion in this scheme. With the EU ETS, carbon prices will be brought into the maritime sector for the first time. The ETS implies a cap-and-trade philosophy, where a declining number of emission allowances will be auctioned and traded in the market (DNV, 2023b). The carbon price will rise over time due to declining allowances available, and the costs will eventually add to chartering rates, making ship operations that drive fuel consumption more expensive. Emissions will need to be reported on a voyage level, to settle transactions related to the emission allowance costs.

Synergistic multi-use of vessels for co-located offshore wind and aquaculture can reduce fuel consumption during transit by cutting the number of voyages needed, if one roundtrip voyage can support several production systems. The transparency that is needed for the cost of allowances to be allocated to specific charter parties, could also provide novel opportunities to define contractual terms for splitting the cost of carbon among several charterers, e.g., a collaboration between an offshore wind operator and an offshore fish farm operator.

Besides the impact of carbon pricing and reporting requirements related to fuel consumption for the vessels themselves, co-existence is increasingly taken into consideration in the tendering processes for new offshore wind farms (DNV, 2023d; Pettersen et al., 2023). Showcasing multi-use concepts like the dual use of vessels for offshore wind and aquaculture during an offshore wind tendering process could strengthen future applications, depending on the

### SPECIAL SHIP CAPABILITIES IN THE PROJECT LIFECYCLE

In this section, we introduce key vessel segments that support marine operations in aquaculture and offshore wind, in order to assess whether the distinct operations allow for some sharing of vessel capabilities. Figure 3 provides an overview of the main lifecycle phases of any offshore wind or offshore fish farming project, emphasizing the marine operations where there is a need for support from vessels. Green shows operations with a lot of commonalities, light blue shows offshore wind operations, and dark blue shows offshore fish farming operations. Dashed green boundaries imply that there is some weaker commonality in the types of operations required.

**Figure 6: Lifecycle activities with main vessel operations reflected, for offshore wind and offshore fish farming.**

From the lifecycle overview of key functions that need vessel support, it is clear to see that there are already some clear commonalities. We review the lifecycle phases, except decommissioning, and address common and distinct needs in offshore wind and offshore fish farming below. We then summarize the qualitative assessment of potential for multi-use synergies.

## **Project planning phase**

*During the project planning phase* offshore wind makes use of both geophysical survey vessels and vessels for geotechnical surveys. Geophysical surveys make use of non-intrusive methods like multibeam echo soundings, sonars, and seismics to map the seafloor.

Geotechnical surveys are the more intrusive of the two and include sampling of rock and soil by methods like boreholes and cone penetration testing to understand specific seabed features and soil behavior under dynamic loading from wind, waves, and currents. Geotechnical survey vessels often have onboard laboratories for processing of the samples (The Crown Estate & ORE Catapult, 2019). To anchor larger offshore fish farm structures, many of the same methods will be required to verify the integrity of anchoring and mooring systems.

Environmental sampling of seabed (benthic) marine life is also becoming more important during project planning, as an understanding of ecological baselines becomes more important with ocean industries increasingly required to report on their biodiversity impacts (Pardo et al., 2023).

## **Commissioning and installation**

*During commissioning and installation*, both offshore wind and aquaculture will require transportation of major equipment to the site, as well as anchoring. Bottom fixed offshore wind turbines need to be installed in multiple steps, with final assembly taking place on site. The installation of the tower and turbine itself (with nacelle and blades) is normally done by large wind farm turbine installation vessels (WTIVs) with large cranes having significant reach (+200 m above sea level) and capable of lifting 1500 tonnes or more. These vessels can also install the foundations unless these are lowered by use of heavy lift vessels.

Floating structures like large fish farms or floating wind foundations can be transported to site by towing or on the deck of semi-submersible heavy-lift vessels. Semi-submersible heavy-lift vessels have already been used for transportation of several high profile offshore fish farms, such as Nordlaks' Havfarm (Baird Maritime, 2020). New concepts for wind turbine installation are emerging, as floating offshore structures and larger turbines set new requirements to lifting capabilities (Zwaginga et al., 2021). When the wind farm is located close to shore, or the weather conditions are such that the technicians needed at the wind farm can be transported every day to/from a nearby port without getting seasick, crew transportation vessels (CTVs) are often used.

Commissioning support tasks in offshore wind are increasingly provided by commissioning service operation vessels (CSOVs). While SOVs typically provide support in the operations and maintenance phase of the lifecycle, CSOVs support the commissioning phase. CSOVs are often with larger capacity to accommodate people onboard, while many of the other capabilities are similar to the smaller SOVs. Helideck is one option you can find on both SOVs and CSOVs (but not a standard), while CSOVs are often outfitted with bigger cranes for offshore use. Since CSOVs can provide commissioning support, they are typically hired for shorter contract periods than SOVs., and may command much higher chartering rates. Both SOVs and CSOVs often work together with one or more daughter crafts or fast crew transport vessels (CTVs) to ensure faster mobilization of people to multiple turbines when this is required. With larger offshore wind farms, where rotor and turbine components increase in size, some developers are changing their O&M planning, so that CSOVs increasingly are engaged on long term contracts to meet the more complex maintenance needs. Notional design parameters for a typical SOV are contrasted with those of an CSOV in Table 3.

**Table 3: Some key design parameters of SOVs**

	SOV	CSOV
Length (incl <b>average</b> )	57-93 m ( <b>80 m</b> )	80-108m ( <b>90 m</b> )
Gross tonnage	2900-6800 GT	5500-7300 GT
Accommodation (People on Board - POB)	36-124 ( <b>60 POB</b> )	60-135 ( <b>120 POB</b> )
Deck area	200-750 m <sup>2</sup>	320-750 m <sup>2</sup> (one with 1000 m <sup>2</sup> )
Gangway + Offshore crane	Motion compensated	Motion compensated
Fuel	Marine gas oil (MGO)+hybrid/battery + prepared for alternative fuel	MGO+hybrid/battery + prepared for alternative fuel

Anchor handling tug supply (AHTS) vessels commonly used during rig moves can contribute if there are towing operations, and during installation of mooring systems. AHTS vessels will likely be taking on role during the installation phase in both offshore wind and offshore fish farming. To some extent, offshore fish farms can be built to( be relatively easy to remove and for some concepts the primary maintenance strategy is to carry out repairs in port, potentially making AHTS day rates the driving factor in offshore aquaculture OPEX. Similarly, there may be opportunities for complex offshore support vessels to provide construction support, including lifting operations, as well as support to underwater inspection and repair services. These vessels will prioritize offshore O&G support work as long as the rates are higher in that market. One additional factor to consider for possible cross industry work is the limitations that may be imposed on the operators from investors or other important stakeholders, typically related to ESG (Environmental, Social, Governance)-aspects (e.g. some investors will not accept services to be delivered from the financed asset like an SOV to other industries than the renewable industry).

Other specialized offshore vessels at use in offshore wind operations includes cable-layers and subsea rock installation vessels. There could be some cable installation needs to connect offshore fish farms with nearby wind farms for powering. However, with a need for stable powering, such solutions will require storage to reduce intermittency challenges. Besides this, with a relatively low energy consumption in the first place, offshore fish farms will likely still be fueled by diesel.

## Operations

*During the operational phase*, offshore wind and offshore fish farms share several needs. Both sectors will require inspection, maintenance, and repair operations, emergency preparedness, and accommodation for personnel. Additionally, continuous monitoring operations will likely be required for future operations to understand nature impacts.

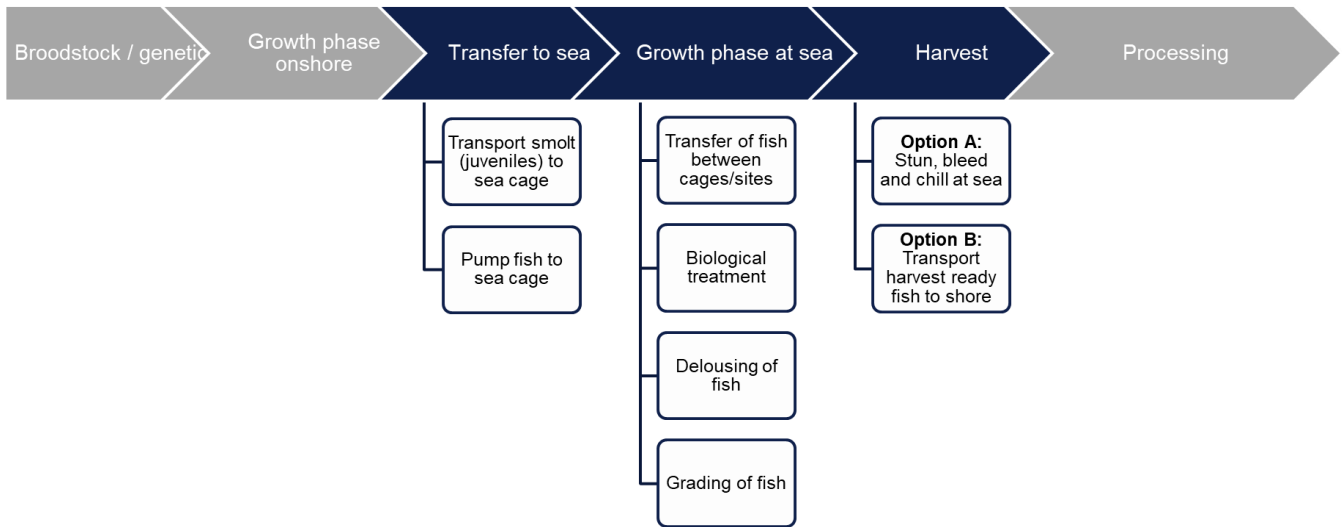

**Underwater inspection, maintenance, and repair tasks.** Underwater inspection services will largely be performed by ROVs launched from service vessels through moonpool or over the side that inspect wind farm foundations, floating structures, fish farm nets, and mooring systems. Some diving support is also used both in established wind farm operations and in coastal aquaculture. In aquaculture, diving support operations are often carried out using smaller fast-moving vessels. With deeper waters, diving operations will potentially be reduced in favor of ROVs, as diving in deeper waters comes at higher risk and requires technically complex support systems found onboard offshore O&G diving support vessels.

**O&M support, crew transfer, and accommodation.** Operations and maintenance support to wind turbine components located above the foundations or floaters are normally done by technicians landed onto the turbines from either crew transfer vessels or from motion-compensated gangways onboard service operation vessels (Irawan et al., 2023; Lazakis & Khan, 2021). SOVs have quickly become the work horse of the offshore wind industry, as wind farms have grown and are located further from shore. Where crew transfer vessels, often catamarans, are used for transport of technicians to smaller wind farms close to shore, SOVs provide accommodation and a stable platform for safe crew transfer to turbines in rough weather, thereby increasing the size of weather windows for maintenance and repair (Irawan et al., 2023). With the space to carry spare parts and workshops to carry out smaller repair work, purpose-built SOVs have made it more challenging for PSVs repurposed from offshore oil and gas to compete in the offshore wind market (The Crown Estate & ORE Catapult, 2019), without first being retrofitted with additional accommodation space and W2W functionality.

SOV functionality will also be useful in the fish farming context. While the industry will want to move towards autonomy in offshore fish farms to reduce risk to crew, they will likely need to have personnel onboard often to manage the operation (e.g. managing feed distribution, inspecting structures, handling dead fish). A concept of operations where an SOV provides accommodation and safe transfer to wind farms and offshore fish farms that are located sufficiently close to each other, could result in shared, and thereby reduced, chartering costs. W2W functionality provided by actively motion-compensated gangways could be one example of a ship function from offshore wind that easily contributes to improved personnel safety in offshore fish farm operations.

On the other hand, there can only be a limited role for aquaculture service vessels in supporting wind farm operations. The types of services these vessels provide are often related to simple lifting operations, including net handling and cleaning.

**Fish handling.** Handling live fish requires a lot of specialized functionality that has no use in offshore wind. Figure 7 presents the key functions performed as part of the live fish logistics.

**Figure 7: Salmon lifecycle with emphasis on key ship functions.**

Well boats or live fish carriers play a key role in the transportation functions and are built around holding tanks designed to carry fish, with associated circulation systems to maintain good water quality. Importantly, well boat design considers biosecurity measures, to mitigate the risk of disease transfer between fish farm sites. Grading, delousing, and biological treatments are often also performed using well boats. In some cases, these functions are performed by specialized delousing vessels. Like in the offshore wind market, there have also been examples of PSVs retrofitted with delousing equipment for work in the aquaculture industry (AquaShip, 2021; Dixon, 2020).

Fish handling logistics could change because of larger distance to shore and more rough weather. With larger fish cages further from shore, newbuilt well boats have also become larger and more complex. More ships will likely be built with stun, bleed, and chill functionality to avoid detrimental fish health impacts from sloshing during transit from offshore cages to shore. Still, fish handling logistics will to little extent be affected by potential multi-use synergies.

**Emergency response.** Besides similarities in the need for accommodation for personnel, both offshore wind and offshore fish farming will need emergency preparedness. The emergency response needs of the sectors will only partially align, due to the presence of personnel working at sea. Beyond responding to incidents that could harm personnel, the emergency response system in aquaculture also needs to consider fish-related incidents. Compared to the use of emergency response and rescue vessels (ERRVs) in offshore oil and gas, the risk to personnel is smaller in both offshore wind and aquaculture.

Fish escape incidents, algal blooms, and disease outbreaks constitute key concerns in aquaculture that typically will be addressed using vessels with specialized fish handling capabilities (Slette et al., 2022). Disease outbreaks are often managed by removing dead fish and by slaughtering sick fish earlier than planned (Barrett et al., 2022).

### Commonalities in mission requirements

We now turn to providing a summary, qualitative assessment of ship capabilities and commonalities in mission requirements. Table 4 summarizes vessel capabilities needed in offshore wind and offshore fish farming. Eight of the identified special ship types provide functionality that is interesting for both segments. The largest potential for exploiting synergies will be in the project planning and operational phases. In the commissioning and installation phases, highly specialized capabilities are needed on the offshore wind side, that do not lend themselves well to aquaculture.

**Table 4: Ship types and use in marine operations in offshore wind and offshore fish farming. Ship types highlighted in italics score above ‘Low’ in technical feasibility for both offshore wind and fish farming.**

Ship type	Lifecycle stage	Main functions	Offshore wind	Offshore fish farming
<i>Geophysical survey vessels</i>	<i>Project planning</i>	<i>Non-intrusive seafloor mapping, environmental monitoring</i>	<i>High</i>	<i>High</i>
<i>Geotechnical survey vessels</i>	<i>Project planning</i>	<i>Rock and sediment sampling, onboard processing, environmental sampling</i>	<i>High</i>	<i>High</i>
Wind turbine installation vessels	Commissioning and installation/ Decommissioning	Installation of wind turbines	High	Low
<i>Heavy-lift vessels</i>	<i>Commissioning and installation/ Decommissioning</i>	<i>Installation of substations, floating structures, turbine foundations</i>	<i>High</i>	<i>Medium</i>
Cable laying vessel	Commissioning and installation	Installation of inter-array cables inside wind farms, installation of export cables	High	Low
Subsea rock installation vessels	Commissioning and installation	Install scour protection for foundations and cables	High	None
<i>Anchor handling, tug, supply vessels</i>	<i>Commissioning and installation/ Operation/ Decommissioning</i>	<i>Towing operations, installation of mooring system</i>	<i>High</i>	<i>High</i>
<i>Commissioning service operation vessel</i>	<i>Commissioning and installation/Operation</i>	<i>Accommodation, walk-to-work (W2W) system, workshops, spare part storage, lifting operations, construction support, repair</i>	<i>High</i>	<i>Medium</i>
<i>Offshore support vessels (O&amp;G)</i>	<i>Commissioning and installation/ Operation</i>	<i>Inspection, maintenance, and repair operations, lifting operations, diving support, ROV support</i>	<i>High</i>	<i>High</i>
<i>Service operation vessel</i>	<i>Operation</i>	<i>Accommodation, walk-to-work system, workshops, spare part storage, repair</i>	<i>High</i>	<i>Medium</i>
Delousing vessels	Operation	Biological treatments, removal of sea lice from fish	None	High
Well boat	Operation	Transport of live fish (smolts) to offshore fish farm; transport of live fish (mature) to harvest site on land; delousing operations	None	High
Slaughtering vessels	Operation	Onboard slaughtering facilities, cooling and freezing	None	High
<i>Aquaculture service vessels</i>	<i>Operation</i>	<i>Lifting operations, towing, (some) delousing operations, net cleaning</i>	<i>Medium</i>	<i>High</i>
Bulk carriers/multi-purpose vessels	Operation	Transport of fish feed, transport of frozen fish	None	High
Feed barges	Operation	Store and distribute fish feed (integrated in some offshore fish farm structures)	None	Medium

During project planning, the synergies mainly lie in about data and data sharing. By sharing data from previous surveys, impact assessments and seabed surveys could be fast-tracked for a second user of the same marine space.

In the operational phase of the lifecycle, multi-use synergies are present over a long period, making it potentially commercially interesting to take advantage of resource sharing schemes that is enabled by the fact that multiple users operate in the same area.

## Estimate of potential savings

In the final part of this section, we provide a simple estimate of the power savings potential from multi-use synergies, considering the reduction in transit need if logistical demands can be coupled. We also comment briefly on potential fleet level impacts on capital expenditure.

A typical offshore support vessel spends close to 40% in transit, or around 3,000 hours per year (Lindstad et al., 2017). If we assume a similar pattern for special ships servicing the new offshore industries, and that half of the roundtrips are used to service both a wind farm and an offshore fish farm, then the transit time will be reduced by 25%. For simplicity, if we then assume that the same amount of time will be spent in transit at higher speeds, as these are likely missions with higher criticality, and therefore maintains some conservatism in the estimate of savings. If we then assume the average power requirement and specific fuel consumption for a variable speed engine with a specified operational mode, as suggested by Lindstad et al. (2017) and partially reproduced in Table 5, we observe fuel savings of around 5%, as the annual consumption reduces from almost 2,900 tonnes to just over 2,700 tonnes. This calculation assumes the use of diesel oil (for simplicity), and the actual savings potential will also depend on the dynamics of the future fuel mix (including new fuels) and the pricing of these alternative fuels. The effect of the reduced transit on costs might well be bigger, when taking into consideration the pricing of alternative fuels (DNV, 2023b).

Note that the share of time on dynamic positioning and for port loading operations increases when vessels are shared, meaning that there is an even greater potential for fuel saving, as batteries can play a key role during DP operations providing more flexible load. If offshore charging infrastructure is developed at wind farms, batteries may become an even more important part of the fuel mix of vessels serving offshore wind and could realize its potential to improving DP operations providing more flexible load (Lindstad et al., 2017; Holmefjord et al., 2020). Adding to this, we already discussed the role of the EU ETS in incentivizing shipping emission reductions (DNV, 2023b), and note that, all else kept constant, the carbon intensity of the fuel consumed will remain an important operational parameter in years to come.

**Table 5: Example of change in operating profile and annual fuel consumption from shared offshore vessel capabilities.**

Operational mode	Original operational profile		Lower (75% of original) transit share of operational profile – due to co-location		Average power	Specific fuel consumption (variable engine speed)	Annual fuel consumption	Annual fuel consumption
	Annual hours	Share of time	Annual hours	Share of time			(original operating profile)	Lower transit share operating profile
	Hours	%	Hours	%			Tonnes	Tonnes
<i>Dynamic positioning (DP)</i>	2400	27	2920	33	1600	210	806	981
Standby	600	7	600	7	1500	205	185	185
Port	2270	26	2500	29	336	265	135	149
<i>Transit ECO</i>	3000	34	2250	26	2300	200	1380	1035
Transit 12 kn	400	5	400	5	3300	197	260	260

Besides the effects on operational issues like emissions and operating costs, synergistic multi-use will also impact capital expenditure (CAPEX). For a single design case, the CAPEX will likely increase due to the need of catering to requirements for operations in several different market segments. Cost-related pitfalls of multi-functionality as pointed to by e.g. Gaspar et al. (2015) and Garcia et al. (2016) need to be avoided, and principles related to operational flexibility (Lindstad, et al., 2017; Rehn et al., 2019; Pettersen et al., 2020) adhered to, for this to remain a viable business case for ship owners. On the level of the support vessel sector as a whole, successful exploitation of synergistic multi-use logistics means that fewer vessels are needed to service a set of ocean assets. This means that less steel will be needed, further reducing the environmental footprint, and reducing CAPEX on the level of the whole industry. The same could hold true for the fleet design problem facing those ship owners that seek to take advantage of synergistic multi-use logistics.

## OPPORTUNITIES AND BARRIERS

Sharing resources among several actors in the ocean space can be an opportunity to reduce costs, emissions, and to create a culture of collaboration across sectors that otherwise would compete for access to ocean area. We have established where the potential for sharing and synergistic multi-use lies, by identifying ship types that provide functions that can be useful in a multi-use setting. We now turn to discussing what key opportunities and barriers that exist to realizing this potential.

### Opportunities

#### *Reducing fuel consumption and operating costs by sharing logistics*

From the perspective of an offshore wind farm or an offshore fish farm, the costs associated with chartering in special ships for the operational phase will constitute a relatively small share of the lifecycle cost. In offshore wind, operating costs overall constitute 25-30% of the lifecycle cost, of which a relatively small part will be vessel chartering during the operational phase. Still, sharing can constitute an interesting cost cutting measure, when seen along with developments like the introduction of carbon pricing. If shared logistics, as indicated in Table 5, in some cases can realize a 5% fuel saving, this is an opportunity that should be welcomed by ship owners and charterers.

The previously referred *NEXUS* project also provided some new insights into the feasibility of fully electrical operation of vessels at a wind farm (Holmefjord et al., 2020). Such operations are feasible provided sufficient infrastructure for charging is in place together with sufficient onboard energy storage (e.g. batteries). The opportunity to use renewable energy directly from a wind farm to charge offshore vessels is now being explored by several (Stillstrom, 2023; Memija, 2023), while ship designers are working on conceptual designs where space for sufficient energy storage and charging technology is integrated in close dialogue with owners and regulatory bodies (flag authorities and classification societies as DNV), see e.g. The Naval Architect (2024).

#### *Reducing conflict potential through co-existence and multi-use*

Besides the purely technical-economical argument above, the reduction of conflict potential that can be enabled by multi-use is substantial. From the discourse on the impact of offshore wind on other stakeholders, there is still a clear tendency to focus on the conflicts, which could hamper the “social license to operate” that any sector will be dependent on to some extent. This is most clearly seen in the relationship between offshore wind and the fisheries. Again, focusing on the potential synergies of this situation, rather than the trade-offs in what is quickly perceived as a zero-sum game, can create an atmosphere of collaboration between stakeholders.

The clearest marine design dimension to this question is the use of vessel capabilities for new types of operations. In the spatial relationship between offshore wind and the fisheries, compensation schemes to fisheries due to their exclusion from certain areas have been discussed. From other offshore sectors like oil and gas, there are examples of fishing vessels playing a key role in supporting emergency response operations, as exemplified by the Vessels of Opportunity-scheme deployed to participate in oil spill clean-up operations after the Deepwater Horizon accident (Pettersen et al., 2020). Identification of *latent capabilities* that were not intentionally designed for, can make fishing vessels useful in offshore wind operations or offshore aquaculture and could be a path to explore further.

#### *Novel ways of meeting offshore wind tendering requirements*

Co-existence is also finding its way into tendering requirements for offshore wind. In some cases, this could take the form of binary conditions, e.g. “it is required that the applicant has a co-existence plan”. In other cases, non-price criteria are being shaped to award offshore wind tenders based on more quality parameters, including the design of specific measures that will ensure successful collaboration with other ocean stakeholders over the field lifecycle. This can be measures such as nature restoration by re-introduction of lost habitats (Pardo et al., 2024), or farming of blue mussels and kelp to extract excess nutrients from the sea, thereby improving water quality and/or providing human food.

Taking the arguments made in this paper further, these overarching government tender requirements could also percolate down to the specifications of chartering arrangements that ship owners will need to comply with to win contracts. For instance, could the future see chartering contracts being more explicit on the vessel’s ability to also provide support to a co-located aquaculture operation?

## Barriers

### *Technical barriers*

Technical barriers to realizing synergistic multi-use related to the functionality of specific solutions. If there are significant amounts of mission-related systems onboard which are useful in the context of offshore wind, but without applications in the other sector to service, e.g. offshore aquaculture, then there is limited potential. The discussions in earlier parts of this paper largely screened for vessel types that can have applications in several sectors and sought to answer to what extent functionality from ship segments serving offshore wind, e.g. SOVs, could service offshore aquaculture. If similar solutions are sought out, for instance heavy-compensated gangways to improve operability and personnel safety, then the design features on the side of the offshore fish farm should be introduced to ease the compatibility with SOVs. For instance, the DNV class rules for floating fish farm installations lists “offshore gangways” as a relevant optional class notation (DNV, 2022a).

### *Operational barriers*

Multi-use concepts have been observed to cause certain ambiguity in risk ownership, causing some authorities to impose operational restrictions for safety reasons (van den Burg et al, 2020). For instance, safety zones are one example where other activities are effectively banned from the vicinity of another. These might have good reasons, as in the case of oil and gas installations, but might be too strict for other types of offshore platforms.

Furthermore, if multi-use concepts are not restricted by e.g. safety zone issues, there still might be the need for development of appropriate operational procedures to allow for new types of vessel-structure interactions, for instance when an SOV services an offshore fish farm. In such cases, the successful operation of vessels in a multi-use logistics context also becomes a function of organizational factors like crew competence, training, and experience.

Finally, mission criticality considerations will also play a role as an operational barrier, seeing that an unplanned repair operation at the wind farm may need to take priority over a planned mission to service the offshore fish farm. If so, what should dictate when an unplanned mission at production system *A* should take priority over a planned mission at the co-located production system *B*? And who should pay?

### *Commercial barriers*

The question posed above illustrates the core limitation to realizing synergistic multi-use logistics from the commercial point-of-view. Chartering arrangements need to reflect the co-use of vessels for both purposes and determine how the risks associated with the operations should be spread. The ease of creating a joint chartering arrangement could come down to factors such as organizational structure of the offshore wind/offshore fish farming operator. For instance, does common ownership over both production systems imply that establishing a joint chartering arrangement is easier? Would horizontally integrated companies that operate across several blue economy sectors like renewables and seafood more easily see the potential for multi-use synergies, and be more likely to realize them?

A second commercial barrier is related to the cost of managing the complexity of two disjoint operations. We observed earlier in the paper that the share of vessel-related costs during the operational phase of a wind farm (or a fish farm for that matter) is only a small share of the total operating costs. Hence, the increase in transaction costs related to managing a much more complex chartering arrangement may not be worth it, from the point of view of the charterer. Also on the supply side, a similar problem might exist, particularly in good times, when rates are high. Who would then bother taking on a more complex arrangement that may not pay a sufficient premium?

## CONCLUSION

In this paper, we have introduced the concept of multi-use of marine space to the ship design audience. Where ideas of multi-use and co-existence have emerged in the marine spatial planning research community, there has so far been little work on understanding the roles special ships can take in a Blue Economy shaped by the need for sharing of maritime resources. We have provided an overview of some key drivers for marine multi-use and sharing of vessels in this setting and provided a qualitative assessment of key operations performed in offshore wind and aquaculture, aiming to identify areas for synergistic multi-use.

We have also provided insight on the key pros and cons of moving towards synergistic multi-use, pointing to drivers like reduced costs and emissions, as well as reducing conflict levels. The need for emission reductions and stakeholder collaboration appear to be the strongest drivers. On the side of barriers, chartering needs to take into consideration longer response times to missions of high criticality, and to consider how risks should be allocated.

While there are clear benefits, we ended the discussion with a set of more cautious remarks about the barriers. Further research could take a closer look at the shipping economics at play, the trade-offs, and the conditions under which synergistic multi-use would make sense. Assessments of multi-purpose platforms so far, at best, provide a mixed bag of results and with the previous experience from multi-functionality in offshore support vessels, there is reason to approach the concept with cost and emission reductions in mind first.

# Utilizing Amphibious AGVs to Optimize Container Transshipment for Deep Sea and Hinterland Operations

Abhishek Rajaram<sup>1,\*</sup> and Lavanya Meherishi<sup>2</sup> and Jovana Jovanova<sup>1</sup> and Andrea Coraddu<sup>1</sup>

## ABSTRACT

*Transshipment is a key component of modern-day shipping logistics. Container supply chains rely on transshipment hubs to access remote locations. With globalisation driving growth in container trade, maritime congestion is rising at container terminals in ports worldwide. This is expected to worsen as demand continues to grow. This research explores novel maritime equipment designs that can contribute to solving problems in the trans-shipment chain. One such idea is that of the Amphibious Automated Guided Vehicle, an innovative concept that travels on both land and sea. Envisioned as a tool to minimise the rehandling of containers, the Amphibious AGV forms the heart of the new changes that this research proposes for the future of trans-shipment. Complementing swifter trans-shipment, the research also proposes complementary design concepts such as floating terminals to add more flexibility for container ships and Amphibious AGVs applied to exchange containers offshore. To validate these ideas, an agent-based modelling methodology was used and replicated in the environment of the Hong Kong- Pearl River Delta. This work, therefore, opens up an intriguing future scope for maritime transshipment that is both sustainable and adaptable while also discussing limitations and concerns that need to be carefully considered.*

## KEY WORDS

Marine Design, Transshipment network, Floating Terminals, Amphibious AGV, Agent-Based Modeling

## INTRODUCTION

Globalisation has sprung up a huge surge in international trade. With the increase in international trade, container trade has also seen a substantial increase in the last few years. With container ships getting bigger, both inland and deep sea terminals are seeing massive volumes of container flow daily. Consequently, hinterland transportation networks have become extremely important for trade and accessibility worldwide. In this era of globalization, an increasing number of inland cities are playing pivotal roles in global trade by supplying electronics, essential goods, and even food items. However, with this growth, deep sea terminals that are often the gateways for inland container traffic become congested with the influx of multiple barges. In the ports of Rotterdam and Antwerp, terminals that often only see 1 ultra-large container ship a day would see 23 barges dock by the terminal (Shobayo and Van Hassel, 2019).

This number amplifies to 120 barges in busier ports like Hong Kong (Seatrade Maritime News, 2015). This contributes to arrival/departure problems, berth planning issues, and quay crane allocation problems in ports (Tang et al., 2022). Often, terminals are forced to use deep-sea berths to unload waiting container barges, preventing bigger ships from docking. Congestion in many other regions of the world, such as the United States, has taken a different turn, with the Port of Los Angeles

and Savannah seeing queues of up to 100 vessels, of which 70 of them were container vessels (Bu et al., 2023). Ports in the United States saw a massive increase in dwell times by 27.4% in 2021 compared to 2016. Similarly, in the Port of Rotterdam and Antwerp, only 41% of barges arrived/departed within a two-hour window that is usually reserved for barges. From a policy side, congestion has caused tensions between barge operators and deep sea terminal operators since the former and latter do not share any contractual relationship (van der Horst et al., 2019), therefore not obligated to pay berth fees while spending 1/3rd of their operational time at deep sea terminals (Konings, 2007).

Compounding the issue, when the world's two busiest waterways, namely the Rhine and Yangtze rivers, were compared, their different upstream and downstream dynamics warrant solutions that are globally applicable to solve congestion (Notteboom et al., 2020). In the context of barges and inland waterways, congestion is also caused by multiple trips originating from the same inland port, which is a direct consequence of low container call sizes. Port of Rotterdam and Antwerp have seen this problem escalate at their deep sea terminals with call sizes as low as 6 TEU per barge trip with an average of just 33 TEU per deep sea terminal during a barge trip (Konings, 2007). This has meant that despite a priority for deep sea ships, some deep water berths are forced to block 3000 TEU+ ships to unload barges (Shobayo, 2023). This has also mounted to the congestion in container terminals with repetitive barge trips. Historically, this has called for better coordination and information exchange between deep-sea terminals and hinterland barge operators, but such alliances are not in place, and expect to take a long time before anything materialises (Wiegmans et al., 2018). When the issue is analyzed from a global perspective, the urgency to solve the problem of congestion is underlined by the fact that seaport/terminal inefficiency in handling container shipments will lead to higher maritime transport costs, which will eventually influence the prices paid by consumers for goods due to container holding costs (Sanchez et al., 2003). In its worst manifestation, COVID-19 showed how these prices could worsen when holding containers raised shipping costs 10-15 times in 2021 (Freightos, 2023). For instance, in 2021, freight rates for shipping a 40ft container from the USA to China skyrocketed to \$20,600 (Regular cost- \$1400). While congestion is never expected to impact trade as COVID-19 did, inefficiency in the supply chain can compound existing delays. Maritime congestion, therefore, sees terminal inefficiency as one of its leading causes. With the enormous growth in container trade and more markets and inland ports being breached, congestion at deep-sea terminals is imminent. This would essentially segue well into exploring terminal and port expansion through land reclamation, but this has many inherent issues. Singapore, one of the most prominent ports in the international shipping line, expanded in 2014 to increase the number of deepwater berths to 15, aiming to boost container throughput to 50 million in the coming years. However, this was not without its drawbacks, as the expansion severely impacted the ecological welfare of nature reserves despite preventive measures (Lian et al., 2015). This warrants a solution that is also sustainable. From a social sense, taking the example of the Port of Hong Kong, the terminals, which see 120 barges/day, are unable to expand due to the impending housing crisis in Hong Kong, which has threatened to close some terminals to create space for housing complexes and settlements (Chong and Li, 2020). Congestion in such circumstances will only worsen with fewer avenues of expansion. This has knock-on effects on daily schedules with worsening berth management issues. Shifting hub ports like Hong Kong to another place or creating new hubs is not viable in the maritime industry as various inland waterway ports are directly linked to these hubs. Some examples include Hong Kong- Pearl River Delta, Antwerp/Rotterdam- Rhine, and Shanghai- Yangtze. However it is not only the lack of expansion space affecting terminals, congestion is both a consequence and a cause of inefficient container handling operations that are seen today which is a constraint of technology and manpower. While ports have become more autonomous and have achieved the pinnacle of technology with the introduction of AGVs, automated quay, and yard vessels, it has still not solved vital issues such as rehandling of containers where a lot of time is lost even today (Caserta et al., 2011). Most containers lose time transiting between different types of vehicles, both in port and on water. A container transfer between two terminals would need the use of an AGV+Barge (Schroër et al., 2014), or the use of a truck which would have to travel 20+ km on land when the terminal is just 2km across water (Ghiridharan, 2023). Both transfer methods lead to delays in handling incoming and outgoing container consignments from partner terminals or inland entities, leading to higher dwell/waiting times for deep sea ships and especially barges, which generally look for quicker turnaround times (Chen and Schonfeld, 2010), given their low call sizes. This is also a domino effect, with rehandling often leading to container relocation problems in stacks/yards. Looking at the bigger picture to understand the cascading phenomenon, ship delays due to congestion have seen an increase in rehandlings by 44% in worse-case scenarios, and it gets worse with growing demand call sizes and container reshuffles aggravating maritime congestion (Gharehgozli et al., 2017).

Deep Sea- Hinterland transportation, therefore, has multiple challenges. It has to grow sustainably while addressing congestion, efficient inter-terminal and inland transport, and minimize or eliminate land reclamation while opening new avenues for expansion. With global trade set to grow by 70% in 2030 (Gibson, 2021), container handling at both deep-sea terminals

and hinterland must be efficient to enable seamless trade windows for international deep-sea vessels and domestic barges. The trade targets also bolster the need for new perspectives in container shipping for the future. Thus, this paper describes and analyzes the implementation of marine design concepts that can provide a novel outlook for deep sea to hinterland transportation.

According to the literature review, we identified four areas that would need new perspectives. These include: i) the minimization of container rehandling, ii) addressing low call sizes of barges, iii) identifying alternate avenues for expansion, and iv) an integrated network design and methodology to implement this novel trans-shipment idea. Most of the research carried out so far has emphasized on optimizing existing networks through various analytical and lean approaches to address bottlenecks (akin to point iv). However, as seen in the introduction and problem analysis, it is clear that certain design concepts are directly responsible for increasing container handling and barge congestion. This is where novel design approaches and methodologies are needed to enhance the performance of major container transshipment networks.

Therefore the goal of this work is to introduce such novel designs addressing each of the four points listed above and applying it to a real-world container transshipment network namely the Hong Kong- Pearl River Delta with the aim to reduce barge congestion, maintain stable container throughput and container transport time while also enabling future avenues for growth in such ports. This work aims to present preliminary design concepts that can enable a framework to address the four burning issues of this research.

The structure of this paper is organized as follows: Section **Related Work** introduces the state-of-the-art, providing a foundation for the research. This is followed by a detailed presentation of the methodology in Section **Methodology**, where we outline the authors' proposed approach for addressing the transshipment problem, encompassing both the theoretical design and practical implementation aspects. Subsequently, Section **Case Study** describes the validation of the proposed transshipment solution through a meticulously conducted case study. The findings from this case study are thoroughly examined in Section **Results**, where the effectiveness of the new transshipment method is evaluated. Finally, Section **Conclusions** concludes the paper, offering key insights derived from the research and suggesting directions for future work in this area.

## RELATED WORK

This section is dedicated to providing a comprehensive overview of the existing literature and prior work that has significantly shaped the direction of our study. Much of the research in the maritime domain has traditionally been conducted with a focus either on design aspects or optimization techniques. However, instances where both design and optimization methods are integrated are notably rare. This gap highlights the unique contribution of our work, as we aim to synthesize these two approaches to address the challenges in the maritime field more effectively.

**Barge Congestion Challenges- Addressing Call Size Variability:** the congestion of barges at deep-sea terminals and along inland waterways presents a significant challenge, arising from a blend of operational and policy-related issues. This subsection explores the variability in call sizes across different ports, such as Hong Kong, and discusses the economic advantages of barge transport. It highlights the efficiency and cost benefits of barges compared to other modes of transport, emphasizing the global shift towards increased hinterland transport. The congestion of barges at deep-sea terminals and along the inland waterway has generally been caused due to a combination of operational and policy issues. One of the recent works aimed at solving barge congestion in part uses an agent-based modelling approach (Shobayo and Van Hassel, 2019) and makes important suggestions on how a mandate/contract needs to be agreed upon for a minimum number of containers that a barge calls at a terminal. The work suggests 30 TEU for the environment of Rotterdam and Antwerp as a minimum call size. The effects of this would be reduced port calls, and therefore reduced congestion. An earlier work which focused on opportunities to handle denser barges in the future (Konings, 2007) also corroborated the idea of having a minimum agreed-upon call size. This figure, however, is not universal with the port of Hong Kong recording call size anywhere between 50 TEU (Seatrade Maritime News, 2015) TO 120 TEU (Post, 1994) with 120 barges a day. The motivation to use a higher (and minimum agreed upon call size) is also complemented by research which has shown that barge transport costs as low as 12.6 Euros per 1000 Ton kilometers when compared to trucks and trains that cost 4 times as high (Gharehgozli and Zaerpour, 2018). Similarly, even regarding mileage, barge transport records 576 miles/ton/gallon compared to 413 in trains and 155 in trucks (Bu et al., 2023).

Ports worldwide are also increasing the proportion of hinterland transport given its cost and fuel benefits, with Rotterdam and Antwerp increasing the share to 45% by 2030 (Gumuskeya et al., 2020). Higher call sizes, in that sense, would benefit both barge companies and terminal operators in reducing trips. Congestion, when seen from a sustainable expansion point of view, brings numerous possibilities. A general deep sea terminal has provisions for deep sea ships, feeders, and barges.

**Innovative Terminal Solutions to Combat Congestion:** innovations such as dedicated handling spaces and the barge hub concept are explored here. These solutions aim to efficiently reconfigure terminal space, promoting larger call sizes and potentially reducing congestion, while also addressing their scalability and feasibility challenges. This section covers the development of integrated terminal ship transfer systems and other direct trans-shipment methods. Such advancements aim to streamline operations, reduce the use of unnecessary vehicles, and offer cost-effective alternatives for terminal expansion. Research has also explored dedicated handling spaces for barges and feeders, with the barge hub being a prominent example of reconfiguring existing terminal space without unnecessary land reclamation (Pielage et al., 2007) (Konings et al., 2013). A barge hub would be an intermediate terminal that extends hinterland services by shifting the centre of congestion from deep sea terminals to an area accessible by hinterland actors. This concept also encourages larger call sizes to flow in at once drastically reducing barge frequency. A major drawback of this shown in research (Nicolet et al., 2023) is that barge hubs work predominantly for small cargo volumes given that expansion would result in similar problems to deep-sea terminals and could cause similar levels of congestion. Location often would also become a contentious point if even feeders and deep sea ships had to be handled, reducing versatility (Konings, 2007). The Barge hub would still need investment in the yard, vehicles, and straddle carriers. A more flexible concept has been seen in floating terminals, which have been explored in various sustainable and modular forms. Initial concepts include repurposing post-panamax vessels with on-board harbour cranes for loading and unloading containers (Baird and Rother, 2013). The quay of 300 m would be long enough to support up to 3 standard rhine barges or two feeder ships and would cost 1/3rd of a regular terminal. Despite its cost benefits and stability certification, such a concept would not be able to accommodate as many quay cranes as needed and would lose time in loading, unloading, and transfer, thereby contributing to higher waiting times and congestion. When connecting this idea with container rehandling concepts are needed to reduce this rehandling, desirably through direct transfer trans-shipment between ships, minimising storage for repositioning (Shen and Zhang, 2015). These have been manifested in a 2020 work that discussed exploratory concepts for floating terminals (Iovanova et al., 2022). Simulated in the Port of Genoa, the floating extensions were modular and used carrier cranes that could simultaneously transfer containers overhead from one vessel to another. This would essentially reduce rehandling and the number of ground vehicles and space in the process. The drawback here was that the lack of yard space meant that even temporary storage was not possible. However, a work within the same timeline by Johannes March proposed an integrated terminal ship transfer system (March, 2020). While this is not a floating terminal out and out, the benefits of direct trans-shipment were shown using a similar over-the-head crane that spanned across an ultra-large container vessel, a feeder/barge, and also part of the quay/yard. This concept eliminates unnecessary vehicles and simplifies container access points from respective ships/yards. The research also claims a 50-80% reduction in overall investment and is an important consideration for alternate container expansion approaches. However, hub and spoke limitations and approaches concerning hinterland hubs also need to be considered regardless of floating terminal versatility as depicted in works done on Port of Antwerp and Rotterdam (Caris et al., 2011; Konings et al., 2013).

**Rehandling of Containers during Inter-Terminal Transport to Reduce Congestion:** technological innovations, including waterborne AGVs and the Amphibious AGV, are discussed for their potential to transform inter-terminal transfers and reduce container handling points, illustrating a shift towards autonomous and efficient maritime logistics operations. The port feeder barge concept is examined here, highlighting its potential to improve inter-terminal transport efficiency through faster loading and unloading processes. The potential resistance from traditional terminal operators to this innovation is also discussed. Addressing an identified problem of inter-terminal transport through trucks, another important idea in research that looks to solve container rehandling, call size issues, and congestion is the Port feeder barge idea (Malchow, 2020). This is essentially a crane-on-barge concept with a capacity of 168 TEU, aimed at serving small inland barges with swift loading, unloading and instant transfer. The port feeder barge has the potential to shorten multiple inter-terminal transfers on water (from 20km to 2km (Ghiridharan, 2023)) and reduce the overall time spent for barges within the port. While this idea is promising to solve congestion, as pointed out in another research (Nicolet et al., 2023), deep-sea terminal and hinterland operators could resist the involvement of a third party for stevedore operations. Eliminating the hassle of operators, the waterborne AGV was developed with a vision to enable swift inter-terminal transfer and transshipment. Envisioned to be operated by deep sea terminals, the waterborne AGV is essentially a 2 TEU AGV that traverses on water instead of land (Zheng et al., 2017). The waterborne AGV uses azipod thrusters for propulsion and is currently in the prototyping phase at TU Delft. The waterborne AGV is

promising, given its autonomous nature and the extensive research in inter-terminal transport. Complementing its significance, waterborne AGVs have also been simulated in cooperative control using a fleet of WAGVs either as a swarm or platoon in Port of Rotterdam conditions, displaying its versatility (Chen et al., 2019). Given the Maasvlakte's expansive layout, literature has also corroborated with Waterborne AGV's efficiency over trucks in reducing time, distance, and emissions for container transfers (Zheng et al., 2016). However, container rehandling remains an issue. Recalling previous literature accounts and sections, just as how an AGV or Truck + Barge is needed to move containers between terminals, similarly the waterborne AGV would still be involved in a switch with another truck or ground AGV. The handling points in the system would remain the same and in case of any ship delays, as seen earlier (Gharehgozli et al., 2017), handling times could compound by 44% or worse. Furthermore, this adds to the high number of trucks and AGVs that the terminal already has to operate, aggravating land and water-based congestion. The handling point can only be eliminated or reduced if a concept combines land and water handling capabilities. That is where the Amphibious AGV(AAGV) comes into the picture, a nascent yet significant concept in the broader terminal operations picture. The AAGV is again another 2 TEU vehicle that can travel on both land and water. Envisaged as an instrument to reduce container handling points in the supply chain, the AAGV was first designed as a general transport vehicle in 2019 (Kleefstra, 2019). It was subsequently redesigned by a TU Delft project team featuring the primary author of this research paper. The AAGV in preliminary findings (Abhishek Rajaram, 2023; Ghiridharan, 2023) produced a 21% saving in transfer times between container terminals. In both the aforementioned recent works, the AAGV reduced handling points, reducing barge/feeder waiting times and opening avenues for versatile implementation in tandem with concepts such as floating terminals.

**Simulation Techniques for Congestion Analysis:** this section delves into the use of simulation techniques, such as discrete event simulation and agent-based modeling, in analyzing maritime congestion and evaluating the effectiveness of proposed solutions. Recent advancements in addressing barge congestion have leveraged agent-based modelling techniques. Studies have effectively used agent-based modelling to address call size issues by implementing a minimum call size for barges at terminals, with recommendations for specific sizes in ports like Rotterdam and Antwerp, to alleviate congestion. When seen from an implementation point of view, maritime networks often follow either hub and spoke theories, point-to-point theories, or a combination of both (Tagawa et al., 2021). From a simulation standpoint, various approaches have been discussed to present the barge congestion situation accurately. One is by sequentially planning events, and this is discrete event simulation in research; this has been successful in modelling waterways (Bu et al., 2023), berth planning (Legato and Mazza, 2001) and also container yard management (Kotachi et al., 2016). However, this type of simulation is not capable of doing parallel processing, which would otherwise be possible in an agent-based modelling approach. Agent-based modelling (ABM) approach is an approach where every entity has autonomy while interacting with other entities. These entities are the agents in the simulation. For example, suppose a barge, Quay Crane, and Container terminal are considered agents. In that case, these agents have their functions, such as loading, unloading, and container inventory management, while they have separate interactive functions, such as loading and then leaving. ABM has found its relevance in various areas of container shipping, namely in frameworks for reducing congestion (Shobayo and Van Hasse, 2019), container terminal productivity (Mazloui and van Hasse, 2021), and most importantly, in both inter-terminal transport (Iqbal, 2015) and interland (Feng et al., 2015).

A review of existing research and best practices has shed light on how to tackle the complexities of transshipment between deep sea and hinterland terminals. This exploration revealed four crucial areas demanding attention: i) minimizing the number of times containers are picked up, moved, and put down is essential. Streamlining container movement within terminals is key to achieving efficient operations; ii) traditional methods of expanding container terminals may not suffice. Exploring innovative solutions is crucial to accommodate the ever-growing volume of cargo; iii) currently, barges might not be filling to capacity, leading to inefficiencies. Optimizing barge loading schedules and sizes is essential for a smooth flow of goods.; iv) implementing a novel transshipment network requires a comprehensive strategy. This includes carefully planning and managing the system to ensure its effectiveness. This narrative approach uses figurative language and storytelling elements to make the content more engaging and easier to understand. It highlights the challenges in a way that is clear and memorable.

## METHODOLOGY

The methodology of this work is divided into four distinct phases. The first phase targets the rehandling of containers. This is considered an important link, given that rehandling can only be addressed using a different transporter design. Subse-

quently, the next phase targets alternate avenues for expansion with the same design description. The third phase will focus on addressing existing barges' low call size situation. Since this is not a conceptual or cosmetic design change but merely an increase in call size, this will not be explained in detail. The final phase of the methodology describes a comprehensive design of the transport systems network implemented with a simulation approach. This methodology will then be validated through simulations in a real port environment that connects the deep sea and hinterland.

## Phase 1 - Address Rehandling of Containers

### *Amphibious AGV Design*

The review of the state of the art has helped identify key problem areas such as rehandling of containers between truck and barge, and longer and unnecessary routes for inter-terminal transfers. Several promising concepts were studied, namely waterborne AGVs, Port Feeder Barges, and Amphibious AGVs. Port feeder Barges suffer from operator compatibility issues (Nicolet et al., 2023). While waterborne AGVs were promising in their design and research availability, it became clear that rehandling issues still appear despite the reduction in inter-terminal transfer time and distance (Zheng et al., 2017). As the related work section states, Amphibious AGV is a container AGV that can traverse on land and water. This was specifically designed to address container re-handling problems and reduce inter-terminal distance. The Amphibious AGV went through various design cycles with three concepts being considered. This included a standard AGV chassis modification as the first idea, with hovercraft and catamaran designs also being considered. After being evaluated on a multi-criteria analysis of stability, complexity, manoeuvrability, efficiency, and cost, the standard AGV design was chosen owing to its design and dimensional compliance with current container AGVs on the market. As depicted, the design of the Amphibious AGV has been adapted specifically to handle geographical disparities. Changes in this include creating space for the water propulsion system. Since this is envisioned as a sustainable vehicle, the propulsion is all electric. Therefore, space is also made for the battery pack placed in the centre of the main chassis. This is shown in the form of boxes in Figure 2. The battery pack is estimated at 600 kWh. The battery pack itself is made up of 42 modules of 6.3 kWh each. These are stacked in three separate blocks of 12, 12 and 18 modules, amounting to 710 kWh. The chassis itself measures 16.6 m (length) x 3 m (width) x 1.8 m (height). This allows enough space for mounting a fully loaded 40-foot container (or two 20-foot containers) and space in front and rear to accommodate the pump jet system, marked in red in Figure 2. The pumps are also flanked by 4 electric motors at the wheels for ground propulsion. The Amphibious AGV also has more angled edges than regular ground AGVs. This makes it hydrodynamic, and the edges serve as a breakwater against waves should it encounter waves in port waters. The original design of the Amphibious AGV also had 4 holes to incorporate a SAE 316 stainless steel-based locking system to connect with other Amphibious AGV. However, this system has been disbanded for this work since such contraptions on water could create more instability. To enable floatation on water, the Amphibious AGV also has pontoons which will be delineated later. Given that the Amphibious AGV will also be in contact with water, choosing non-corrosive and water-resistant materials was important. While stainless steel would have been the best choice, due to cost concerns carbon steel was chosen for the body of the Amphibious AGV given that it offers similar performance levels as stainless steel. The pontoons have to be of high strength and flexibility. Taking inspiration from hovercraft designs, the pontoons are made of nylon base cloth, with the outer layer being made of natural rubber and neoprene. These are strong enough to resist the internal air pressure and buoyant force.

**Figure 1: AAGV Body Exterior**

**Figure 2: AAGV Body Interior**

The land mode of the Amphibious AGV has been depicted in Figure 3. In this scenario, it is clear that the pontoons can be retracted because they would not be needed on land. Only the electric motors would be at work in land mode, drawing power from the battery pack. The Amphibious AGV was designed with the assumption that they would travel on ramps to enter or exit water. There will be a point between land and water where land and water-based propulsion and powertrains are used to enter water from land or vice-versa. The AAGV in water mode has been depicted in Figure 4. In this mode, the floatation pontoons are activated and marked in yellow in the figures. As mentioned earlier, the AAGV will engage both land and water-based propulsion systems while transitioning from the ramp to water. Subsequently, it will switch to completely water-based pump jet propulsion. The locking mechanism while still present can be used for locking with quays of container terminals but this is optional and does not affect the functionality of the Amphibious AGV.

**Figure 3: Land Mode- Isometric View**

**Figure 4: Water Mode of The AAGV**

The amphibious AGV consists of salient mechanisms that stabilize it on water and lay frameworks for future dual power-train concepts. The idea of pontoons on the AAGV was deemed necessary due to the low centre of gravity of the Amphibious AGV. This is caused due to the 5000Kg battery pack and 7000Kg propulsion. pump and powertrain systems installed. The Amphibious AGV was designed considering short-haul transfer between terminals on water and within, land. The above specifications on power were computed considering a slope of 3 degrees, wind speed of 20 m/s, a maximum operating speed of 12 Km/hr and acceleration of 1 m/s to support a maximum load of 75 Tonnes. Using these considerations, a maximum power rating of 457 kW is obtained for terrain with the slope. It is prudent to note that the ramps used for entry and exit of AAGV from land to water or vice versa are set to 3 degrees. In regular flat terrain conditions, the Amphibious AGV only requires 331 kW of power to transport 75 tonnes. In terms of energy consumption, a container AGV moves a few hundred metres to some km per day. Given the functionality of the Amphibious AGV, each cycle of operation is assumed at 25km over 8 hours after which the battery is swapped. The battery capacity is therefore calculated to be 710kWh. The same Amphibious AGV's

batteries will be swapped when empty and a standard swap takes between 6-7 minutes as mentioned in industry (Konecranes, 2023) and literature (Schmidt et al., 2015). Therefore 3 shifts of an Amphibious AGV is achievable with 75km of daily range. Summary of major power-train specifications are given in Table II.

The water propulsion system will consist of 2 Schottel SPJ 30 C pump jets (Odetti et al., 2019) that can give a combined output of 200 kW. While a maximum of 250 kW was computed for a top speed of 8 knots, it must also be realised that if the admiralty formula (Giernalczyk et al., 2010) is considered, a lower velocity of 6 knots would deem 200 kW as sufficient power to propel 75000 Kg of load. These calculations have been done considering a pressure of 135 PSI at 85% volumetric efficiency. The speed considerations of the Amphibious AGV( initially developed for Port of Rotterdam) are based on their speed limits imposed by the Port of Rotterdam (Centre, 2014). With a near 70% of travel distance slated to be on water, the pumps would consume 495kWh of energy during an 8hr operational period. This is the full load capacity of the AAGV of which 54000 Kg is from the fully loaded containers which can be either a single 40 ft container (29000 Kg) or two 20 ft containers (54000 Kg). The remaining masses are comprised of the Amphibious AGV chassis (8000Kg), the electric drives and motors (8000 Kg), water-based propulsion system (4000 Kg) and the pontoon-based support structures (1000 Kg). On an operational level, the amphibious AGV is assumed to function 24 hours a (Liu et al., 2001) for 315 days a year since some days may also be used for servicing and maintaining the AAGV. This amounts to 7500 operational hours in a given year.

The stability aspect of the Amphibious AGV on water was not tested primarily but computed with logical assumptions. The Amphibious AGV when fully loaded with 2 TEU would weigh 75000 Kg and the design is akin to that of Inland barges which generally have fuller hulls(block coefficient of over 0.8). The Amphibious AGV features a fuller hull as well and places stability over maneuverability given the linear range of routes and guideways on land and water. The Amphibious AGV is also underlined by the fact that when fully loaded 75% of the body will be under water while 25% remain above. To enable this buoyancy, pontoons are inflated before the Amphibious AGV enters the water. With a requirement for 25% buoyancy, the pontoons should provide an upthrust of 185 kN(against a downward force of 735kN). The calculated volume of both pontoons are 24.505m<sup>3</sup> with a radius of 0.736m and a 7.2m pontoon length. The pontoons will be filled with air using Grundfos NB 150-315 pumps(Grundfos, 2024)capable of pumping at a flow rate of 447.8m<sup>3</sup>/hr. This implies that the pontoons will be filled in 1.65 minutes. The pumps are rated at 37kW and at a maximum flow rate, each inflation/deflation would draw an energy of 2.035kWh for both pontoons which is 0.3% of the total battery capacity. It must also be noted that inflation holds more precedence over deflation as most port roads have space to accommodate Amphibious AGVs with fully inflated pontoons in the event of low battery. The pontoons also have 4 equally sized air-tight chambers, which implies that in the event of a puncture and water infiltration, only one out of the four pontoon segments would be impacted and the Amphibious AGV can return to safety. The Amphibious AGV also has space for ballast tanks placed over the battery with dimensions of 7.5m x 2.4 m x 1m translating to a capacity of 18000 Litres of Water which can be adjusted corresponding to on-board payloads or even a pontoon puncture as cited by the reviewers.

**Table 1: Powertrain Specifications**

Specifications	Values
Battery Voltage	720 V
Motor Power Rating(without slope)	331000 W
Motor Power Rating(with slope)	457000 W
Motor Maximum Loading Capacity	75000 Kg
Total Loading on Vehicles	54000 Kg
Distance Covered in a day (3 Shifts)	75 Km
Max Speed on Land	12 Km/hr
Operational Hours per day/AAGV (3 Shifts)	24 hours
Working days in a year	315 days
Operating Hours in a year	7500 hours
Travel in a year	23625 Km

While the author and previous works did not dive into the control system aspect of the Amphibious AGV, the Amphibious AGV is envisioned to function both by itself and in a coordinated control manner akin to the vessel train formation (Chen

et al., 2019) and cooperative control (Chen et al., 2020). The subsequent part of this research in phase 4 will discuss the agent-based modelling implementation that links terminals, containers, and transporters such as barges and feeders) with the Amphibious AGV's schedule. This is linked with routing systems that direct the Amphibious AGV to the concerned berth on water/yard position on land. This will fully utilize the Amphibious AGV's capabilities while also trying to ensure that it runs full-load trips on both journeys in the port conditions. From a stability point of view, ballast tank water levels can potentially be managed by a Model Predictive Control system (Negenborn et al., 2009) that uses a cost function that minimizes instability by maintaining appropriate tank levels.

The Amphibious AAGV will use ramps to enter and exit container terminals. These ramps resemble roll-on/roll-off ramps used in car carriers and ferries. The Amphibious AGV has been designed to handle slopes of 3 degrees at peak speeds. The optimum speed assumed for roll-on roll-off slopes is 9km/hr based on literature (Di Ilio et al., 2021). These will be passive ramps installed at quays of container terminals to enable a smooth transition between entry and exit of the Amphibious AGV. Depending on the quay heights, the ramps can vary in length. For instance, in the author's earlier (Abhishek Rajaram, 2023) work, when the Port of Rotterdam was considered a testing ground, the ramp was 95 m length x 5 m width at barge terminals. In comparison, deep sea terminals with higher quays (12m and above because of draught) had ramp dimensions of 270 m length x 5 m width. Both were at an inclination of 3 degrees slope. Other accessibility details also include a travel delay of 40-100 seconds. The pontoon takes 1.65 minutes to deflate and inflate and this is initiated on the way to the ramp (S.A.S, 2018). This accounted only in the form of a setup/verification time used to check if pontoons are fully inflated and at required pressure (10 PSI). Depending on the length of the ramp, it is expected that the AAGV will spend 1.5 min to 2.5 min on the ramp when taken on a triangular distribution (Park et al., 2023). These assumptions and calculations will also be a part of the phase 4 implementation and validation section. When implemented, the Amphibious AGV will reduce the rehandling point since it can link the yardside and quayside of container terminals with other terminals by accessing both land and water modes and transit via the ramp. This means that any container to be transported to a nearby terminal can merely be loaded from the yard/ship, then take the water route and enter the other terminal. This prevents the need for the truck+barge mechanism or even the longer route of inter-terminal transfer generally taken by trucks. An added aim of the Amphibious AGV is to prevent additional barge and truck fleets in the process, which can also make the chain more sustainable while complementing existing barge networks.

## Phase 2 - Alternative Means of Terminal Expansion

With saturation in terminal handling space, it has become clear that alternate but sustainable sources of expansion are needed to complement current deep-sea terminals. One such solution is the floating terminal, which provides a lot of flexibility regarding its modularity and location. The floating terminal will essentially provide the ability to split the feeder and deep-sea vessel traffic. With constraints in space, a floating modular terminal becomes the only choice that can alleviate congestion while providing more growth opportunities for existing container terminals worldwide. The Amphibious AGV becomes a crucial element in the chain since it is the only vehicle capable of transferring short packages of containers between an on-shore and offshore entity. This is the intersection point where, previously a combination of AGV and barge would have been needed but is now possible with just an Amphibious AGV. While this comes at the cost of some small-vehicle congestion, dedicated route corridors in the future will make it possible for large container ships and barges to not be affected. This is also where a modular floating terminal is needed to handle a versatile set of vehicles. The factors that warranted the need for a novel floating terminal design are lack of yard space in existing ideas (Jovanova et al., 2022) and lack of flexibility and efficiency in terms of loading and unloading (Baird and Rother, 2013). In concepts such as the port feeder barge, there is an issue of operator compatibility with current deep sea terminal and hinterland operators. It is prudent to mention that this research also considered several other concepts, such as barge hubs to handle traffic (Pielage et al., 2007). Still, it was deemed problematic because despite having dedicated space for barges, the barge hub would lack flexibility, especially in terms of location. As seen in the state-of-art section, distance plays a huge role in setting up a barge hub which is not a problem in the case of a floating terminal which can be modular and built anywhere. This also makes the research future-proof. A floating terminal would also require fewer ground resources in terms of vehicles.

From the study of major container hub ports such as the Port of Rotterdam, Port of Antwerp, and Port of Hong Kong, deep sea terminals are primarily congested with not only barge traffic but also feeder traffic. In all three ports where feeders

occupy deep sea berths by default, a feeder requires about 2-3 quay cranes (Meulenkamp, 2023) to load and unload containers. This means that freeing up two feeder berths would free up 4-6 quay cranes, typically needed for a deep sea vessel (Evers and De Feijter, 2004). To maximize the output of existing deep-sea terminals, the authors believe it will be prudent to assign deep-sea terminals to handle only deep-sea ships while the external floating terminal handles both feeder ships and super barges along with the Amphibious AGV. The design of the floating terminal is presented in Figure 5. The proposed design of the floating terminal has a 1km long quay with a yard that is 80 m wide. The terminal houses 10 rail-mounted gantry cranes with simultaneous transfer and exchange capabilities on both sides of the bridge and over-reach. The crane used is akin to those used between rail barges and yard-side equipment. Therefore, the specifications and handling capabilities are based on the Liebherr Rail mounted gantry crane (Liebherr, 2024). The cranes are also equipped with twin spreaders, which enable two containers to be loaded, unloaded and transferred across in one go given the lifting capacity of 65 tonnes. The berths for the floating terminal design can be configured in different ways. A sample has been presented in Figure 5. Three rail-mounted gantry cranes have been enabled for feeder/feeder-max vessels with capacities between 800-3000 TEU depending on size and destination. The presence of twin spreaders will speed up feeder ships' loading and unloading process. Three such feeder ships can be accommodated at once in the floating terminal. Super barges which were introduced in the last phase will use two such rail-mounted gantry cranes to load and unload containers (Meulenkamp, 2023). Three berths have also been assigned for the super barge. The remaining 5 empty slots in the floating terminal will be occupied by Amphibious AGVs as marked in Figure 5. The Amphibious AGV will represent the impactful link between the floating and deep sea terminals for hinterland-bound containers and inter-terminal transfer. Regarding other terminal features, the floating terminal is designed to function without any vehicles and automated stacker cranes. The overhead rail-mounted gantry cranes will serve both yards and vessels, each crane can handle 30-50 moves/hour when modelled on a triangular distribution (Bartošek and Marek, 2013). When this is taken over 350 days across 10 cranes, the terminal can handle up to a maximum of 4.2 million TEU year-round. If the twin spreader is considered, the RMG crane will be operated at minimum speed for safety. However, it can still output 5.04 million TEU at maximum theoretical capacity. Regarding yard space, it has been designed to stack containers 90 length-wise, 25 width-wise, and 6 height-wise to give a total container storage capacity of 13500 TEU at once.

**Figure 5:** The Floating Terminal Design Configuration

The floating terminal will be located close to the deep sea terminal to handle feeder and barge traffic. Feeder ships generally carry containers destined for both inter-terminal transport and hinterland. The deep sea ships which arrive at the respective deep sea terminals also carry a mix of hinterland-bound and inter-terminal-bound containers. Considering the modal split of major ports such as Rotterdam, Antwerp and Hong Kong (Gumuskaya et al., 2020; Marine Department, Hong Kong, 2022), it is estimated that 30% of all containers coming into ports are transported by barges through inland waterways while the remaining 70% are comprised of inter-terminal/export transshipment containers. The research in general is only concerned

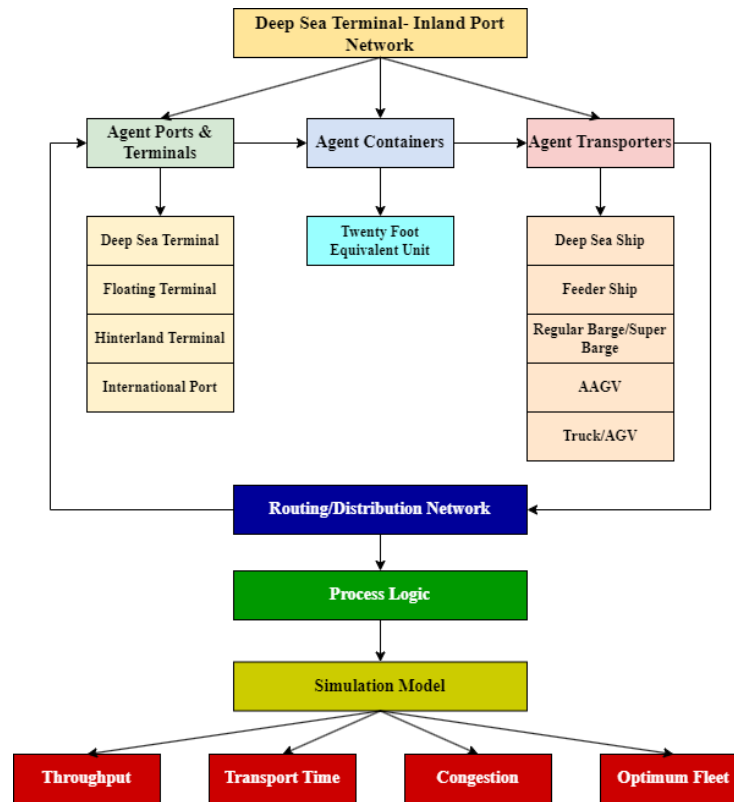

about the 30% containers transferred through the inland waterways. Once transporters such as super barges, feeders and Amphibious AGVs arrive at the floating terminal, the containers are sorted based on destination after which they are directly transferred overhead to the relevant transporter which could be either of the aforementioned. This is why the transporters dock only at berths which are parallel to the transporter to which the container needs to be transferred. For instance, in Figure 5, from the left, we see that the feeder is parallel to two Amphibious AGVs on the first berth. It can be assumed that the container from the feeder has to be transferred to the Amphibious AGV. After the direct container transfer, the transporters leave for the concerned destinations: Amphibious AGV to the deep-sea terminal, super barge to inland ports and feeder departs to the home port.

### Phase 3 - Addressing Low Call Sizes

A predominant reason for the barge congestion today is the extremely low call sizes barges currently resort to. As seen in literature (van der Horst et al., 2019; Shobayo and Van Hasse, 2019), call sizes at deep sea terminals currently range from as low as 6 TEU to 48 TEU with an average of 33 TEU. The irregularities in call size result in less efficient use of berth space and time since many vessels with higher call sizes might be in the queue. This also includes deep-sea vessels despite priority for deep-sea vessels. This would put forth a case for higher call sizes and experience from Antwerp, urging barge operators to follow a standard minimum. Still, higher call sizes have yielded good results, with barge calls falling by 40%, decreasing congestion at DP World Antwerp Gateway (Buitendijk, 2019). Analysing the prevalence of common destinations in major waterways such as the Rhine Delta (Konings, 2007) and the Pearl River Delta, it makes more sense to have higher call sizes per barge trip to ensure lesser congestion along these waterways. These would be transported to the major inland ports. But the absence of such transporters thus far has made it hard to carry higher amounts of containers. However, a sustainable container ship concept has emerged in the form of COSCO's electric ship, which was introduced in 2023. This electric vessel has a total container capacity of 700 TEU currently plying across the waterways of the 1000km long Yangtze river (Lepic, 2023). This inland vessel is 119.8 m long and 23 m wide, falling in between the large Rhine Class Va and large Rhine Class Vb in terms of dimensions, implying that this vessel will fit within existing barge berth dimensions while having a notably higher capacity than current barges (Program, 2019). This vessel has a dead weight of 10,000 tonnes and is powered by two 900 kW propulsion engines. This electric ship has 36 portable container-sized batteries that hold a capacity of 50,000 kWh and are replaced accordingly at various ports of call along the inland waterways. This research will use this inland vessel concept and henceforth refer to it as "Super Barge" owing to its higher overall capacity. The call sizes for this super barge are set at 400-700 TEU, which is approximately 10 times higher than current call sizes. These again will be shipped to the main ports along the inland waterways, which can be distributed to destinations by truck or smaller barges. This would essentially reduce the congestion of barges at the main deep-sea terminal with the denser capacity configurations of 400-700 TEU. The COSCO electric container ship/Super Barge is also sustainable with projected CO<sub>2</sub> reductions of 32 metric Tonnes per 24 hours of operation (Lepic, 2023).

### Phase 4 - Transport Network Systems Design

The methodology's final phase involves redesigning the transport systems network and a means to simulate and implement the networks as depicted in Figure 6. For this, an agent-based modelling is used. The predominant reason for this choice is that this simulation allows major entities in the system to have autonomy while interacting with other major entities. Discrete event simulation is a sequential simulation process which has also been often used for modelling container terminal operations. However, simulation process elements such as simultaneous berth planning and export/import container management warrant parallel processing, which can only be accomplished by agent-based modelling. This also allows for hierarchy in the system. But most importantly agent-based modelling opens up many research opportunities in integrated control for the future given its prevalence. The agent-based modelling system categorises all major elements into three agents: i) Ports and Terminals, ii) Containers, and iii) Transporters. These elements will possess their function besides the interaction with the other agents. To better understand these agents, they can either be a single agent (like a standalone container terminal) or a population of agents (like trucks, ships, or even multiple hinterland terminals). These will be mentioned below.

**Figure 6:** The agent-based modelling simulation of the deep sea terminal and inland network

1. **Agent Ports and Terminals:** this agent comprises international ports, deep sea terminals, floating terminals, and hinterland terminals. Depending on import, or export, this agent serves as the origin, destination or transit/transshipment hub for all containers in the system. Except for hinterland/inland ports, all the other terminals function as single agents. The international ports feature terminals themselves but will be classified as a single agent in this research. These are the origin points for containers in the system and they are picked by feeders and deep-sea ships. Deep sea terminals are intermediary points that function as transshipment hubs. They are a single agent and receive deep sea ships and feeders with containers. Hinterland terminals or ports are the final destination of these containers. In this research hinterland ports have been considered across various locations hence they function as a population of agents. The floating terminal is also a single agent and the new addition to the redesigned transshipment network. The floating terminal agent is also an intermediary transshipment hub complementing the deep sea terminal and handles transporters such as feeders, Amphibious AGVs, and super barges.
2. **Agent Containers:** these are a population of agents that originate from international ports and terminate at inland ports. This research considers standard twenty-foot equivalent units for classification and calculation purposes.
3. **Agent Transporters:** transporters refer to carriers of containers between various ports and terminals. Under this agent, existing concepts such as deep sea ships, feeders, barges, and trucks and the Amphibious AGV concept will form a crucial part of the proposed transshipment networks. All transporters are the population of agents. The Deep Sea Ships form the starting point of the entire process. These are considered vessels with a capacity of 3000 TEU and more, with the biggest capable of carrying 24000 TEU. Generally, they have a draught of 14m or more, hence the name deep sea. Deep sea Ships are also those ships that travel predominantly between major transshipment hub ports owing to the magnitude of containers they handle. They therefore require 6 quay cranes to unload containers (Bartošek and Marek, 2013). The second major actor responsible for bringing in containers are feeder/feedermax ships which have capacities in the range of 800-3000 TEU and travel to both hub ports and inland ports given their draught is less than 14m (Ogunsola, 2022). In most inland and deep sea terminals, barges arriving usually have call sizes ranging between 12 and 50 TEU with an average of 33 TEU (van der Horst et al., 2019). This research considers the upper bound of

50 TEU as the call size, and these are referred to as regular barges in this work henceforth. One of the gaps identified in the literature was the congestion consequences of using small container call sizes while transporting from deep sea terminals to the hinterland. The Super Barge is therefore an exploratory barge concept that addresses barge congestion by carrying larger call sizes of containers from deep-sea terminals to the hinterland. This concept is akin to the 700 TEU capacity electric container ship employed by COSCO in the waterways of Shanghai (Mandra, 2023). This research considers the call sizes from 400-700 TEU per barge trip. The Amphibious AGV envisaged to reduce the rehandling of containers forms the final piece of the puzzle, having the capability to travel on both land and water (Ghiridharan, 2023; Eijk et al., 2023). The Amphibious AGV will replace trucks/AGVs which are also modelled as the population of agents.

This multi-agent network of the aforementioned agents helps define the container transport environment from the international port to the deep sea terminals to the hinterland. This network is then paired with a routing and distribution network which distributes containers as a function of distance, which implies that the closer the destination is, the higher the number of trips to that destination and hence the higher container throughput. A process logic is then used to link all the agents and the routing networks. The process logic defines the container loading, unloading, and transfer sequence to subsequent destinations. This repeated throughout multiple change points. For instance, the benchmark involves entities like international ports, deep-sea terminals, and hinterland terminals therefore this process of loading, unloading, and transfer is seen in all the entities. This is then fed to a simulation model which processes the system's key performance indicators: congestion, container throughput, container transfer time and fleet trade-off. While the first three KPIs directly result from the agent-based modelling simulation, the fleet optimization is done with the help of a genetic algorithm (Yang et al., 2023) that works on the parameters, the objective and constraints shown in Table 2. This optimization aims to find the optimum transporter fleet size for the given utilization, which is set at 85%, considered a standard in literature for container equipment (Koo et al., 2004).

**Table 2:** Optimization Parameter, Variables, and Constraints

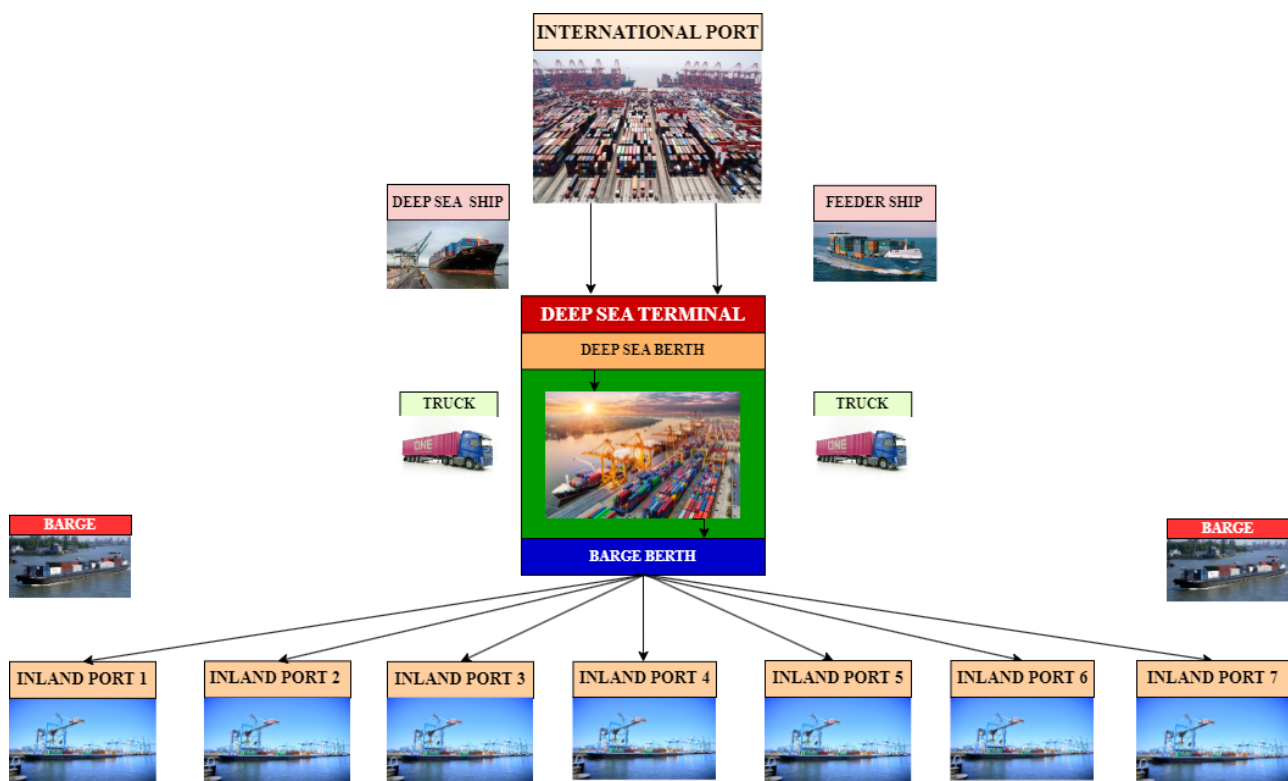

<b>Objective</b>	Maximize Utilization, U
<b>Variables</b>	
Total Transporters	$N = [1, \infty)$
Transporters Used	$T = [1, \infty)$
Utilization, U	$T/N$
<b>Parameter</b>	
Container Agent	Parameter as in ABM
Transporter Agent	Parameter as in ABM
Terminals Agent	Parameters as in ABM
<b>Constraints</b>	
Utilization	$T/N < 0.85$
Total Transporters	$N > 0$
Transporters Used	$T > 0$
<b>Output</b>	
Transporters Used	Optimum T

This agent-based modelling implementation will now be applied to the current transshipment scenario, or the benchmark network design. Subsequently, the new transshipment scenario will also use this agent-based modelling methodology. The benchmark and new transshipment chain results will be compared to see if maritime congestion has been reduced.

### **Benchmark Network Design**

The current transshipment network design is a hub and spoke design that has been followed for a substantial period of container shipping history (Langen and Van der Horst, 2008). An overview of the network with the concerned transporters, ports and terminals, and most importantly the interaction between the entities is shown in Figure 7. To summarise the agents, the

transporter agents involve the deep sea ship, feeders and container trucks. The ports and terminal agents involve international ports (example- Port Klang, Malaysia), deep sea terminals (example- Port of Hong Kong) and hinterland ports ( example- the Pearl River Delta ports). Feeders/Feedermax (800-3000 TEU) and Deep Sea Ships(3000-24000 TEU) bring containers from international ports to deep-sea terminals in the home country. Deep sea ships and feeder ships bring in call sizes on an average of 2000 TEU and 1000 TEU per port, respectively (Shobayo and Van Hasse, 2019). These feeders and deep sea ships dock at the deep sea berths and unload their containers via quay cranes, after which they are sorted for inter-terminal transfer and hinterland-bound containers. The hinterland-bound containers are loaded onto container trucks, which transport the container to the barge berths at the deep sea terminal. This translates to ground congestion of trucks and waiting congestion of barges at berths in deep-sea terminals. The containers from trucks are subsequently loaded to regular barges via barge cranes. For the benchmark per current operation, the average call size of each barge is set at 50 TEU (Seatrade Maritime News, 2015; van der Horst et al., 2019). The barges then transport these containers to inland ports/terminals. A few details to be noted here are that in port waters and till the inland, barge speeds are set at 13 km/hr (Centre, 2014), the operational truck speed is set at 20 km/hr (Duisburg, 2018) with 30-50 moves/hour assumed for quay/barge cranes (Bartošek and Marek, 2013).

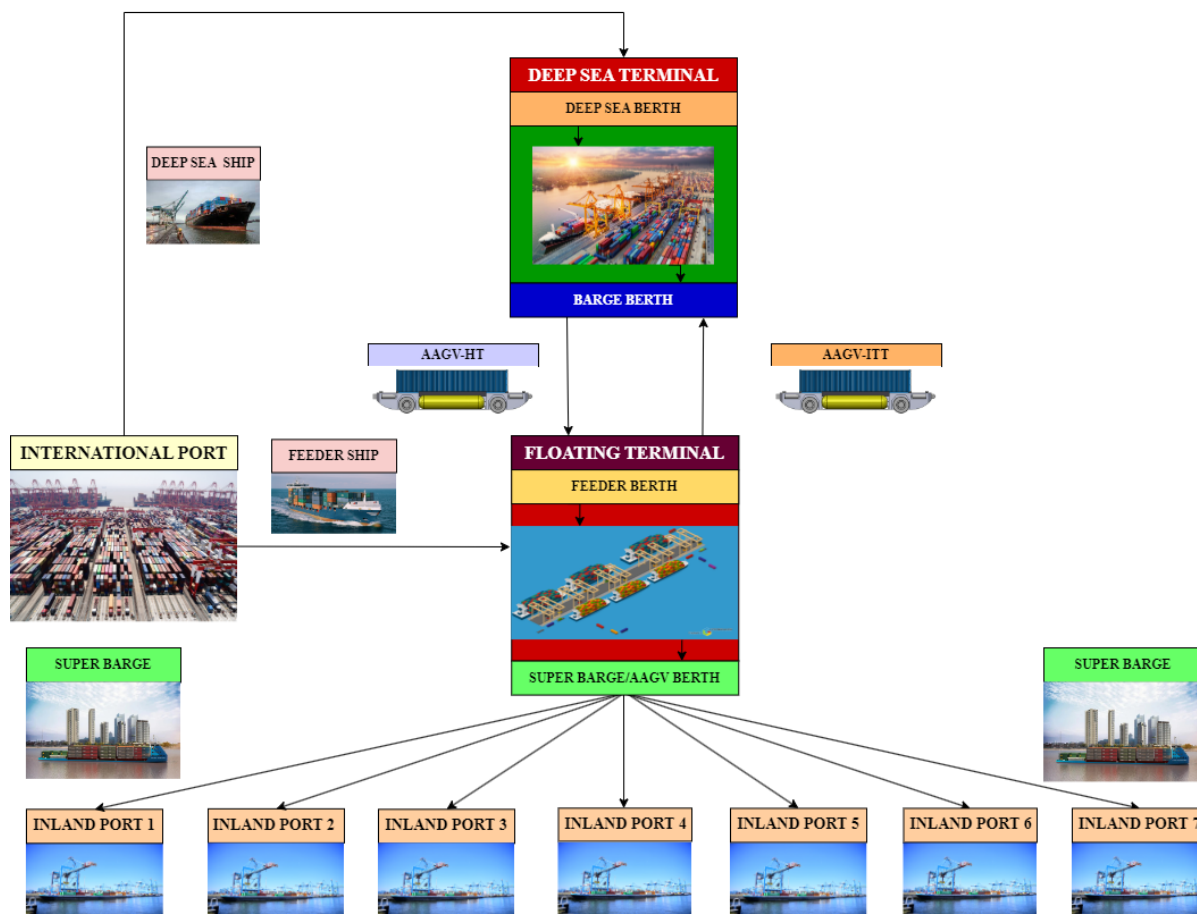

**Figure 7:** Current Transshipment Network- Benchmark

### ***The New Transshipment Chain Solution***

The new transshipment chain solution is also a hub and spoke approach implemented with the same agent-based modelling methodology as done for the benchmark. An overview of the network with respective transporters, ports, and terminals and their interaction is presented in Figure 8. For this network, the transporter agents involve deep sea ships, feeder ships, super barges, and amphibious AGVs. The ports and terminal agents involve international ports, deep sea terminals, floating terminals and hinterland ports. The process for the new transshipment scenario varies from the benchmark, especially concerning transporter and terminal interaction. As in the current scenario, both feeders and deep sea ships are loaded with containers from international ports (for example, Port Klang, Malaysia). However, after this, the process differs. To shift feeder traffic from deep sea terminals, the feeders from the international port dock at the floating terminal while the deep sea ships directly

dock at the deep sea terminal. The Amphibious AGVs now spring into action. The hinterland-bound containers present in the deep sea ship are transported from the deep sea terminal to the floating terminal via the Amphibious AGVs. The feeder docked currently at the floating terminal has a mix of hinterland-bound and inter-terminal transfer containers. The hinterland-bound containers stay at the floating terminal while the Amphibious AGVs take back the inter-terminal-bound containers on their return journey to the deep sea terminal. Upon their return, the Amphibious AGVs take inter-terminal containers to the relevant deep-sea berth or transfer them back to the yard. The hinterland-bound containers in the floating terminal are directly transferred to super barges that also dock at the floating terminal. These super barges take in call sizes of 400-700 TEU and transport them to hinterland ports (for example- Pearl River Delta ports). A subtle difference that is readily noticeable is the fact that in this new method, the Amphibious AGVs will have full load on most of the journeys to the floating terminal and the return back to the deep sea terminal. In the benchmark, this is a problem because trucks are guaranteed to be full only one way of the journey (during berth transfer). The Amphibious AGV's speed will be set at 12 km/hr, while the other parameters remain the same as the benchmark.

**Figure 8:** The New Transshipment Chain Solution

## CASE STUDY

A case study is performed on the Port of Hong Kong and the hinterland of China's Pearl River Delta to validate the proposed transshipment network and simulate its performance. The Pearl River Delta is one of the largest inland waterway networks in the world, with an extensive range of industries from electronics and garments to plastics flanking the banks of the waterway. Due to this industrial productivity and the presence of multiple clusters of tech parks, the Pearl River Delta is also known as the world's factory or more recently the world's design studio of the world (Fuller, 2017). In terms of economic value,

the Pearl River Delta has a GDP of \$1.2 Trillion forming 10% of China's GDP despite accounting for only 1% of China's territory. Of the 14000 Km stretch, 5000 km connects the southwest region through the extensive inland waterway network of barges (Wang and Li, 2012). The main trans-shipment ports here are Hong Kong, Guangzhou, and Shenzhen. Hong Kong stands out as a vital trans-shipment hub due to its robust connections with ports southward, including Port Klang in Malaysia and the Port of Singapore, and northward to the Port of Busan in South Korea and the Port of Taiwan. The Pearl River Delta, comprising nine major cities, contributes 18% to the nation's output and forms 73% of Hong Kong's inward trans-shipment. Despite a drop in Inland Waterway Transport (IWT) from 26% to 5% during 1980-2000, barge transport has rebounded, now holding 10% of the market. Calls for expansion in barge handling and trans-shipment services are increasing, driven by rising demand and sustainability needs, alongside local pressure to address the housing crisis. Recently, this crisis has threatened to close down a part of Kwai Tsing Terminals to build settlements (Chong and Li, 2020). This is where new transshipment solutions can help.

**Figure 9:** The Pearl River Delta (We Build Value, 2017)

**Figure 10:** Floating Terminal & Berths (Google, 2024)

## Hong Kong Ports

The Hong Kong port is located in the South China Sea and comprises a river and deep water ports. The deep water port, commonly known as the Kwai Tsing Terminals, receives an average of 36000 TEU Per Day (Marine Department, Hong Kong, 2022). There are a total of 9 container terminals that are capable of handling 24 million TEU annually. Due to the COVID-19 pandemic, traffic at Hong Kong port declined to 12.869 million TEU in 2022 (Marine Department, Hong Kong, 2022). For this research, HIT and HIT-COSCO terminals with an annual throughput of 8.03 million TEU will be considered. They operate Container Terminal 9S(Left of image, berth in green), and Container Terminals 4, 6, 7 and 8 which are all marked in green in Figure 10. These also represent the 7 deep sea berths. The barge berths spread across terminals 4 and 6 are shown in red. Terminals 4 and 6 combined house 9 such barge berths (Hutchison Ports Trust, 2023). HIT and COSCO handled a peak of almost 6500 TEU per day in 2016, with 120 barges making footfall daily (Seatrade Maritime News, 2015). Looking at the current split between trans-shipment and PRD containers, the HIT-COSCO terminals receive 22000 TEU from international ports such as Singapore, Port Klang, Port of Busan and also from the west such as Colombo, Rotterdam and Port of Los Angeles (Bu et al., 2023; Marine Department, Hong Kong, 2022). This corroborates with the 70-30 split as derived in Phase 2. This translates to 6500 TEU headed to the Pearl River Delta and 15,500 TEU headed to other international ports. Apart from the 120 barges that make footfall, 15-18 (average -17) vessels dock at the deep sea berths daily. These mix feeder/feeder max vessels, panamax and ultra-large container ships (ULCS). The floating terminal is located in the region marked in yellow. This will use the large-scale floating terminal design (Figure 5), which has a 1 km quay with a theoretical

handling capacity of 2.52 million - 4.2 million TEU annually (5.04 million TEU with twin spreader). The berth configurations will be exactly used as shown in Figure 10. Among the 17 ships that dock at HIT-COSCO for benchmark case, 11 are feeder or feedermax vessels. The feeder/feeder max vessel traffic can be shifted to the floating terminal by the new transshipment chain methodology. Three RMG cranes per feeder max vessel will be used to unload and load containers. Owing to the length of these ships, realistically 3 feedermax ships (marked in pale pink in Figure 10), 3 Super Barges (marked in orange) and 5 Amphibious AGVs (marked in blue) can be accommodated at once in the floating terminal. It is also important to mention that despite the presence of the floating terminal, it will always be the deep sea terminal with the higher annual throughput. This is done to retain its competitiveness. Therefore the split of 22000 TEU between deep-sea terminals and floating terminals are tested in two configurations. The first is (14000 TEU at HIT-COSCO and 8000 TEU at the Floating Terminal) and second configuration is (12000 TEU at HIT-COSCO and 10000 TEU at the Floating Terminal).

## Inland Ports in Pearl River Delta

The Pearl River Delta has 2000 inland ports within the region. Seven major import and export inland ports have been chosen for this research: Sanshui, Foshan, Jiangmeng, Shekou, Yantian, Zhongshan, and Humen. The ports are shown in Figure 9. These are ports quite prominent in the automotive, electronics and manufacturing industries given that Shenzhen and the Pearl River Delta region are hubs for mobile and communications OEMs. Currently, barges with call sizes of 50 TEU carry consignments from the Port of Hong Kong to the Pearl River Delta. This will be simulated in the benchmark network analysis. It is envisioned that when the new transshipment chain solution is employed, super barges will carry call sizes ranging from 400-700 TEU to the ports in the Pearl River Delta. The barges in the benchmark will depart from the barge berths marked in red from the HIT-COSCO deep sea terminals. Similarly, super barges will depart from the floating terminal to the Pearl River Delta for the new transshipment chain. The AAGVs will rotate between the deep sea and floating terminals, transporting containers for hinterland and other terminal transfers.

## RESULTS

The Hong Kong-Pearl River Delta simulation presented a very intriguing set of results. The results are presented in Figure 11. The benchmark case from the simulation records 121 barges docking in at Hong Kong's HIT-COSCO terminal to transport 6500 TEU to the Pearl River Delta. This information corroborates with the terminal data of 120 barges a day ([Seatrade Maritime News, 2015](#)). As anticipated this causes an average congestion of 13 barges per berth per day which is disadvantageous given that the HIT-COSCO terminal is forced to use 2 barge quay cranes to unload barges when usually only one quay crane is used. When we shift the focus to the new transshipment scenario, it becomes clear that in both configurations of container split, there is a congestion of only 14 super barges per day. This is a direct result of the difference in call sizes of the respective barges. In the benchmark, the regular barges load or unload call sizes are 50 TEU, while the super barges in the new transshipment scenario take anywhere between 400-700 TEU (consider an average of 550 TEU) per barge trip. This makes it easier to have only two super barges visit each of the major ports in the Pearl River Delta daily instead of having up to 20 separate regular barges visit the hinterland ports in the benchmark case. This work also considered ground congestion as an important metric, and here it can be seen that in the benchmark, there are about 1788 daily truck visits to the berths to deliver containers to and from barge berths to/from deep sea berths/container yard compared to the 2104 and 2511 Amphibious AGV visits to the floating terminal. When the Amphibious AGV congestion is compared, it is clear that the Amphibious AGV has a higher frequency of visits given that it has to transport containers not only to the floating terminal but also on the return journey back to the deep sea terminal or the container yard. This also implies that the Amphibious AGV runs full load on at least 50% - 75% of the journeys (50% in the 12000 DST:10000 FT case, 75% in the 14000 DST:8000 FT case). This is not the case for trucks which run full on only one leg of the journey while transporting containers from the deep sea berths to barge berths. The trade-off is that the Amphibious AGV offers more productivity at the cost of slightly more added congestion. Furthermore, it must be realised that the Amphibious AGV is trying to replace the functions usually done in combination with a barge and a truck. When we analyse the fleet of both the benchmark and the new transshipment scenario in a graph 11, the fleet size of the new solution is 53% lower than the benchmark comprising 14 super barges and 70 AAGVs. This contrasts with the 126 regular barges and 54 trucks in the current solution. A large maritime fleet size and congestion scale have been reduced

by about 80%. The Amphibious AGVs have a larger fleet size than trucks but complete much longer round trip journeys (9km) than an average 2km back and forth berth transfer journey. This makes the Amphibious AGV more competitive per kilometre compared to trucks and justifies the increase in fleet. Also, to reiterate the Amphibious AGV is essentially covering for functions of both the truck and the regular barge. The new transshipment solution also has advantages when it comes to transporting containers to the hinterland. The benchmark posts a transfer rate of 2247 TEU/day to the Pearl River Delta while the new transshipment solution sees a marked 27%-30% improvement in throughput rate (2869 and 2953 TEU/Day) for both configurations. Complementing the throughput rate, the hinterland transport time also sees a 21%-23% improvement in the overall time recorded to move containers to the Pearl River Delta. While both the Amphibious AGV and super barge leg raised advantages over the conventional truck and regular barge, it was noticed that the biggest difference came in the AAGV transfer times which were 30% faster than that of trucks which transfer between deep sea and barge berths. This justifies the increase in the fleet of Amphibious AGVs over trucks. There were also marginal improvements in super barge transfer times compared to regular barges. One positive knock-on effect of implementing the new transshipment solution is that it frees substantial berth space. Since the floating terminal uses three cranes to unload a feeder/feeder max ship, at least 6 feeders can be accommodated over a day. This would essentially free space for two ultra-large container ship berths (18000+ TEU) requiring 6+ quay cranes. This translates to potentially handling 730 new ultra-large deep-sea ships year-round. The opportunities however do not end there. The barge berths at HIT-COSCO originally present in the benchmark also stand unused thanks to the new transshipment solution. These berths can also be repurposed to occupy feeder ships or a Panamax ship (5000TEU) (Ogunsola, 2022). This would mean that potentially 2 ultra-large container ship berths and 3 feeder berths have been identified as possibilities for expansion within HIT-COSCO's existing canvas. If all berths are used at full capacity as mentioned it would push up HIT-COSCO's handling capacity from the current 8.03 million TEU to 12.41 million TEU which represents a 54% increase in container handling capabilities. This makes the solution future-proof. The results also provided other crucial insights that have not been directly depicted in the graph. A pattern noticed here is that Amphibious AGVs become more effective when demand is higher. In the 14000-8000 case, maximum one-way demand is 5560 TEU (4270 TEU on way back) while in 12000-10000 case the max one-way demand is 6950 TEU (3660 TEU on way back). The AAGV performs the best in the latter. The super barges are used with call sizes from 400-700 TEU. Large call sizes can often be very uncertain owing to common delays that occur at points of origin. Therefore, this research deemed it important to experiment with call sizes for super barges ranging from 400-700 TEU. A short graphical analysis was done to find the optimum point for throughput, call size and congestion and here, a maximum throughput of 2927 TEU/Day was obtained at a congestion of 12 barges a day and a call size of around 600 TEU. For context, this result falls within the range seen in the average results for throughput (2869-2953 TEU/Day) and similar congestion for barges (12 v 14 a day). Similarly, when simulations with 400 TEU call sizes were done, a congestion of 17 barges a day was obtained.

Figure 11: Performance Comparison

## CONCLUSIONS

Trans-shipment forms a significant part of the services sector today and enables greater accessibility of industries and businesses located deep inside a country. This is also supported by the fact that the maritime industry takes care of 80% of the international trade volume. With increased trade, bigger ships, limited expansion space for ports, and growing congestion, there is an urgent need to develop future-proof solutions. Therefore this research was initiated to formulate new design and network solutions for the container shipping industry to facilitate efficient deep-sea to hinterland trans-shipment. A breakthrough in this research was introducing and using an Amphibious AGV for inter-terminal transportation. Being a 2 TEU vehicle, the Amphibious AGV provides the capacity of regular AGVs and trucks while providing the flexibility to travel on both land and water. This research also investigated the effectiveness of modular floating terminals as an alternate means of expansion, given the unsustainability of land reclamation. The author proposed a novel terminal design with a capacity of 4.2 million TEU annually. The design proposed a direct over-the-head instant transfer of containers from one transporter to the other, saving yard space and waiting time. To validate the problems faced today in trans-shipment, the Port of Hong Kong and the hinterland ports of the Pearl River Delta were chosen as the ground for the simulation. Using an agent-based modelling simulation on AnyLogic, it was clear that congestion was a serious issue with nearly 120 barges making footfall at HIT-COSCO terminals in Hong Kong, competing for just 9 berths. Essentially these barges were still using quay cranes generally used for deep-sea ships. This represented problems of congestion, saturation in handling capabilities, and other problems such as acute berth planning issues and quay crane allocation. With these constraints in mind, a new trans-shipment network solution involving the Amphibious AGV and the floating terminal was developed to boost handling capabilities by 50% as well as show how instrumental concepts like Amphibious AGV are in enhancing inter-terminal and hinterland transport. A salient feature of this new proposed network was also the use of a Super Barge, which took on higher container call sizes per trip to the tune of 400-700 TEU to reduce overall barge congestion by 80%. Under the new network, the feeder traffic was shifted from deep sea terminals to floating terminals enabling the berths to be occupied by extra deep sea ships. The simulations showed a container throughput increase from the current 8 million TEU to 12.41 million TEU when changes

were implemented. The takeaway from this research is that novel design solutions can indeed be found to address the current growth crisis. From a fleet transportation design perspective, novel network approaches have been implemented to address shortcomings of the status quo. Amphibious AGVs and floating terminals can potentially deliver more applications, such as liquid and dry bulk commodities. Amphibious AGVs were also envisioned to be sustainable and powertrain control is at the forefront with amphibious powertrains being relatively new. On a business level, Amphibious AGVs also have the potential to be effective for small and micro industries located on the hinterland and call for its investigation. The authors also believe that in the coming years, this work will be critically looked at to encourage impactful concepts like Amphibious AGVs and floating terminals to be introduced for the benefit of hinterland transportation that could eventually lower the prices of commodities that we use every day. From a design perspective, this work has proposed a preliminary concept that shows the potential of such an Amphibious AGV contraption is possible within a similar as canvas regular ground container AGVs. Future studies can move in the direction of certifying its stability and interaction with other equipment in the port.

## ACKNOWLEDGEMENTS

This project has received funding from the European Union's Horizon 2020 (MFF 2014-2020) research and innovation programme under Grant Agreement 101036594.

# Iron Powder as a Fuel on Service Vessels

Erik Scherpenhuijsen Rom<sup>1</sup>, and Austin Kana<sup>2,\*</sup>

## ABSTRACT

*This paper investigates the feasibility of iron powder energy generation systems on board a semi-submersible crane vessel. This is done using a design model that integrates design information and a simulated mission profile to determine a hybrid iron powder setup split. This setup is then placed within a set of vessel designs to calculate a base level feasibility looking at the draft, stability, and emissions decrease. For those concepts that were technically feasible, the new hybrid iron powder setup contributed to a reduction of CO<sub>2</sub> up to 25-50% and a reduction of NO<sub>x</sub> emissions between 15-50%, depending on the mission profile.*

## KEY WORDS

Iron powder; alternative fuel; semi-submersible crane vessel design; feasibility study

## INTRODUCTION

This paper explores the use of metal powder as a fuel on service vessels because they are a promising sustainable alternative to conventional energy sources since they are dense energy carriers. The main feature attributed to the iron powder power generation process that makes it such a high potential alternative fuel source is the fact that the combustion of this powder results in no CO<sub>2</sub> by-product (van Rooij et al., 2019). This paper is a follow on feasibility study to de Kwant et al (2023), who looked at the iron powder as a potential fuel on shipping vessels. De Kwant et al (2023) determined that short sea container vessels would be the most promising vessel class for shipping vessels, and that iron powder would could be technically feasible, however, it will likely not be as economically feasible as other alternative fuels.

This paper extends that research by looking into the feasibility within service vessels. This paper will start with a evaluation of the state-of-the-art of iron powder energy generation to determine the most optimal setup to be installed aboard a marine vessel. This will be followed by a study of the marine service vessels to determine which is best suited for an iron powder powertrain installation. The conclusions from these two studies will result in the creation of a design method to test iron powder feasibility on the chosen service vessel type. This method of testing feasibility will then be applied to a set of case study vessels.

## Introduction to iron powder as fuel

Metal powder combustion is one of the promising sustainable power generating alternatives to conventional sources of power such as fossil fuels. Metal powders are dense energy carriers that can be turned into a power source using two processes (Bergthorson, 2018). The first is known as the wet cycle in which the metal is reacted with water at high temperatures for heat and hydrogen production (Dirven et al., 2018). The product can be used either in heat engines or in fuel cells. The second process is the dry cycle in which the metals are directly combusted in an external combustion chamber and converted into mechanical energy directly (Dirven et al., 2018). The dry cycle is a more direct form of energy generation as opposed to the two-step process of the wet cycle. This means that the dry cycle will be more compact in practical use than the wet cycle and require less volume. Therefore, the use of the dry cycle is far more practical onboard a ship with limited area and volume and will be the only one researched.

### ***Iron powder characteristics***

The iron powder energy generation process has multiple characteristics that make it unique, such as its availability, recyclability, and zero-emission aspects of iron powder as an energy source. There are also other characteristics that serve as advantages such as low safety risks, ease of retrofit opportunities, and a significant energy density. Other characteristics such as abrasivity, moisture sensitivity, and a generally low efficiency serve as characteristics that will require further attention.

A key advantage of using iron as a power source is its overall abundance as a resource. Iron makes up around 5% of the earth's crust making it the 4<sup>th</sup> most common element in the crust (Bergthorson, 2018). This means that there will be enough resource availability for this particular use alongside the conventional uses of iron in construction and other sectors. Other metals that can be considered for electrofuels such as cobalt are far less abundant and more difficult to obtain, making them more expensive and less attractive as an alternative fuel.

As can be done with several other metal fuel sources, iron can be fully recycled after the process of energy generation. When iron powder is burned in a combustion chamber, the remaining products are iron oxides. These iron oxides cannot be used again for combustion in the state they are in as they have already been oxidized. Using either coke (a high-carbon distillate of coal) or hydrogen it is possible to reduce the iron oxides back into iron powder making the energy generation process fully circular process, as shown in Figure 1.

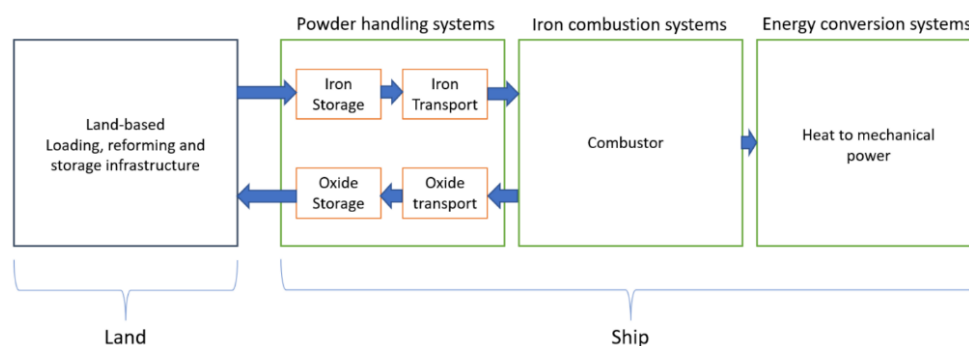

**Figure 1: Metal reduction cycle applicable for iron (Bergthorson, 2018)**

This has the main advantage that generally only one supply of iron powder is required for a specific application as this source can be infinitely reused through the reduction process. This is, of course, not possible with fossil fuels as their combustion products cannot be reduced back into the fuel.

The main advantage of using iron as a fuel source over fossil fuels is of course its extremely low emission in combustion. The combustion of iron releases no CO<sub>2</sub> as a by-product and very low levels of nitrous oxide with a maximum of 94 ppm of nitric oxide and 1 ppm of nitrogen oxide measured in a 100kW test setup by TU Eindhoven (van Rooij et al., 2019). The low level of nitrous oxide by-product is dependent on both the temperature of the combustion as well as the amount of hydrogen atoms present in combustion. For iron powder the temperature still reaches levels where some nitrous oxide may be released however the lack of hydrogen atoms in this combustion ensure this level is extremely low especially when compared to conventional diesel engine combustion (van Rooij et al., 2019).

### ***Iron powder components***

The iron powder powertrain consists of multiple systems to complete the entire cycle of power generation. A large array of infrastructure, systems and equipment are required both on land and onboard to complete the process (see Figure 2).

**Figure 2: An overview of the components in the iron powder powertrain (de Kwant, 2021)**

The land-based components are mainly the storage areas and regeneration plants. These are less important for the ship processes and will therefore not be further investigated in this paper. The components onboard the ship can be split into four different systems: storage, transport, combustion, and energy conversion systems. These systems will be further explored looking at the current state-of-the-art and will be analyzed in context of the challenges that arise with placement onboard a ship.

The storage of iron powder is fundamentally different to the storage of conventional liquid fuels such as marine diesel oil (MDO) and heavy fuel oil (HFO). Whereas liquid fuels are stored in tanks at around 40 degrees, iron powder cannot be stored in tanks and does not necessarily require a specific minimum temperature level (Seijger, 2020). As with all other bulk goods, iron powder is best stored in silos (van Rooij et al., 2019). The powdered form of the iron powder results in a higher volume requirement as well as high mass levels. There are two types of silos that can be used for iron powder storage, a horizontal or vertical silo. A horizontal silo is more comparable to the shape of a tank allowing for much lower placement to ensure a low center of gravity for the vessel. A key disadvantage of the horizontal silo, however, is its lower discharge level in comparison with the vertical silo. The vertical silo can discharge its bulk content through the hopper system mainly through gravitational forces and flow design. Due to its far more limited failure points, the vertical silo is currently preferred over the horizontal silo.

Transport of iron powder particles is best done using a two-phase pneumatic transport system. This transport system transports the bulk material through an air stream rather than direct contact. This air stream is created inside a tubular enclosed piping by a pump or high-power fan to push the bulk materials through the piping. This system can provide transport with sharp turns in any direction. Its high transport speed in the air stream makes it possible to minimize the size of the transport tubes while maintaining the minimum level of flow required. Flow level may need to be reduced to ensure minimal damage due to abrasiveness of the iron powder and oxide powder. The pneumatic two-phase transport system is also able to provide a homogeneous flow rate for transport from the dispersal system to the combustion chamber (van Rooij et al., 2019). This system has already been used for zinc transport whose properties are highly comparable to iron powder (Air-Tech System, 2024). The main concern with this system is the high amount of power required to operate in comparison to most other bulk transport systems.

The process of iron powder combustion is done in an external combustion chamber. This is because the combustion process for iron powder is much longer than is possible in an internal combustion engine. This is coupled with the possibility of clogging of the iron powder particles in an internal combustion engine. To collect the iron oxide particles for storage and reduction back into iron powder, a combination of a cyclone filter and bag house filter setup are used. These are deemed sufficient to match the requirements for an iron powder system with an efficiency of around 38% to reach an oxide collection rate of 99.999% (van Rooij et al., 2019).

The energy generation from this combustion process is best done using a Mitsubishi (Ultra Steam Turbine) UST cycle (de Kwant, 2021). This is a reheated Rankine steam cycle. This setup is pictured in Figure 3. Is fitted with an economiser, evaporator, superheater and reheater. These are connected to a series of three turbines: a high-pressure turbine, intermediate pressure turbine, and a low-pressure turbine. This reheating of the working fluid and passing through this series of turbines increases the efficiency up to 15% compared to standard steam cycles. These systems are in commercial operation and are seen as suitable for iron powder application as well (van Rooij et al., 2019).

**Figure 3: Schematic of Mitsubishi's UST plant, (de Kwant, 2021, Seijger, 2020)**

### ***Iron powder limitations***

There are certain limitations that dictate the iron powder powertrain's output capability. These key limiters are the volume and mass concerns that come with iron powder storage systems, the part load and dynamic load issues that come with energy conversion, and potential filtration issues concerning the heat collection from oxides in the combustion system. Regardless of what combustion process, storage system, transport system or energy conversion system is used, there will be a high volume and mass requirement for the iron powder powertrain. From vertical storage silos to filtering systems to the boiler system and turbine the total volume taken up by the entire powertrain becomes significant with regards to ship stability. This requires a deep dive into the possibilities for different configurations of this system keeping in mind the high energy cost for pneumatic two-phase transport between these systems.

One of the main drawbacks of using a steam cycle for energy conversion is the low capability for part load conditions as well as dynamic loading. When the ship is in part load condition, the power requirement is lower than the design point of the power generation and conversion system. At this point the system is no longer working at optimum efficiency as this is only the case at the design point. This is the case with most power units however the drop in efficiency for a steam cycle can be quite stark. One of the most prominent solutions to the part load concern pertaining specifically to transit is the use of a controllable pitch propellers (van Rooij et al., 2019). This allows the ship to travel at different speeds without changing the steam cycle from its nominal power output. A hybrid configuration can be used to make up for the load variations (van Rooij et al., 2019). The main power source can be used for propulsive power and the secondary power source can be used for additional loads such as hotel, equipment, and crane loads.

### **Introduction to Service Vessels**

The term service vessel encompasses a large variety of ship types with varying sizes and functions. These vessels were put through a two-phase down selection starting with the wide range of service vessels and ending with one, most optimal service vessel type. First, a list of different types of service vessels was made and their feasibility for an iron powder powertrain was determined based upon size and range. A select few vessel types were then further analyzed based on their operational modes and missions. These operational profiles were used to make an estimated load variation over the course of a mission and of the total output requirements along with their initial iron powder volume and mass requirements.

#### ***Phase one***

Phase one of the down selection starts with a list of the service vessels to be considered, categorized into four areas: Transport, Support, Construction and Specialty, see Table 1.

**Table 1: List of commonly used service vessels.**

Transport Vessels	Support Vessels
<ul style="list-style-type: none"><li>- Walk-to-work Vessel</li><li>- Platform Support Vessel</li><li>- Heavy Lifting Cargo Vessel</li><li>- Daughter Craft/Crew Transfer Vessel</li></ul>	<ul style="list-style-type: none"><li>- Tugboat</li><li>- Anchor Handling Tug Supplier</li></ul>
Construction Vessels	Specialty Vessels
<ul style="list-style-type: none"><li>- Offshore Subsea Construction Vessel</li><li>- Semi-submersible Crane Vessel (SSCV)</li><li>- Jack-up Vessel</li></ul>	<ul style="list-style-type: none"><li>- Pipe-laying Vessel</li><li>- Research Vessel</li><li>- Dredger</li></ul>

These vessels were assessed for potential compatibility with an iron powder setup based upon their size, range, and functions. This very basic assessment allows certain vessels such as the daughter craft, tugboat, and pipe-laying vessels to be filtered out due to size and volume constraints. Long range research vessels can also be eliminated due to their likely high bunker requirement in comparison to their shape and size. Certain remaining vessels such as the walk-to-work and platform supply vessels are combined as they are highly similar in size and function.

#### ***Phase Two***

From this first phase of the down selection, only four different vessel types remained: the platform supply vessel, the jack-up vessel, the semi-submersible crane vessel (SSCV) and the (limited range) research vessel. These vessel types were singled out in the 1<sup>st</sup> phase due to opportunities presented regarding either their size, their typical range of operation or the complexity of their functions. While all of these vessel types provided opportunities in one or two of these categories, none were ideal and would require a deeper dive to determine whether the opportunities presented were enough to make the idea potentially feasible. Through a further analysis of operational profile and load profile, an optimal vessel type of these four can be determined.

The main concern with platform supply vessels and research vessels is the relatively small capacity for extra volume and mass. These vessels are largely under 100m in length with largely varying loads over the course of a mission. Another issue is the densely packed state of the hulls of these smaller supply vessels, with minimal room on deck and below deck, placement of the silos will prove difficult. The main issue with the jack-up vessel is the high mass level in relation to its jacking-up process. The extra mass of an iron powder setup is considered too high for the jacking mechanism to still be able to lift the vessel.

The overall size and lightweight of the SSCV and its hull form make it far more ideal for iron powder powertrain implementation. From previous research testing the iron powder setup on short sea shipping vessels, one of the conclusions drawn from the results were that the volume and mass of the setup had a significant impact on the arrangement and performance of the vessel. These results were interpreted as, in order to minimize the impact of the mass and volume requirements of the iron powder powertrain a vessel with appropriate dimensions and tonnage is required. The large pillars connecting its pontoons to the deck box are ideal for silo placement. The general size of these SSCVs ranging from 130m up to 210m will likely decrease the total impact of the iron powder powertrain on the design of the vessel with regards to volume and mass constraints. While the level of power and energy required by a SSCV cannot be fully supplied by the iron powder powertrain, the load profiles have shown a potential for a hybrid installation which will ensure the power requirement of the vessel is satisfied while still decreasing the GHG emission. Therefore, the choice is made to test an iron powder setup on a SSCV.

## METHOD

To test the feasibility of a hybrid iron powder setup on a SSCV, information is required on both the characteristics of the SSCVs as well as the systems to be placed aboard. The main inputs are the main dimensions and operating profiles of a selection of SSCVs. These are used to generate load profiles from which the hybrid split can be determined. With this hybrid split the weight estimations are made and used to test for stability and feasibility. Finally, an emissions comparison is made to assess the environmental impact of the hybrid setup. This process (Figure 4) is structured in a way that will maximize the limited inputs available for SSCVs where only main vessel dimensions, and high-level operating profile and load profile data is available.

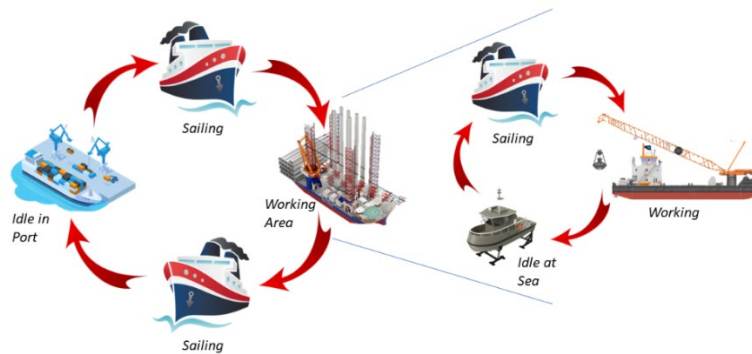

Figure 4: Method diagram showing steps to determine base feasibility.

## Key Information

To ensure the reliability of results, existing vessel information is needed. In this case, a market study has been performed on the existing worldwide fleet of SSCVs. From this study, a set of four SSCV designs, each with differing main dimensions, power outputs and crane capacities were selected to form a case study. The information from these vessels is crucial in determining load distributions, weight estimations and stability calculations. Determining the operational profile of SSCVs means looking at the operating modes of the vessel, the distribution of time spent in a particular operating mode and using this information to create a realistic mission profile with an accurate range.

The operational profile of a semi-submersible crane vessel can be viewed over two timespans, over the space of a year and over the space of one mission. The standard SSCV has three operating modes; idle and repair, sailing, and working mode (Hagen, 2021). The idle and repair mode is assumed to be split between three sub modes: repair, idle at port and idle at sea. A SSCV mission can be described using a long and short cycle. In this case the 'long cycle' consists of the time spent loading, bunkering, and unloading at port coupled with the time taken to sail from port to the working area. The 'short cycle' then consists of all the time spent in the working area, this includes the time spent installing the offshore structures as well as potential idle times at sea and sailing time between offshore construction locations. This cycle is visualized in Figure 5.

**Figure 5: Diagram of the short and long cycles performed by a SSCV over the course of a mission.**

The mission duration for SSCVs can vary greatly ranging from 7 weeks up to 15+, with bunkering occurring every 7-12 weeks. (personal communication, March 10, 2023). The missions for SSCVs vary significantly based upon what structures need to be installed, changed, or decommissioned. The sheer variety in operations makes it near impossible to simply take an average of all mission types and create a generic load profile. Therefore, the choice was made to focus on one specific mission type that is becoming increasingly common with installation vessels: wind turbine and mono-pile installation.

## Load Distribution

Using the information provided about operating profiles, and general mission durations, the power and energy demands of the vessels can be estimated. The load profile determination starts with an understanding of the load types and how these power demands can be estimated from existing information to generate a time vs power graph. According to the results of the load profile simulations, the existing powertrain can be adapted to a hybrid powertrain. There are three main load types to be considered on a SSCV: the hotel load, thruster load, and crane load.

The load per operating profile is determined based upon the data available for one SSCV, to be used as a reference. The power level required for each operating mode is available for this vessel but not for the rest of the vessels. Due to most hotel systems being aimed at crew comfort or are systems used by the crew it is most likely that the hotel load can be scaled according to the crew capacity of the vessel. Using this reference vessel as a base, half of the factor difference in crew capacity is used as the difference in hotel load. This is because apart from the extra crew quarters, many areas such as the mess hall will not require as significant an increase in hotel load to accommodate for more crew. The thruster load of a vessel is mainly dependent on the installed thruster power. This is available for all vessels and can therefore be scaled to the same level as for the reference vessel. This can be assumed because of the tier III DP requirements applicable to all SSCV available reference vessels. The thruster loads in dynamic positioning mode will be determined by a maximum thruster load and a base thruster load. Finally, the crane load is scaled based on the total powertrain of the vessel as the hotel load and thruster load have already been determined. This means that the remaining load for each operating mode is covered by the cranes. The variable crane loads are determined by a maximum crane load and a base crane load.

These loads per operating mode are the basis of the load profile estimation. Each operating mode is simulated for the previously determined mission type for the determined mission length. As the operating mode of the simulation varies over the mission, so does the power requirement of the vessel. This gives an indication of the total power requirement needed for each vessel as well as where the hybrid split should be made. Firstly, a load profile containing the three main consumers is created to show the variation of the power requirement over the course of a mission as well as where the peak loads occur. These are then summed up to create an estimation of the total power requirement of the vessel.

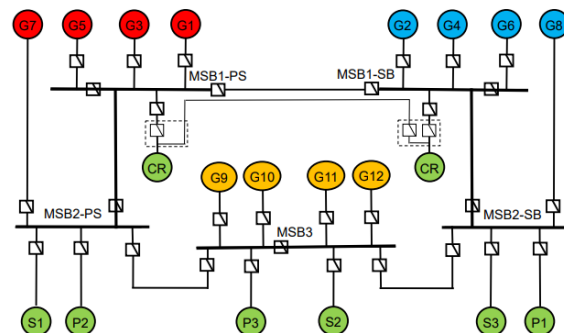

It is important to note that these load profiles are generated from assumptions made for the load requirement of each consumer. While the simulation of a relatively constant load such as the hotel load is quite simple, the simulation of a varying load is more complex and results in a wider range of results with each simulation. This is mainly the case for the thruster and crane load when the vessel is in working mode. With the base and peak load estimations made, the probability of the load requirement being any value between the base and peak load must be determined. This was done based on the existing crane energy demand data available from one of reference SSCVs, shown in Figure 6.

**Figure 6: The energy demand of the reference SSCV's cranes during one day in working mode, (Hagen, 2021)**

This frequency of peak power demand over one day for each crane was extrapolated for an entire operation in working mode. By calculating the number of times certain power demands were reached over the course of a day, a probability of a certain power demand could be generated and applied to each vessel. While this does not perfectly reflect the reality of the power demand for each vessel, it does give sufficient and reliable indication of the distribution of power demand for both the cranes and the thrusters. The thrusters in working mode are set to dynamic positioning mode and these often work in tandem with the crane operations. When the crane undergoes a large movement, it requires a large amount of power for lifting but also for the dynamic positioning to stabilise the vessel. This coupling of the thruster and crane in working mode allows this distribution of power demand to be used not only for the crane loads but also the thruster loads.

A full depiction of a typical powertrain from power generation to power consumption is given in Figure 7 depicting the full powertrain of one the reference SSCVs with 3 engine rooms. In this schematic the red, blue, and yellow components describe the generator sets in their respective engine rooms while the green components are the main power consumers such as the cranes and thrusters. This general layout of the powertrain systems will be used in the hybrid setup.

**Figure 7: Powertrain schematic for one the SSCVs, (Lyu, 2016)**

Keeping in mind that the power levels will differ significantly per vessel, an outline is made of the general layout of the hybrid powertrain. The main difference between the original powertrain and the hybrid powertrain is the addition of an extra engine room with an iron powder setup. Each vessel will consist of four engine rooms. Three of these engine rooms will be similar to the original engine rooms in that they will be equipped with diesel generator sets to provide the variable load required for the vessel. The iron powder engine room will be equipped with two boilers and turbine sets to provide redundancy. The rated power of each setup will be equal to the base load determined from the load profile. The rated power of the remaining diesel generator sets in the other three engine rooms will be determined based on the redundancy requirements used for the original powertrain design. Two of the remaining three engine rooms must be capable of providing the peak load requirement minus the output of the iron powder setup. The layout of this hybrid powertrain is modelled in Figure 8.

**Figure 8: Simplified diagram of hybrid powertrain**

## Dimensions and weights

The load profiles show both the power and energy requirements of the vessels, the key information needed in order to properly size the powertrain components. The dimensioning and weight estimation is split into three main categories. First, the estimation of the iron powder components is done including everything in the engine room as well as the silos and filters. Next, the diesel generator sets are estimated as well as the bunker tanks. Finally, the main elements of the ship are estimated.

### *Iron powder components*

The iron powder components to be estimated are the steam turbines, boiler, filters, and silos. These dimensions will vary per vessel as they are dependent on the base load required for each vessel as well as the overall kWh needed over the course of a mission. The method of dimensioning and weight estimation is based largely on the methods used by de Kwant et al (2023) for a similar iron powder setup.

### *Diesel generator components*

The diesel generator components are far simpler to estimate as these are far more common and readily available for commercial use. This is also the case for the bunker tanks for the marine diesel fuel as the tanks have far more flexibility for placement compared to the silos for iron powder storage.

### *Ship main elements components*

The ship structural elements consist of the remaining weights on the vessel required for an accurate stability calculation. These include the cranes, the ballast, thrusters, and the structural weight of the vessel. These elements are estimated separately despite the lightweight of all four reference vessels being given due to their varying placement aboard the vessel, these weights and their centres of gravity are required for a more accurate stability evaluation.

## Feasibility

Using the information from the dimensioning and weight calculations, some base stability calculations can be made to determine both the feasibility of a hybrid setup on a SSCV as well as how this would look like. Due to a lack of information regarding the motions of these types of vessels as well as the exact internal layout of the vessels only the intact stability will be evaluated. Firstly, a look at the impact of the hybrid setup on the draft of the vessel is investigated. This is followed by the intact stability evaluation which is comprised of a transverse meta-centre height check and a longitudinal balancing leading to a general arrangement of the feasible vessels.

### ***Draft***

The draft of SSCV is used as a variable that can increase a vessels stability in working condition. The draft is lowest in sailing condition to minimize the underwater surface area and therefore resistance of the vessel. The draft is highest when performing heavy crane operations as the increased draft ensures a lower ship response to wave loading. The draft is essentially altered through creation of extra deadweight through pumping ballast water into the pontoons and occasionally pillars of the vessel. This increase in vessel weight increases the draft of the vessel. This change in draft is estimated for each vessel depending on their increased mass due to the iron powder setup.

This value is especially important for the transit draft condition as this cannot be compensated by simply pumping less ballast as is the case for the vessel's maximum draft. This increase in draft will certainly increase the underwater surface area which in turn will increase the resistance of the vessel changing its transit speed. This is an issue that may require a redesign of the vessel geometry to account for the added weight. If the draft at transit level increases to above the height of the pontoons, the issue is deemed serious and requiring significant redesign considerations. If the draft at transit level increases but not above the height of the pontoons, it is considered an issue requiring less significant and far-reaching redesign considerations.

### ***Transverse stability***

The transverse stability of SSCVs is generally quite high to accommodate for large moments caused by crane operations. Although the vessel motions due to wave loading are significantly reduced at maximum draft, the metacentre height (GM) is significantly reduced. Therefore, the assumption is made that if the GM is acceptable at maximum draft in fully loaded condition, the GM will be acceptable for all other drafts and conditions as well. According to classification rules for heavy lift vessels in Part 5: Ship Types, Chapter 10: Vessels for special operations, 2021, the 'GM at equilibrium shall not be less than 0.3 m'. Further criteria include that the 'positive range of the GZ curve shall be minimum 15° in conjunction with a height of not less than 0.1 m within this range'. Finally, the 'maximum righting arm shall occur at an angle of heel not less than 7°'. To determine whether this vessel fulfils these criteria, the GM is determined as well as the GZ-curve for the first 15 degrees.

### ***Longitudinal stability and general arrangement***

The longitudinal stability is largely dictated by the distribution of ballast across the length of the vessel. This allows the trim of the vessel to be managed in different circumstances and drafts. The general arrangement of the vessel dictates to what degree the ship will trim and to what extent this trim must be controlled.

This placement of the various components to fulfil transverse and longitudinal stability creates a general arrangement of the vessel. The components are placed within the bounds of the geometry of the vessel at various heights along the length of the vessel. The placement will be symmetrical along the breadth of the vessel as is the case with almost all seagoing vessels. This general arrangement will be displayed in the 3D Rhinoceros model made for each vessel with side and top views of each level shown as well.

### **Emissions**

The key advantage of iron powder as a power source is its significantly lower greenhouse gas emission in comparison the marine diesel fuels being used. It is assumed that the installation of an iron powder hybrid setup will likely incur technical concerns regarding the vessel design. The emissions decrease is weighed against these concerns to determine whether the degree of feasibility of installing an iron powder hybrid setup on a particular vessel is worth the effort and cost. This is done by having the emission reduction potential be a key factor alongside feasibility in making a final recommendation in the conclusion. Firstly, the pollutants to be considered are determined as well as their output for each power source and then the original powertrain is compared to the hybrid powertrain to determine the level of emissions reduction.

## **CASE STUDY**

For this case study, a set of four semi-submersible vessel (SSCV) designs was chosen to be a representation of the SSCV fleet. Each vessel design has a slightly different geometry, size, and crane capacity. These four vessel designs are considered sufficient to represent the global SSCV fleet. The differing geometry and capacity allow for a clearer comparison between the vessels when evaluating the reasons for technical feasibility.

### **Key information**

The four vessels have varying main dimensions, carrying/lifting capacities, and powertrain setups. The main information on each vessel is provided in Table 2, and will be used to help create suitable load profiles and general arrangements.

The only missing base information regarding these vessels was the powertrain configuration and total power output capability of Vessel C. The main features shared by all four vessels is the tier III dynamic positioning capability since this is a requirement

for the heavy lifting operations. This means that the thrusters for each vessel are azimuth thrusters. All vessels have a transit depth of 11-12m with maximum depths ranging from 25m to 32m. These maximum depths are only reached during heavy lifting operations in which the dynamic positioning is also active. The crew accommodation also vary from 400 persons up to 736 persons. These main points of information are used to determine the expected power requirements for each operating mode.

**Table 2. SSCV main dimensions and key information**

Dimension	Symbol	Vessel A	Vessel B	Vessel C	Vessel D	Unit
Length	$L$	220	201.6	154	137	m
Breadth	$B$	102	88.4	106	81	
Min Draft	$T_{min}$	12	11.9	11	11.28	m
Max Draft	$T_{max}$	32	31.6	25	26.4	m
Depth	$D$	49.5	49.5	42	39	m
Crane Capacity	$C_{cap}$	2x10,000	2x7,100	2,721 + 3,628	2x1,800	T
Transit Speed	$V_{tr}$	10	7	5	8	Kts
Thrusters	$T$	8x5.5	6x5.5	7x3.5	6x3.8	MW
Powertrain	$P_E$	12x8	6x4.9, 4x4.5, 2x5.5	N/A	8x3.86	MW
Total Power	$P_T$	96	58.4	N/A	30.88	MW
Accommodation	$N_{per}$	400	736	394	618	-

### Load Distribution

Taking information from the power requirements of an existing SSCV (Hagen, 2021), the power ranges were extrapolated to each of the four vessels based on the information in Table 2 on each vessel. These estimated power requirements were split over the three main consumers: the thrusters, cranes, and hotel load, and are presented in Table 3.

**Table 3: Estimated power ranges for each vessel**

	Hotel Load [MW]				Thruster Load [MW]				Crane Load [MW]			
	Vessel											
Vessel	A	B	C	D	A	B	C	D	A	B	C	D
Idle	4-5	6-7	4-5	5-6	0.15-0.3	0.15-0.3	0.15-0.3	0.15-0.3	0-3	0-2	0-1	0-1
Sailing	6-7	9-10	6-7	8-9	29-31	22-23	16-17	15-16	0	0	0	0
Working	1-4	1-6	1-4	1-5	5-22	4-16	3-12	2-12	2-40	2-15	1-4	1-3

Using this information and the distribution of time spent in working, sailing and idle mode, the following load profiles were created shown in Figure 9. Each vessel was given the same mission time of 12 weeks and the loads were split between each main consumer; cranes, thrusters, and hotel load. From this split, a total power profile was created by summing the load requirements of each consumer. The total power consumption for each vessel was determined as the average over the 10,000 load profile simulations run.

Through further analysis of the range of load profile simulations of each vessel, the general split between iron powder and MDO power can be shown in the form of a percentage range of the total power requirement of the vessel. These values are shown in Table 4 for all four vessels.

**Figure 9a: Vessel A**

**Figure 9b: Vessel B**

Figure 9c: Vessel C

Figure 9d: Vessel D

Figure 9: The power profile of each vessel as the total load required

Table 4: Range of percentage total power demand covered by base and variable load.

	Base Load % of Total Demand	Variable Load % of Total Demand
Vessel A	18-45	55-82
Vessel B	31-63	37-69
Vessel C	41-67	33-59
Vessel D	45-73	27-55

## Dimensions and Weights

The dimensions and weights were categorized into the engine room weights, bunker weights, and ship element weights.

### Engine Rooms

One of the four engine rooms on each vessel will be fitted with the iron powder setup. This engine room will contain the turbines, boiler, and the electrical motor. The dimensions of the engine room are therefore determined by the dimensions of the turbines, boiler and electrical motor combined. A minimum additional margin 10% of length, breadth and height is added for other components as well as to give space for engineers. The length, breadth, height, and the total mass of each engine room is listed in Table 5.

Table 5: Main dimensions for each iron powder engine room

	Length [m]	Breadth [m]	Height [m]	Total Mass [t]
Vessel A	14	6	7	572
Vessel B	16	10	7	734
Vessel C	14	6	7	572
Vessel D	15	9	7	662

The breadth and total mass are double the amount needed for one UST setup as the engine room will need to fit two setups to ensure the strict redundancy criteria of semi-submersible crane vessels are fulfilled.

The diesel generator engine rooms are determined by the size and number of generator sets assigned to each vessel. Three of the four engine rooms to be placed on the vessels will be fitted with diesel generators. As with the iron powder engine room, a margin of at least 10% extra length, breadth and height are added for the remaining smaller components as well as room for engineers. The length, breadth, height and total mass of each engine room is listed in Table 6.

Table 6: Main dimensions for each diesel-powered engine room.

	Length [m]	Breadth [m]	Height [m]	Total Mass [t]
Vessel A	13.5	15	5	616
Vessel B	12	10	5	363
Vessel C	11	9	5	228
Vessel D	11	10.5	5	327

The mass and breadth of Vessel A are multiplied by four as this is the number of engines to be fitted in one engine room. The mass and breadth of the remaining vessels is multiplied by three as these engine rooms are fitted with one less generator set each.

### **Bunker**

The design of the silos is dependent mainly on the dimensions of the vessels. These silos will be placed in the pillars of the main structures of each vessel and each vessel has different sized pillars. The height of the pillars is the main factor in determining the dimensions. The number of silos is taken as the number of silos needed to carry the required bunker including the bunker margin plus the additional 4 empty silos required for initial oxide deposit. The total number of silos must be an even number to allow for even distribution among the pillars on each side of the vessel. The main dimensions and volume of one silo as well as the number of silos required and total iron powder bunker mass for each vessel are listed in Table 7.

**Table 7: Main dimensions for the silos on each vessel.**

	Total Height [m]	Diameter [m]	Number of Silos	Total Mass [t]
Vessel A	21.6	3.93	34	16600
Vessel B	21.5	3.91	46	23200
Vessel C	20.7	3.76	38	16600
Vessel D	18	3.27	66	19900

The bunker level is determined based off of the specific fuel consumption of the chosen generator sets. The bunker will be placed in the remaining available area in the pillars. The total MDO bunker level required for each vessel as well as its mass are listed in Table 8.

**Table 8: Required weight and volume of the MDO bunker on each vessel.**

	Bunker Mass [t]	Bunker Volume [m <sup>3</sup> ]
Vessel A	5030	5650
Vessel B	2610	2930
Vessel C	2140	2400
Vessel D	1930	2170

### **Ship Elements**

The ship structural elements contain the remaining significant elements of the vessel who have a significant mass and therefore significant impact on the ship stability calculations. These include the crane, ballast, thrusters, and structural weight of the vessel. The total mass of each of these elements are listed in Table 9.

**Table 9: Mass estimations of key ship elements.**

	Crane [t]	Ballast [t]	Thruster [t]	Structural [t]
Vessel A	6850	113000	512	83500
Vessel B	5980	120000	384	66100
Vessel C	5160	30000	329	44100
Vessel D	2240	21000	282	31100

These values alongside the other estimated masses for each engine room will be used to calculate an initial static stability to evaluate the feasibility of a hybrid iron powder configuration and to visualize how this would best fit.

### **Feasibility**

The feasibility of an iron powder hybrid configuration on a SSCV can be measured in many ways. In this case, due to a limited amount of information about these vessels and their dynamic seakeeping behavior, the choice was made to keep to a base feasibility determination. This means that the main static stability criteria will be evaluated such as the draft, transverse stability, and longitudinal stability. Calculations will be made for each of these categories and the results will be compared to either the original powertrain setup of the vessel or the Det Norske Veritas (DNV) classification bureau stability requirements for SSCVs [Part 5: Ship Types, Chapter 10: Vessels for special operations, 2021].

### **Draft**

The draft is one of a SSCV's key feature in that it should be able to increase and decrease its draft according to its operating mode. A significant change in the total mass of the bunker will increase the draft of the vessel. By comparing the hybrid bunker mass level with a marine diesel fuel only mass level, the change in draft due to the increased bunker mass can be calculated. This is most important in the transit mode as ballast reduction is not possible in this mode meaning the draft increase cannot be simply compensated. The resulting draft increase is listed in Table 10.

**Table 10: Draft increase due to increased bunker mass.**

	Increase in Bunker Mass [t]	Increase in Draft [m]
Vessel A	15200	1.16
Vessel B	21200	2.22
Vessel C	15200	6.02
Vessel D	18300	8.06

The results are quite varied for each vessel as could be expected. This change in draft depends on both the mass increase as well as the ship's waterline area. The draft change was measured at minimum or transit draft as this is where the change in draft has the most impact. The maximum draft level can be much more easily maintained by adjusting the level of ballast. This is not the case for transit draft as there is no ballast to adjust. Of the four vessels, the only vessel indicating that the increased bunker will not necessarily require a redesign of the pillars and pontoons is Vessel A. The draft increase on Vessel C and Vessel D are mainly due to their small waterline area over all their pillars especially when compared to Vessel B and Vessel A. The substantial draft increase on these two vessels points to a need for a pontoon and pillar redesign if it is to accommodate the expected iron powder bunker level. While the increase in draft is not as severe as for Vessel C and Vessel D, Vessel B will likely also require a redesign of the vessel to a lesser extent. This is due to the draft now being above the pontoon height.

### ***Transverse Stability***

The metacentric height (GM) can be calculated for each vessel. Due to the limited information available for these vessels, only a base static transverse stability calculation can be made from which any reasonable conclusions can be drawn. Table 11 lists the KB, KG, BM, and GM values for each vessel in a fully loaded condition at the maximum draft.

**Table 11: Transverse stability values for each vessel**

	KB [m]	KG [m]	BM [m]	GM [m]
Vessel A	11.4	35.7	28	3.62
Vessel B	12.2	30.9	25.1	6.35
Vessel C	9.05	30.8	26.8	5.11
Vessel D	7.61	26.7	19.6	0.52

According to the classification rules by DNV [Part 5: Ship Types, Chapter 10: Vessels for special operations, 2021], the minimum allowed GM of 0.3m at maximum operating draft has been met by all four vessels. Vessels A, B and C even have a wide margin of safety above the minimum required GM value. This indicates that it may be possible for the iron powder hybrid configuration to be installed without negatively impacting the transverse static stability of the vessel. It must be considered that these GM values are determined based off rough estimations and may in fact not reflect reality. There are certain extra mass elements aboard the vessel that may not be as large as the ones considered but may add up alter the estimated KG value. This is why the margin of a few meters regarding the GM values of Vessels A, B and C are more promising than the 0.2m margin for Vessel D. If these estimations were to be altered and the GM were to lower, the chances of Vessels A, B and C still fulfilling the initial transverse stability criteria are far higher than that of Vessel D. On top of this, Vessel D has a righting arm that reaches only a maximum of 0.05m at 15 degrees of heel, which is only 50% of the minimum requirement stated by DNV. This means that Vessel D does not meet the stability requirements and cannot be deemed feasible with an iron powder setup.

### ***Longitudinal Stability***

The longitudinal stability of each vessel is largely determined by the trimming moment created by the vessel. The trimming moment is dependent on the longitudinal center of gravity of each component/element placed on the vessel. Each vessel has its own longitudinal center of buoyancy and its own structural longitudinal center of gravity. These elements cannot be altered same as the longitudinal center of gravity of the cranes, thrusters, and ballast. The trimming moment is minimized by keeping the total longitudinal center of gravity of each vessel within one meter of the longitudinal center of buoyancy of each vessel. The longitudinal center of gravity of the engine rooms and bunker tanks/silos have the largest impact on the longitudinal center of gravity of the vessel. Table 12 shows the needed longitudinal centers of gravity of the engine rooms, fuel bunker and iron powder bunker to ensure this minimal trimming moment.

**Table 12: Longitudinal centers of gravity for each element that can be placed for each vessel.**

	LCG Engine Rooms [m]	LCG MFO [m]	LCG Iron Powder [m]
Vessel A	75	156	90
Vessel B	70	163	80
Vessel C	50	100	60

These conditions alongside the vertical component placement conditions determined for the transverse stability can be used to create a general arrangement for Vessels A, B and C shown in figures 13, 14, and 15.

**Figure 10a: Vessel A**

**Figure 10b: Vessel B**

**Figure 10c: Vessel C**

**Figure 10: Perspective view of each vessel's hybrid general arrangement**

## Emissions

The environmental impact of installing a hybrid iron powder powertrain on these SSCVs can be determined through an emissions comparison. The distribution of base versus variable power varies significantly for each vessel and is in this case taken as a range of output values as opposed to a singular value. This is due to the high variance in the variable load as it is simulated using probabilities of peak loads occurring. Table 13 shows the total calculated emissions output comparison for both carbon dioxide as well as nitrous oxide.

**Table 13: Total CO<sub>2</sub> and NO<sub>x</sub> output comparison for single year of 3 missions.**

Vessel	CO <sub>2</sub> Total Output [kg/kWh]		NO <sub>x</sub> Total Output [kg/kWh]	
	Hybrid	Original	Hybrid	Original
Vessel A	44100	66900	175	226
Vessel B	27900	46800	93	162
Vessel C	18300	31500	61	116

This comparison is based off of the assumption that three 12-week missions will be completed in a year to leave over 10 weeks for non-mission transit and potential maintenance and repair. The total CO<sub>2</sub> reduction is significant reaching around 20,000 tons of CO<sub>2</sub> a year for each vessel. The total NO<sub>x</sub> reduction is not as large as the total output values are far lower than the CO<sub>2</sub> output. A reduction of around 50 tons of NO<sub>x</sub> yearly can still be achieved which is in the case of Vessel C is around half of its total expected NO<sub>x</sub> output.

## CONCLUSION

Based on the results, certain feasibility evaluations can be made. First, it was determined that there is an optimal iron powder setup that can feasibly be placed aboard a marine service vessel. Furthermore, it was determined that a SSCV would be the most optimal vessel on which to place this iron powder setup. From this literature level research, the importance of implementing a hybrid setup was made clear. Through application of a model and simulation of said model on a case study of a set of SSCVs, the level of base feasibility can be determined for each vessel as shown in Table 14. In this table, the impact of the hybrid setup on the draft, stability and emissions of each vessel is compared. In the case of the draft, '1' indicates the lowest increase in vessel draft due to the increased mass while in the case of the stability '1' indicates the highest level of metacentric height and initial righting arm. In case of the emissions, '1' indicates the largest estimated decrease in CO<sub>2</sub> and NO<sub>x</sub> emissions.

**Table 14: Short comparison table ranking the feasibility of each case study vessel.**

	Draft	Stability	Emissions
Vessel A	1	3	2
Vessel B	2	1	1
Vessel C	3	2	3
Vessel D	4	4	N/A

Vessel A claims the second highest feasibility level as it is least affected by the mass increase in terms of both draft and stability while still seeing significant emissions reductions. Vessel B has highest feasibility with only a minor concern regarding draft increase and satisfying the initial stability estimations whilst having an estimated highest emissions decrease. Vessel C is still considered base level feasible despite its issues with increased draft as its initial stability levels are more than sufficient. Vessel D is considered not feasible at a base level due to its lack of stability coupled with a high draft increase at a higher mass making an emissions comparison unnecessary. This leads to the main conclusion that the larger SSCVs are generally considered to be more feasible candidates for iron powder hybrid powertrain installation as they generally shaped to provide a larger water-plane area and equipped with a far larger deadweight carrying capacity. The key points of concern when trying to implement an iron powder powertrain on a SSCV include:

- Hybridization will be required due to the high variability in SSCV load profiles as well as increased mass of the iron powder bunker
- Balance needs to be found regarding the amount of power delivered by the iron powder powertrain (emissions saved) and the impact of its bunker on the vessel's stability and operability
- Larger SSCVs provide more sizing possibilities with comparatively lower vessel stability impact

## FUTURE WORK

As the main concerns regarding iron powder implementation on marine vessels lies largely in the technical feasibility study, it was this area that was focused on most. There was not sufficient time to conduct a proper cost estimation for the vessels. This would provide interesting context to the technical feasibility as the initial costs of the setup can be compared to conventional

energy sources as well as the yearly bunker costs. This is especially interesting considering the iron powder cycle and the possibility of becoming a fully cyclical energy source meaning only one initial bunker cost is made for the lifetime of the powertrain. Redesign costs and port infrastructure costs can also be considered in this economic feasibility analysis to provide a full picture of the potential of iron powder as an energy source.

This research was done as an in-house project meaning that there was no continuous contact with companies within this field during the research. This meant that the information provided about certain iron powder powertrain components and the SSCVs was generally quite limited. The key information used as the main inputs of the method in were taken from official vessel brochures and reports that highlight the operating profile of select SSCVs. This information was then taken and extrapolated as carefully as possible to be applied to a wider range of SSCVs with the knowledge that the results would not be a complete reflection of reality. While these results were considered sufficient for evaluating a base level of feasibility for each vessel, more base information would allow for a more in-depth analysis of the impact of a hybrid iron powder setup. This includes a look at the impact of crane operations on the stability with a hybrid setup as well as a potential damage stability simulation to provide a more rigorous analysis of the stability of the vessel. More information regarding the performance and output of the existing SSCVs would contextualize the emissions results outside simply the estimated original setup for each vessel. With continuous contact with experts in these fields, it is likely that even more measures of feasibility can be considered to go beyond simply a base level feasibility.

# Grounded Ambitions: A Lean Approach for Assessing Beachability in Concept Design

Austin Shaeffer, PhD<sup>1,\*</sup>, Sam Murphy<sup>1</sup>, Tim McIntyre<sup>1</sup>, Alex Wiggins<sup>1</sup>

## ABSTRACT

*Littoral operations have become an increasing interest for defense stakeholders over the last several decades. Many navies currently operate ship-to-shore assets that are designed to travel shorter distances exclusively in the littorals between a ship and the beach. New concepts are being designed to transit much longer distances from shore-to-shore in both blue water and littoral regions. This Concept of Employment (CONEMP) drives these ships to displacements that are orders of magnitude larger. Compared to smaller vessels where seakeeping and maneuverability performance in the surf-zone are a significant area of interest, larger vessels have a comparatively greater risk with respect to the ability of the ship to get far enough up a beach to safely deliver assets and then get off the beach. This research presents the foundation for a new simulation tool to analyze how far up the beach a ship will be able to get given loading condition, initial speed, beach condition, and hull shape. The focus of this research is to provide a low computational-cost method for analyzing the beachability of a ship that still considers the dominating physical phenomena of grounding at early stages of design. The tool will need much faster turnaround times than high-fidelity Reynolds-Averaged Navier-Stokes (RANS) or Finite Element Analysis (FEA) simulations to support the rapid and evolving environment of concept design timelines.*

Amphibious; Landing; Computational Methods; Ship Concept Design; Beaching

## INTRODUCTION

Landing ships and craft play a critical role in delivering people and supplies to areas with limited infrastructure, during both war and peacetime. They have been the vanguard in many operations such as the Normandy landings during WWII, Incheon Bay during Korea, as well as being some of the first on the scene during disaster relief efforts such as during Operation Sea Angel following the 1991 Bangladesh cyclone and Operation Unified Assistance following the 2004 Indian ocean tsunami (Lewis, 2023; Smith, 1995; Tsunami aid: Who's giving what, 2009). Landing ships and craft enabled each of these operations by facilitating the movement of people and supplies in a way that was unachievable by air and ground means. Landing craft remain a major interest to the world's navies, with most major navies having a significant amphibious force in their fleet (Baker, 2023).

Amphibious landing operations conducted by the Allies during WWII often saw the use of Landing Ship Tanks (LST), which were ocean-going ships that would carry heavy equipment such as main battle tanks and smaller landing craft. LSTs could travel long distances in shore-to-shore scenarios, as shown in Figure 1, that smaller landing craft cannot. LSTs were not only important for large amphibious operations, but also for supplying troops in areas with no infrastructure such as the Pacific Islands as shown in Figure 2. The director of the Southwest Pacific forces during WWII, Daniel E. Barbey, said of the LST, "Without these ships there would have been no Southwest Pacific Force. Without these ships the major amphibious invasions of Europe and the Pacific could not have been undertaken" (Barbey, 1969). D-Day, in which over 4,000 landing craft of various types were deployed, was delayed in part due to the required 230 LSTs that were not yet ready, as they were necessary to deploy the five sea assault divisions and heavy armor companies (Koenig & Doerry, 2018).

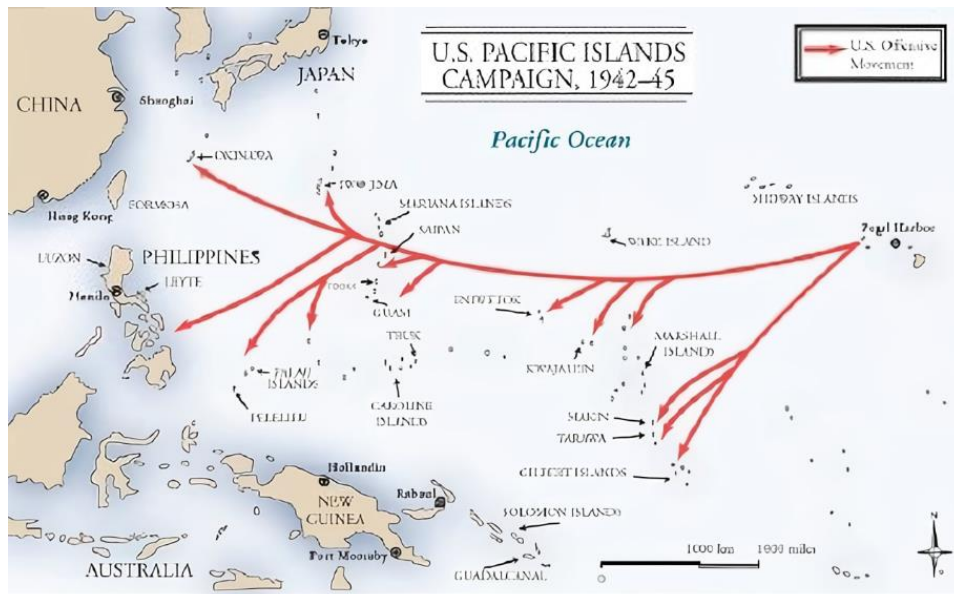

Figure 1: WWII Pacific Island Hopping Campaign (Kuehn, 2015)

Figure 2: LST Unloading Equipment at Iwo Jima (Navy History and Heritage Command, 2016)

Following WWII, changing operational needs drove the amphibious force away from the LST to the Landing Ship Dock (LSD), a type of ship that can carry several coastal, short range landing craft and does not beach itself, unlike the LSTs. The advantages of the LSDs are that they are generally faster than LSTs and can be outfitted for multiple roles when compared to the more restricted LST (Hope, 1991). Across the world, LSDs and LSD type ships like Landing Platform Docks (LPD) and Landing Helicopter Docks (LHD) are either being designed or acquired by many navies due to the flexibility that these types of ships offer (Keane et. al, 2009). The last major LSTs designed by the United States were built in the mid to late 1960s and have since all been decommissioned from the US fleet.

As a result, and demonstrated by the current United States amphibious fleet, most existing vessels that physically land on the beach are small craft like Landing Craft Air Cushion (LCAC), Landing Craft Utility (LCU) and Assault Amphibious Vehicles (AAV) that operate between the larger LSDs, LPDs, and LHDs and the beach. The LCAC, an unconventional landing craft, shown below in Figure 3 has an operation range of 200-300 nm (Naval Sea Systems Command, 2021). The average concept of employment (CONEMP), a use-case-oriented description of a system, for these crafts only necessitates shorter transit distances near the coast. This, in addition to host ship requirements has driven the size of these ship-to-shore

crafts much smaller than the LSTs of WWII. LCUs can be better categorized as boats, generally, due to their operational profile between the coast and host ship (Raunek, 2022). Because boats are generally smaller, a major focus during their design is on performance in a near-beach seaway as the waves can have a significant impact on their ability to safely arrive and land on the beach. This has prompted most of the research and development for landing craft to be focused on small craft with an emphasis on how they handle in the surf zone or very large ships that do not contact the beach directly. For purposes of this paper, large ships will be considered as those that must transit open ocean and usually have a displacement greater than 1000 tonnes.

Figure 3: LCAC Unloading (Naval Sea Systems Command, 2021)

The flexibility of the LSD type ships is not without its drawbacks. Reliance on multiple smaller craft to bring equipment and supplies to the shore functionally limits the missions and quantities the ship can deliver. To overcome this limitation, there has been a push in recent years to develop a larger beaching vessel, operationally similar to the LST that can land heavy equipment as well as transit the open ocean. The ability to perform both of these functions means that a large landing ship will be able to operate independently of ports and landing craft. This falls in line with the concept of the fast moving, self-supplied marine littoral regiment (MLR), which will provide mobility and flexibility for littoral combat operations (U.S. Marine Corps, n.d.). In addition to supporting an MLR, a large landing ship will be able to deliver supplies and troops across the area of operations with minimal infrastructure support and aid the Naval Construction Force (SEABEES) in establishing infrastructure. An artist's rendering is shown in Figure 4 (Harper, 2022).

Figure 4: Artist's Rendering of Potential Large Landing Ship (Harper, 2022)

Due to the shift towards LSD type ships and small beaching craft, a knowledge gap exists for large, LST-like, landing ship design; which makes the acquisition of these ships particularly high-risk. Additionally, since WWII, ground vehicle weights have increased, with the heaviest vehicles, main battle tanks, increasing from 30.3 tons during WWII, to 61 tons when the

M1 Abrams was first developed, to the massive 75 tons the Abrams is currently (Larson, 2021). This increase in weight creates design challenges in landing these heavy vehicles, posing risk to new landing craft designs. Increased costs and complexities since WWII also means that ships are harder to build and replace, with Fletcher class destroyers costing \$102 million in current USD per ship while the Arleigh Burke Flight III costs \$1.45 billion per ship (Hill, 2023). Increased cost means that high risk factors, such as beaching ships' ability to get up the beach, need to be more heavily scrutinized in the early design stages.

To address knowledge gaps, larger ship acquisition costs, and increasingly short timeframes, modeling and simulation is being implemented across the ship design space to maximize ship performance regarding mission requirements (Cole, 2022). Modeling and simulation, a capability that didn't exist in a comparable state to the modern era when LSTs were designed, provides a low-cost solution to address potential risks in ship designs. To pare down risk and address the knowledge gaps specific to large landing ship beaching, this paper outlines the theory for developing a simulation tool for the large ship beaching problem.

If there was a tool that filled the knowledge gap identified, it would provide a critical new capability in the ship concept design space. Currently, the impacts of ship design characteristics on hydrodynamic performance, like resistance and seakeeping, are well known. Additionally, there exist an array of available ship design analysis tools to determine the seakeeping and resistance performance of a ship. This is not the case for beaching analysis; therefore, there is a need for development of an analysis method to accurately assess the beaching problem and determine the relationship between ship design characteristics and beaching performance. With a method available to assess beaching characteristics quantitatively, a trade off in performance for these three areas of hydrodynamic design can be determined, driving ship design forward and delivering well rounded ships to complete the specified mission.

Application of this tool in the design spiral paired with beaching Top Level Requirements (TLR) will be a driving factor for hull shaping and displacement. Using provided requirements for the beaching environment, ramp angle, ramp length, and fording depth, a designer would be able to assess bow shaping impacts and determine necessary ship conditions for beaching such as trim and displacement. These discoveries would inform the amount of payload the vessel would be able to carry, the arrangement and amount of ballast tanks to meet a required trim, and the opportune bow shape for a beaching operation. These impacts are critical components of the design of beaching ships and this tool provides a way for ship designers to identify risk and communicate capabilities of concept designs in a quantitative and comprehensive manner.

## BACKGROUND

The United States Defense Acquisition Process can be summarized into multiple milestones as shown in Figure 5. Discussion in this paper is pre-Milestone B with a focus on Milestone A, Material Solution Analysis. According to Defense Acquisition University (DAU), "Phase activity will focus on identification and analysis of alternatives, measures of effectiveness, key trades between cost and capability, life-cycle cost, schedule, concepts of operations, and overall risk" (DOD Instruction 5000.84 "Analysis of Alternatives", 2020) During preliminary design, naval architects must deal with several technical challenges with tight timelines and budgets. Despite only 5% of costs being expended in preliminary design, 60%-80% of lifecycle costs are usually determined from decisions made in this stage. Visually, this is demonstrated in Figure 6. Being able to perform analysis early in the design process is a necessary way to buy down risk and lower program costs (Gaspar, 2011).

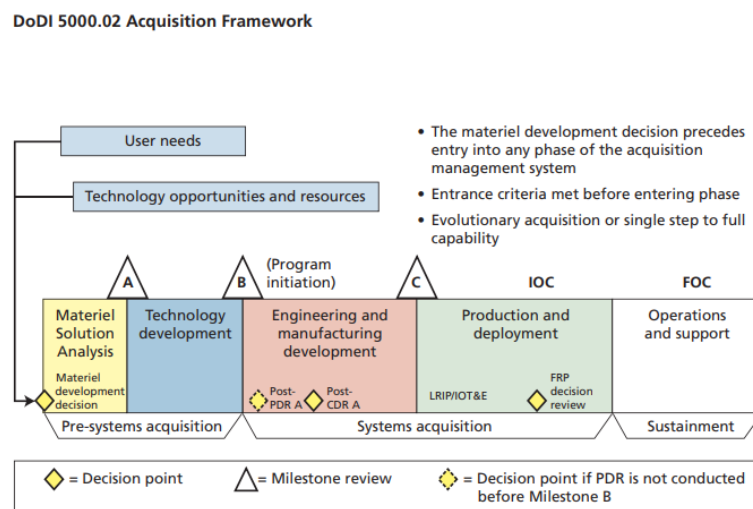

Figure 5: Defense Acquisition Lifecycle (Drezner, et al., 2011)

Figure 6: Overall Ship Cost by Milestone (Gaspar, 2011)

Due to the numerous, interrelated aspects of ship design, naval architects often refer to the design process as the design spiral shown in Figure 7 (Gaspar, 2011). Starting very broad and assessing one aspect of the design at a time, the design should eventually converge to meet requirements. It is expected that as the design changes, setbacks will occur, and specific aspects of the design will need to be assessed multiple times. For example, as displacement increases, draft increases and resistance on the hull form must be re-assessed. If resistance increases too much, larger engines must be selected to meet speed requirements, which will again increase displacement and have additional impacts on ship performance and cost. To add more complications, requirements at this stage of design are often fluid and design teams must adapt quickly and be flexible to these changes.

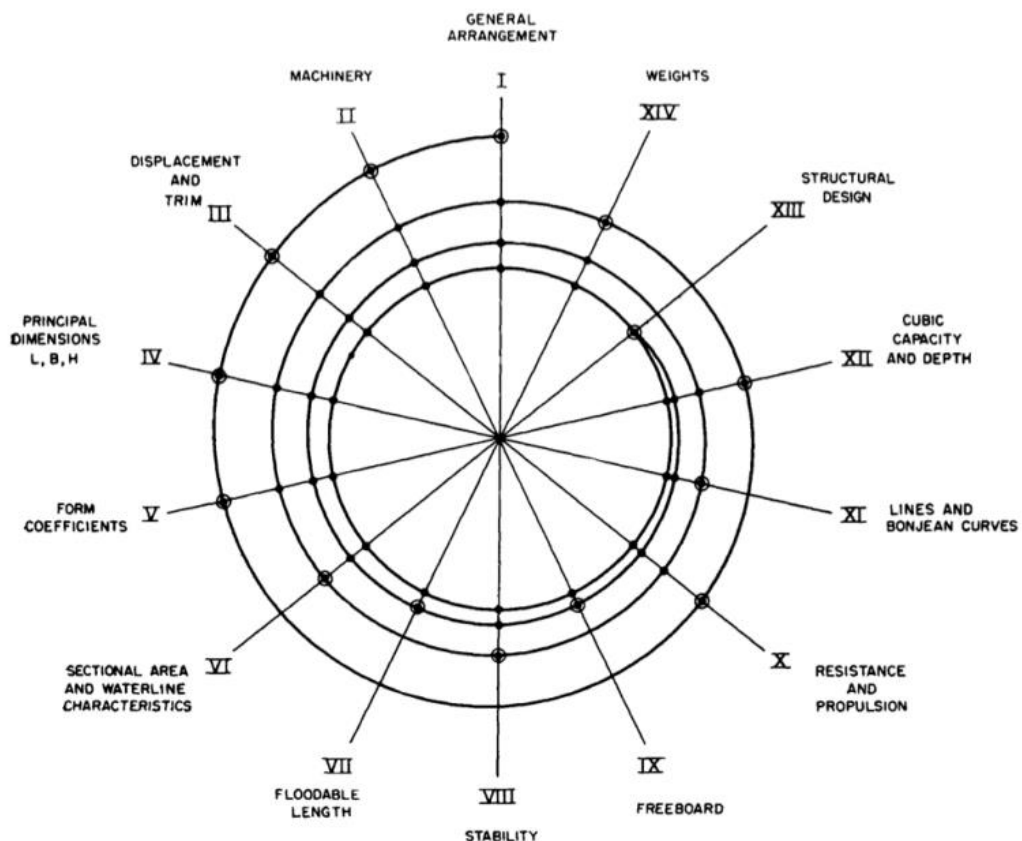

Figure 7: Ship Design Spiral (Gaspar, 2011)

Concept design makes up various aspects of the solutions analysis and concept refinement steps shown in Figure 8 (Schank, et al., 2014). Project durations often range from small 3-month excursions to large multiyear efforts. Each type of project having its own complexities and complications. In comparison to other design stages, this is a relatively short period of time for a "typical" USN ship design cycles shown in Figure 9. Examples of the work naval architects do include integration studies, Analysis of Alternatives (AoAs), Requirements Evaluation Teams (RETs), and full ship concept designs sometimes referred to as indicative designs. During the CVX AoA, roughly 70 ship studies were developed and evaluated (Raber & Perin, 2000). The magnitude of these design programs creates a dire need for tools to deliver fast, accurate results. Fortunately, developments in recent years have made analysis in many areas of ship design quite agile. In the example of an AoA, it is necessary for technical experts to have the ability to assess several designs against Key Performance Parameters (KPPs). Design Space Exploration (DSE) is another growing area of interest in naval architecture in which a full range of parameters are varied in order to study a wider scope and gather quantifiable data to inform decisions (Robertson, et.al., 2022). DSE is increasingly valuable in situations when there may be design bias or a lack of clarity in requirements. An effort conducted at Naval Surface Warfare Center (NSWC) Carderock Division generated 2,916 individual hull forms to evaluate the impacts of varying hull characteristics on resistance, stability, and seakeeping (Strickland, Devine, & Holbert, 2018). Doing such analysis on hull shape provides valuable insight as to the preferred design for resistance, seakeeping, or other metrics such as beachability. This makes DSE yet another use case for a beaching tool that is capable of accurate results and short run times. The concept design environment can be fluid, fast paced, and often necessitates naval architects to be able to quickly run analysis, often with turnaround times less than 24 hours, or against hundreds to thousands of design points. Although concept design is a small portion of the overall ship design life cycle, it informs and drives the rest of the cycle, making it a critical step in ship acquisition.

ground reactions, which is computationally expensive and complex. As shown in Figure 10, this approach requires a well-defined mesh that is recalculated at every time step to account for soil deformation, driving up computation costs. The same group also worked on a lower fidelity solution which uses data from higher fidelity models to drive outputs, however this means large changes in the design will require additional simulations with the high-fidelity model (Yamashita, et al., 2023). Since concept design often requires significant design changes, this approach is not a viable method. In summary, due to high computational costs, long set up and run times of high-fidelity codes, as well as a heavy focus on seakeeping, small craft beaching research is not applicable to pre-Milestone B applications or for scaling to larger ship sizes.

Figure 10: Boundary Mesh of the Wheel of the Quad Ski (Yamashita, et al., 2022)

Separate work has been done to characterize the deformation of saturated soil using LS-DYNA, a commercial structural deformation code that has large material libraries and experimental validation, making it ideal for quick simulation development (Flores-Johnson, et al., 2016). However, these studies and LS-DYNA solve material interactions on the grain scale, which leads to high computational costs and heavy reliance on user knowledge for setup (Flores-Johnson, et al., 2016; Sturt, et al., 2021). It has been used in applications of saturated sand deformation, making it applicable to the beaching problem, however, LS-DYNA does not calculate hydrodynamic interactions making it difficult to use in landing vessel applications (Flores-Johnson, et al., 2016). Additional research has been done on the effects of ship-structure interactions on larger commercial ships; generally, regarding the effect of grounding of the ship or the effect of a ship striking an offshore platform. Many of these studies used Finite Element Analysis (FEA) approaches within LS-DYNA to quantitatively define the effect of ship strikes on the sea floor as well as offshore platforms (Nguyen, et al., 2011; Yu, et al., 2016). Like other LS-DYNA codes, the main issue with these methods is that they require long setup times, large amounts of computational resources, and high user expertise, making them unsuitable for a concept design problem. Research done by Hansen, et al. (1995) attempted to define how far a ship will travel up a beach during grounding. They utilized a pressure method to calculate soil reaction, which was experimentally verified as shown in Figure 11. (Sterndorff & Pedersen, 1996). This method, while less computationally complex than LS-DYNA, still required a significant amount of computational resources and would require additional experimental data to support the analysis of vessels with other than simple, conventional bows.

Figure 11: Full Ship Grounding Experiments Conducted by Sterndorff & Pederson (1996)

In other technical disciplines related to naval architecture, there are concept design tools, such as Total Ship Drag (TSD) for resistance prediction and Ship Motion Program (SMP) for seakeeping evaluation, that allow naval architects to evaluate concepts rapidly (Wilson, et al., 2011). These concept design tools, while physics-based, generally have less fidelity than some of the more computationally intensive tools, however, they provide a reference point to compare multiple designs and inform the stakeholder on the best path forwards. These tools have quick setups and run times, which make them appealing for the fast-paced environment in pre-Milestone B work, but lack both accuracy and flexibility compared to more expensive solutions.

TSD is a low-fidelity tool that provides resistance predictions within seconds by reducing the physical problem using potential flow and Thin Ship Theory assumptions. A critical component of TSD that makes it well suited for early stage design work is that it is relatively easy to use. For example, the simulation is relatively insensitive to the input mesh, removing the need for sensitivity studies and allowing for reduced set up times. The low-cost of TSD make this tool ideal for evaluating a large trade space of concepts. The validation of TSD explains that TSD, “does a good job of providing quick and reasonably accurate evaluations for typical US Navy hull forms.” (Wilson, et al. 2011).

The studies previously mentioned have demonstrated that there is work being done to evaluate beaching in a high-fidelity environment, however, there is a need for beaching analysis programs equivalent to TSD. Only one known method exists for evaluating beaching in a low fidelity realm: a quasi-static state solution, solving an energy balance equation. Based on a paper written by Pedersen (1995), this method considers a two phased approach in which; the first phase considers a ship with velocity  $V$  contacting a sloped beach and trims about a prescribed contact point until the ships trim is equal to the beach slope, and a second phase that considers the hull to then slide up the beach with the entire keel in contact with the beach. The second phase is only entered in this calculation if there is kinetic energy remaining after the ship reaches the trim of the beach. This model is limited in that the flat sloped beach is considered to not deform. This limits the effect of the beach on the ship to a simple frictional force in accordance with Amontons-Coulumb law, using a constant kinetic friction coefficient,  $\mu$  (Pedersen, 1995).

The major limitations of this method are: the two phased quasi-static approach, and the severely limited consideration of hull shape on beach deformation. The quasi static approach limits the actions to large time-step phases where the physics is simplified using different methods in each phase. In both phases, this method ignores the interactions between the relevant physical features. For example, any translation of the hull up the beach as it rotates about its contact point in phase I is neglected. Additionally, ignoring hull shaping would reveal the same result for two hulls approaching the beach with the same velocity and mass, one having a broad blunt bow with a bulb and another with a skinny sharp bow, so long as they had the same contact point. Considering the large scale impacts of bow shaping on other hydrodynamics, like fluid resistance, this is a major problem that the current strategy overlooks and severely limits designers’ ability to compare beaching results across a trade space of differing hulls, a common activity in pre-Milestone B. Therefore, ignoring the deformation of sand is an overly-broad simplification of the interaction and has resulted in low confidence in the results. Additionally, no validation of this method has ever been performed. Given this evaluation method, any engineer would be ill prepared to answer the questions they are currently being asked.

## PROPOSED APPROACH

Language like beaching, beachability, or grounding are all terms that need definition before proceeding. For the purposes of this paper, beaching and grounding are synonymous in defining the act of a vessel impacting, riding up on, and embedding into a beach. This maneuver is intentional and a critical part of the prospective vessel’s CONEMP. This does not include accidental grounding (i.e. a sandbar). Beaching and grounding start when the hull, likely to be near the intersection of the bow and keel, contacts the beach and ends when the vessel comes to a static equilibrium. Beachability is a qualitative measure of how reliably and safely a ship can deliver a payload from ship to shore.

Beachability is generally, quantitatively measured as an achievable fording depth or required ramp length or angle. Factors, such as the final position of a ship after beaching can be used to inform ramp design or evaluate against current ramp characteristics. Ramp angle defines the angle from the horizontal that the ramp contacts the beach. Ramp length defines how far, in any dimension, the ramp can extend from the hinge point. Fording depth represents the distance from the point where the ramp contacts the beach to the water free surface. This functionally represents the maximum depth of water the payloads will encounter during the beaching operation. Different payloads will have different requirements for each of these criteria. For example, vehicles with large separation between axels might have a minimum ramp length or maximum ramp angle to prevent chassis contact with the hinge point of the ramp. Other payloads might have fording depth requirements like vehicles, which cannot have their exhaust stacks submerged otherwise they risk down flooding into the engine. Additionally, ramp length, ramp angle, and fording depth can have significant impacts on the duration of the beaching mission, which can be a critical component of performance.

## Assumptions

The proposed tool will consider a simplification of the physics of beaching to reduce runtime to fit within the discussed concept design framework. The considered physics include: kinetic energy transformed to potential energy from the vessel moving up the beach, energy losses from deformation of the beach, and other hydrostatic losses. These aspects of the physics have to take into account hull shape. The problem needs to be solved as a time series to capture the simplified physics to capture small changes in the state of the ship and the interaction of these changes over time. The theoretical assumptions that are taken to reduce the computational complexity of this problem are listed below. Should future Verification and Validation (V&V) efforts determine that any of these assumptions have significant detrimental impacts on the simulation, modifications will be made to remove or modify that assumption.

- The origin will be at the intersection of the stem and the waterline when the ship contacts the beach with the positive X axis traveling away from the bow of the ship. That means the stern will be at a negative length from the origin at  $t = 0$ . The Y axis will be 0 on the centerline, negative to port and positive to starboard. This assumes that the contact point is on the centerline. The Z axis travels from keel to weather deck with  $Z=0$  at the waterline. The coordinate system can be seen in Figure 12.

Figure 12: Coordinate System for beach modeling

- Sand is treated as a dense fluid with no viscous impacts on the simulation;
- Buoyant force from the beach acts normal to the beach surface;
- Sand friction will be calculated as a solid-on-solid interaction;
- Beach surface is a flat plane with a specified slope about the Y axis;
- Representative beach geometry will not undergo deformation as simulation progresses;
- Displaced sand moves vertically and once it is moved it is no longer considered in the simulation;
- $C_F$ , coefficient of wetted frictional drag, is calculated via the ITTC '57 equation (Zubaly, 1996);
- $C_r$ , coefficient of wetted residual drag, will be provided via external, supplementary analysis;
- Shallow water effect can be ignored at reasonably low speeds;
- Water is calm, environmental and ship generated waves can be ignored;
- Ship is not powered forward after contact with the beach;
- Ship motion is restricted to three degrees of freedom: surge, trim, and heave;
- Ship will rotate about a traditionally calculated center of flotation (CF);
- This simulation will occur ignoring the effects of a third fluid, being air.

The primary objective of this model is to consider the interaction of the hull form with the beach. Simplification of the beach definition, deformation, and interaction with the hull will be critical to the design purpose of this tool. Modeling the true physics of sand that can become saturated due to fluid interactions with the hull is an unreasonable problem to solve with current technology due to the sheer amount of interactions (Goodman, 2017). The proposed solution is to use first principles and basic definitions of fluids and solids interactions to reduce the complexity of the problem.

While a major component of the hull-beach interaction is the displacement of sand, capturing the true mechanics of this would likely require complex and computationally expensive meshes like the one shown in Figure 10. In order to account for the beach deformation in a computationally feasible manner, the beach will be assumed to be a dense fluid and be in a

constant shape and location. As a fluid, there is a simple computation to determine the normal force from the beach. This assumption is supported in a paper by Kang in Equation 1 which relates the buoyant forces ( $F_{ZB}$ ) of granular media to,  $\rho$ , density of sand,  $g$ , gravity, and  $V$ , volume of displaced sand. This relation is reliant on an experimentally determined coefficient,  $K$  (Kang et al 2018). This assumption allows a computationally efficient method for accounting for the normal force caused by the beach.

$$F_{ZB} = K\rho gV \quad \text{Equation [1]}$$

A difficult component of treating the sandy medium as a fluid is that it would complicate the computation of frictional force between the beach and the hull. The classic computation of force, shown in Equation 2, requires an empirically determined coefficient (Zubaly, 1996). A literature review reveals that no coefficients of frictional drag for a sandy beach handled as a fluid exists. Additionally, existing research has proven that the friction of a solid and a saturated granular medium adheres to the Amontons-Coulumb law which requires a direct relation of the quantity of frictional to the normal force on the medium. (Divoux & G'eminard, 2007). For these reasons, it is assumed the most reasonable approach to calculate the frictional force of the beach on the hull as if they act as solids. This assumption not only supports the Amontons-Coulumb law but also allows this simulation to utilize existing empirically derived frictional coefficients of sand which are only relevant for the solid-on-solid interaction.

$$Force = \frac{Coefficient * Density * Surface Area * Velocity^2}{2} \quad \text{Equation [2]}$$

An additional complicated component of the beach problem is how to define the beach geometry, particularly complicated by handling the sandy beach as it acts as both a fluid and a solid. In order to simplify the problem, initial geometry of the beach is assumed to be a flat plane at an average slope representative of the desired operational area. This assumption seems reasonable considering beach topography changes relatively rapidly overtime when compared to acquisition timelines, and therefore modeling specific beach geometry is unnecessary, and computationally costly. It is known that as the hull displaces sand, some will rise above the presumed surface of the beach. This deformation would be influenced by the topography of the beach. If the beach is assumed to be flat then it must also be assumed that the sand is dissipated after it is deformed. With these assumptions, a geometrically varied and physically complex composite material is simplified to three inputs; a coefficient of friction,  $C_f$ , a beach slope,  $\theta$ , and density,  $\rho_B$ .

While the physics of the interaction between the hull and the beach are considered primary in this simulation, the hydrodynamic and aerodynamic physics are considered secondary. Considering the relatively slow speeds associated with the beaching mission and the relatively large size of the ships of focus, fluid dynamic impacts are assumed to not be critical to consider to a high level of fidelity. Air resistance and wind heeling is assumed to be reasonably small, and can be ignored. Additionally, hydrodynamic effects and problems are generally complicated to implement and expensive to run. Assuming forward approach speeds,  $V_0$ , are less than roughly 5 knots, it should be reasonable to assume that hydrodynamics associated with forward speed and momentum can be neglected or simplified. For the purposes of calm water resistance, it is assumed that the coefficient of residual drag is constant throughout the simulation. With the availability of reliable resistance tools, residual resistance or  $C_r$ , will be provided externally for a single initial speed condition. Frictional fluid resistance or  $C_F$  will be approximated with the ITTC '57 equation. Sinkage due to sea floor interactions will be neglected at this level of detail due to a lack of inexpensive and reliable computational methods and for consistency with the already neglected seafloor topography.

As discussed at length in the background and introduction to this paper, the majority of recent research prior to this study has been invested in the interaction of small bodies in near-beach surf zone waves. Previous studies underline how difficult the seakeeping problem in the surf-zone is to simulate. In order to simplify the proposed simulation presented in this study, it is assumed that the ships used in this model are reasonably large (i.e. less than 1000 tonnes) to ignore significant wave-induced motions. Additionally, it is assumed that wave-induced motions do not have significant impacts on the final location of the ship with respect to the beach. Neglecting seaway-induced motions enables the simulation to be fixed in roll, sway, and yaw which offers additional computation cost savings and is relevant since the beach and hull geometry are assumed to be symmetric across centerline,  $y=0$ .

## Proposed Solution

The backbone of this beachability tool is a time-domain solution, executed as a series of computations at discrete steps through time and space. The tool will be implemented in python in a modular format such that future levels of detail and fidelity could be easily added, based upon need and resources.

The hull form will be modelled as a coarse surface mesh and the fluid free surface will be modelled as a z-plane at location  $z=0$  with the hull located such that the baseline is at the given load condition waterline. The code will begin at time = 0 and  $i=0$  at the moment of impact with  $i$  being the time iterator and time being a scalar in seconds. The hull form will move forward in the x-direction through the stationary free surface (water) and into the static beach surface. At each time step the transformation of kinetic energy,  $KE_i$ , will be determined as follows in Equation 3, until the ship reaches zero kinetic energy. Based on Equation 4, the ship will have achieved a static condition, zero velocity, on the beach at this final iteration.

$$KE_i = KE_{i-1} - \Delta PE - W_w - W_B - W_D \quad \text{Equation [3]}$$

$$KE_i = (m_s * v_i^2)/2 \quad \text{Equation [4]}$$

$KE_i$  will be determined as the remainder of kinetic energy at each iteration after considering the change in potential energy,  $\Delta PE$ , as defined in Equation 5, work done on the wetted hull by water,  $W_w$ , as defined in Equation 6, work done by the friction with the beach,  $W_B$ , as defined in Equation 7, and work done by deforming the beach medium,  $W_D$ , as defined in Equation 8. The change in potential energy will be variable with respect to the heave,  $z$ , of the ship at each time step with respect to the constants gravity,  $g$ , and ship mass,  $m_s$ .

$$\Delta PE = PE_i - PE_{i-1} = m_s * g * (z_i - z_{i-1}) \quad \text{Equation [5]}$$

$$W_w = \left( \frac{\rho_w * SA_w * v_i^2 * C_T}{2} \right) * \Delta x \quad \text{Equation [6]}$$

$$W_B = (m_B * g * C_f) * \Delta x \quad \text{Equation [7]}$$

$$W_D = W_{DZ} = m_{Bk} * g * \Delta z_{Bk} \quad \text{Equation [8]}$$

Work done by the water, as defined in Equation 6 is the force caused by the fluid multiplied by the distance the ship travelled in the direction of the resisting force,  $\Delta x$ . The resistance on the hull caused by the fluid is proportional to the fluid density,  $\rho_w$ , wetted surface area,  $SA_w$ , velocity,  $v_i$ , and the coefficient of total drag,  $C_T$ . The wetted surface area,  $SA_w$ , will be computed at each iteration. The coefficient of total drag is a summation of residual,  $C_r$ , and frictional,  $C_f$ , coefficients of drag per Equation 9. As stated in the assumptions, the residual coefficient of drag will be provided by an external simulation. The frictional coefficient of drag will be computed via the ITTC '57 approximation in Equation 10 which related  $C_f$  to the Reynolds number,  $Re$ , defined with respect to length on waterline,  $LWL$ , ship velocity,  $v_i$ , and dynamic viscosity,  $\mu$ , as defined in Equation 11 (Zubaly, 1996).

$$C_T = C_r + C_f \quad \text{Equation [9]}$$

$$C_f = \frac{0.075}{\log(Re - 2)^2} \quad \text{Equation [10]}$$

$$Re = \frac{(v_i * LWL)}{\mu} \quad \text{Equation [11]}$$

Work done by the friction with the beach,  $W_B$ , will be calculated as a coefficient,  $C_f$  times a normal force in Equation 7. The normal force is assumed to be equal to the weight of the vessel that the beach will support. Based on the assumption that the sandy beach acts as a dense fluid, this weight is being determined using the assumption that the deformed beach provides a buoyant force according to Archimedes principle (Kang et. al, 2018). This force will be determined at each times step via Equation 12, mass of the displaced beach,  $m_B$ , times gravity. The calculation of  $m_B$  can be seen in Equation 12 where  $\rho_B$  is the density of sand and  $\nabla_B$  is the volume of displaced sand.

$$m_B = \rho_B * \nabla_B \quad \text{Equation [12]}$$

As stated in the assumptions, deformation of the beach will not be explicitly modelled geometrically, however the simulation will still consider the work done in the act of moving the displaced sand. To approximate this deformation work,  $W_D$ , the change in potential energy of the displaced sand will be determined at each iteration via Equation 8. The mass of sand that is displaced,  $m_{Bk}$ , will be determined at each time step as the difference in the total mass of the beach the ship displaces from the previous time step as explained by Equation 13. In order to determine the change in potential energy of the sand a segmented approach will be used, iterating over the mass,  $m_{Bk}$ , and calculating the vertical distance  $\Delta z_{Bk}$  required for that mass to be entirely above the beach plane as show in Figure 13.

Figure 13: Sand Displacement

$$m_{Bk} = m_{B_i} - m_{B_{i-1}} \quad \text{Equation [13]}$$

Expanding and transforming Equation 13 by inserting Equations 4, 5, 6, 7, and 8 results in Equation 14. This allows Equation 3 to be rewritten in terms of  $v_i$  in Equation 14. This equation represents the proposed total energy conservation considered at each time step during the simulation. An additional system of equations will be required at each time step to determine the location in space of the hull form as it pitches and heaves. The pitch and heave of the hull will be calculated with a moment and force balance equations, Equation 15 and Equation 19 respectively. The moment balance equation, Equation 15, requires the sum of the moments caused by the buoyant force from the water,  $m_w d_w$ , buoyant force from the beach,  $m_B d_B$ , and the weight of the ship,  $m_s d_g$  to equal zero. It is assumed that the sum of the mass of displaced water,  $m_w$ , and the mass of displaced sand,  $m_B$ , is equivalent to the mass of the ship,  $m_s$  as shown in Equation 19. It is assumed that the ship exclusively rotates around the center of floatation,  $CF_x$ , with the moment arms  $d_w$ ,  $d_B$ , and  $d_g$  calculated as the difference between the center of action and the center of floatation in Equation 16, Equation 17, and Equation 18. The center of action for buoyancy due to water and beach are determined to be the center of volumes,  $x_{wCV}$  and  $x_{BCV}$  respectively. The center of action of the mass of the ship is the center of gravity,  $CG_x$ , and is a required input to the simulation.

$$v_i = \sqrt{\frac{2}{m_s} * \left( \frac{m_s * v_{i-1}^2}{2} - m_s * g * (z_i - z_{i-1}) - \left( \left( \frac{p_w * SA_w * v_{i-1}^2 * C_T}{2} \right) + (m_B * g * C_f) \right) * \Delta x - (m_B * g * (z_{Bk} - z_{Bk-1})) \right)} \quad \text{Equation [14]}$$

$$\sum M_{CF} = 0 = m_w d_w - m_s d_g + m_B d_B \quad \text{Equation [15]}$$

$$d_w = x_{wCV} - CF_x \quad \text{Equation [16]}$$

$$d_B = x_{BCV} - CF_x \quad \text{Equation [17]}$$

$$d_g = CG_x - CF_x \quad \text{Equation [18]}$$

$$\sum F_z = 0 = (m_s - m_w - m_B) * g \quad \text{Equation [19]}$$

## Algorithms and Methods

The initial information required at the start of the simulation at which point the ship has just initiated contact with the beach and  $i=0$ , is listed below. The hull geometry is proposed to be a coarse surface mesh in the form of a PLY file. CAPSTONE, a HPCMP CREATE product can easily create simple surface meshes, from many of the classic geometry file types used in naval architecture. PLY is accepted in python mesh libraries Trimesh and VEDO (Haggerty, et al., 2019) (Musy, et al., 2021). These open source python libraries are proposed for handling mesh intersections. Working in python allows for plug-ins to the Leading Edge Architecture for Prototyping Systems (LEAPS) tool suite (Shaeffer, et al., 2020). Longevity of tools in the concept design space rely on integration with existing products or projects. Python is a well-known language commonly used in the naval architecture realm, therefore, generation of a python based tool will allow for integration in many existing projects.

Inputs:

- Coarse Hull Surface Mesh
- Ship Velocity ( $v_0$ )
- Ship Loading Condition
- Density of Water
- Beach Slope
- Density of Sand
- Coefficient of Friction of Sand

The proposed processes for the simulation are discussed below with the aid of flow charts in Figure 15 and Figure 16. These flow charts follow the color based key in Figure 14. Blue rectangles represent information that discuss inputs or conditional changes. Yellow squares use a calculation that is either represented by an equation in this paper or a query mesh intersections. Red triangle is a decision, evaluating against a criteria, typically in the form of an IF statement. Green ellipse represent output information.

Figure 14: Flow Chart Key

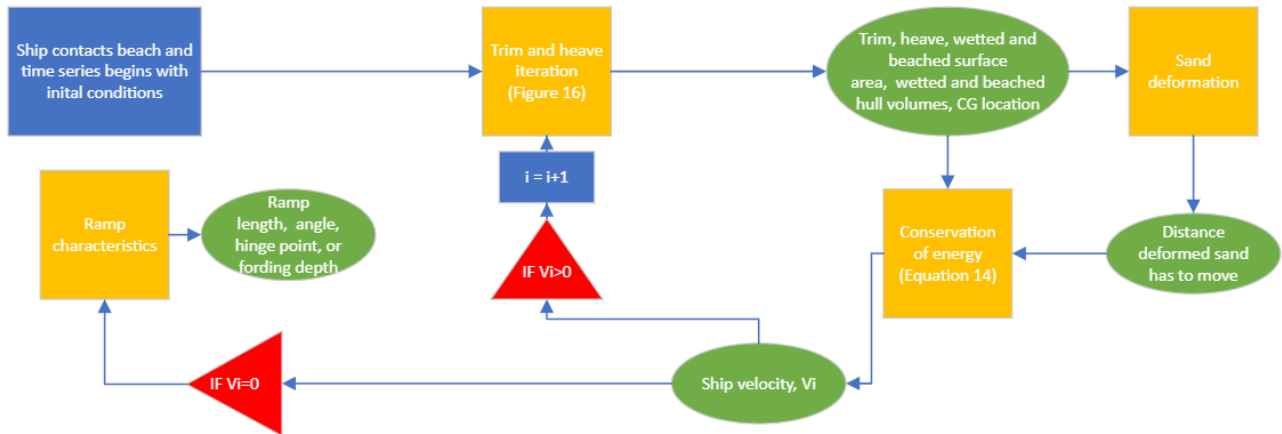

Figure 15: Beaching Tool Flow Chart

The objective of this simulation is to output ship position when ship reaches a static condition. The simulation will iterate over time and space to determine ship velocity,  $v_i$ , and hull position at each time step until the ship comes to a static equilibrium,  $v_i = 0$ , which is represented in the bottom left red triangle in Figure 15. Given this information, ramp characteristics and beachability can be determined easily. At the start of each time step, the new hydrostatic condition of the ship is calculated based on the workflow in Figure 16. Given the updated hydrostatic condition, change in velocity at each step is calculated via the conservation of energy given in Equation 3 and Equation 14. The simulation will continue to iterate until the ship velocity approaches very near to zero and is assumed to have met a static equilibrium.

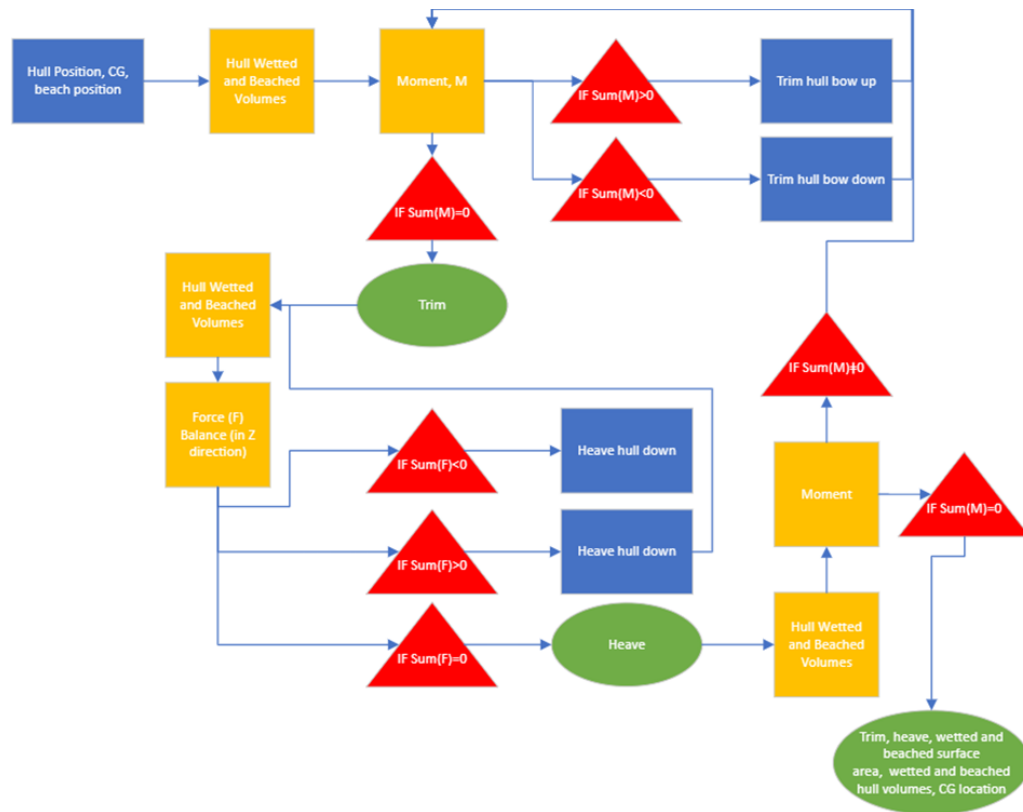

Figure 16: Trim and Heave Iteration Flow Chart

Separate trim and heave iterations occur at every time step. These loops are separate, but also dependent. This can be seen after the output of the force iteration returning to a moment calculation box on the right in Figure 16. The result is an iterative solution towards determining the ship's hydrostatic condition at each time step. In order to reduce computational time, the step size used in the iterative solution will be adaptive, dependent on how far the solution is from equilibrium. A critical component of this calculation is that the hull geometry directly drives the outcome which is a notable improvement over existing state-of-the-art beachability analysis in early-stage design discussed previously.

Following the flow chart in Figure 16, starting in the top left, these loops require information about the hull geometry, beach surface, wetted surface, and hull characteristics. The tool queries the mesh intersections to calculate wetted and beached volumes. The beached volume can be seen in yellow in Figure 17 and 18. Multiplying these volumes by their respective densities and distances to the center of rotation, CF, gives a moment balance equation seen in Equation 15. The assumed convention is a counterclockwise moment with the ship approaching the beach from the left being positive as seen in Figure 17. It is clear that a positive moment results in bow up trim and a negative moment results in bow down trim. The force and resulting moment are predicated on treating sand as a dense fluid that acts a buoyant force on the hull through the beached volumes centroid (Kang, et al. 2018).

Figure 17: Trimming Moment

The trim angle will be adjusted as shown in the top right of the flow chart in Figure 16 until the moment is balanced, within a given tolerance, to zero using Equation 15. The updated trimmed position will provide new wetted and beached volumes to the force calculation in the middle of Figure 16. Equation 19 will then balance the forces in the  $z$  direction. With a positive force convention being up, if the force is positive the hull will experience positive heave and, if negative, negative heave. These heaving forces are shown in Figure 18. After  $\sum F_z \approx 0$ , the moment is calculated once more. If  $\sum M \approx 0$  the hull mesh is queried.

Figure 18: Heaving Force

## CONCLUSIONS

As discussed in this paper, beaching has had a long and critical history in navies under taking amphibious operations around the globe. Delivering reinforcements and resources is vital to successfully providing disaster relief and maintaining a forward position in war. Both large and small beaching vessels are necessary to accomplish this during times when port infrastructure is contested or not available. Following WWII, the focus regarding beaching has shifted toward smaller craft. However, due to advances in technology and an uncertain warfighting environment, much is unknown as to the needs of the future. Looking objectively at the current amphibious fleet, a lack of knowledge in the areas of large beaching ships has been identified. This gap is aimed to be addressed through the development of a low fidelity beaching analysis tool.

With such a tool, naval architects will be able to quickly and accurately assess risk and costs associated with designing a large beaching ship. For the development of this tool, a first principals' approach has been taken to develop a time-series based simulation using conservation of energy. In order to evaluate a bounded and simplified trade space, the critical physical components of the beaching problem needed to be identified and fully considered. The interactions that will be evaluated or simplified in this tool are primarily focused on the beach-ship problem. Confirmation of these simplifications and assumptions is difficult due to a lack of Subject Matter Experts (SMEs) in the beaching domain problem and existing body of knowledge. Specifically, little research has been aimed at the hull form and beach interaction problem compared to the seaway induced motions problem. Due to the lack of available expertise, a verification and validation (V&V) effort

will be required to provide confident use of this tool within ship acquisition frameworks. As previously noted, decisions made early in the design, especially at the preliminary design stage, can ultimately determine the future success of a ship acquisition program.

## Future work

The effort to develop the simulation discussed in this paper is intended to be completed by the end of FY24 (September 2024). A validation effort is planned to begin in late FY24 and completed in FY25. Due to a lack to higher fidelity simulation data, model testing is being pursued. Utilizing modeling expertise at NSWC Carderock Division and partnership with the model test basin at the Engineering Research and Development Center (ERDC) (ERDC Overview, n.d.), testing results can be obtained which a beaching tool should be able to emulate within some tolerance. Planning for this level of model testing began in early Calendar Year (CY) 24. Scaling as well as other unidentified topics are of concern and will be addressed as planning is refined and resources and time are available.

Additionally, future efforts aim at considering developmental improvements to the simulation based on time and resources. There are two notable features which have been identified. Firstly, the development of a method to objectively assess and compare the beachability of different concepts and enable automated design space exploration. The primary measure for beachability is the ability of the ship in its beached position to deliver its payload to the beach. This payload can vary depending on CONEMP. Different types of payloads have different requirements usually revolving around fording depth, ramp angle, and ramp length. These ramp characteristics that will enable objective assessment of beachability are included in the flow chart in Figure 15 with the path once  $v_i = 0$  is satisfied. The approach is to find the intersection of a ramp line, starting at the hinge point with slope of ramp angle, and beach line, with the beach slope. Then, the vertical distance from the waterline to that intersection point has to be measured and reported as the fording depth. This final calculation has not been discussed as part of the current effort of the tool. This information is critical to the beaching design problem and can be calculated external to the tool, based on the solved final ship position. Integration in the tool is intended to reduce additional steps, total time, and errors.

Secondly, since these ships eventually need to extract themselves from the beach, it would be useful to integrate both beaching and extraction into the same tool. There are two possible methods for a vessel to get off the beach: under propeller load, utilizing the assistance of kedge anchors, or a combination of both. The force that the propeller and kedge anchor must overcome to get off the beach will be a result of wetted drag from water, skin drag from beach, etc... This will require additional investigation, however, it is likely to have an overlap with planned capabilities within the base version of the tool.

In later developments of the tool, adding options for specifying ship thrust throughout the simulation, seaway conditions, and beach approach angle are all areas of interest. In practice, many beaching vessels continue to generate thrust from the propellers after impact with the beach in order to increase the distance they can travel up the beach. In order to assess this, additional sources of power will need to be included in the energy balance. For seaway conditions and approach angles, a 6 degree of freedom (DOF) analysis will be required and assumptions of symmetry will have to be overcome. This adds more complexity to the simulation, however, is not unusual for tools to offer both 3-DOF and 6-DOF analysis options. This will be further considered and researched as development continues.

Rather than just adding additional features, future developments will also attempt to improve fidelity while retaining rapid assessment capability. This means exploring other potential simplifications and existing theory, such as resistive force theory (RFT) to achieve more defined ground reaction forces. RFT is a theory that uses linear superposition of experimental results to generate lift and drag forces on a body independent of the body's orientation (Zhang & Goldman, 2014). The advantage of using RFT for this project is that it can be computationally inexpensive while still being relatively high fidelity since it relies on experimental data to drive responses. Additionally, there are many well documented sources about its use in different environments since the theory was developed in the 1950's (Marcotte, 2016). There are a few potential disadvantages of RFT. It has only been used to predict interactions at very low Reynolds numbers ( $Re \sim 10^{-2}$ ), beaching will mostly occur at higher Reynolds numbers ( $>Re \sim 10^5$ ) so it will need to be explored if RFT can be reasonably scaled up (Rodenborn, et al., 2013, Zubaly, 1996). Most RFT tools also require experimental testing to quantitatively determine the reactions of the granular material and that is an expensive and lengthy process. Some work has been done to empirically define these reactions which may be useful for this project (Marcotte, 2016). RFT is just one of many potential methods for improving fidelity that could be explored. Hopefully, this paper will encourage conversation and gather attention from experts in the field with knowledge of other applicable theories. Truly and accurately solving the beaching problem could have wide impacts and will require collaboration from various disciplines beyond naval architecture.

# Modernisation of Domestic Ro-Ro Passenger Ships Operating in the Philippines

D. Vassalos<sup>1,\*</sup>, D. Paterson<sup>2</sup>, F. Mauro<sup>2</sup> and A. Salem<sup>2</sup>

## ABSTRACT

*This paper forms part of a wider study in the form of a Formal Safety Assessment of the domestic passenger ships operating in the Philippines, undertaken on behalf of the Philippines Government, and financed by the World Bank and the International Maritime Organisation. The paper focuses on design deficiencies of the domestic RoPax ships, primarily in damage stability. The process of ship selection for representation of the wider fleet risk assessment is explained, leading to one medium RoPax and one large RoPax, typical of some 500 of these ships, serving the open sea domestic trade in the Philippines. To this end, the selected designs have been subjected to a systematic process of damage stability and flooding risk analysis in order to identify design vulnerabilities, leading to risk estimation in the form of Potential Loss of Life. A number of risk control options have then been identified, enabling a thorough risk assessment and identification of cost-effective RCOs, as well as impact assessment, using IMO risk acceptance criteria as basis. Despite the poor state of the domestic Ro-Ro passenger vessels operating in the Philippines, many of these aged, badly retrofitted, poorly maintained, and operated, it has been possible to identify cost-effective design solutions to raise the damage stability (and safety) standard of these ships to international standards of newly designed ships; it seems an unprecedented achievement, but evidently true. This presents the Philippine Government and the owners of these vessels with a unique opportunity to upgrade their domestic fleet of RoPax vessels and showcase these against the best in the world. Because of the similarity in the approach, the selection of risk control options and the overall analysis adopted, only one of the typical RoPax vessels selected is presented in this paper.*

## KEY WORDS

Domestic Ro-Ro Passenger Ships; Damage Stability Failure; Flooding Risk; Cost-effective Risk Control Options

## INTRODUCTION

One way of ensuring that action is taken before a disaster occurred is to use a process known as a Formal Safety Assessment (FSA, MSC-MEPC.2/Circ.12/Rev.2.). This has been described as "a rational and systematic process for assessing the risks associated with shipping activity and for evaluating the costs and benefits of IMO's options for reducing these risks.". Such options have invariably been extended to other stakeholders (Flags, Administrations, Class, Shipyards and Ship operators), aiming at identifying cost-effective solutions to improve the safety standards of existing ships and new buildings. As the nature of this undertaking is highly technical, it is vitally important that the proposed solutions in the form of recommendations are properly communicated to ensure that all stakeholders gain sufficient information at a level that is readily understood to support effective decision-making (Vassalos et al., 2022a). One way to achieve this is by comparing proposed changes with existing standards, targeting life-cycle implications (design, operation, emergencies) to enable a balance to be drawn between technical and operational issues, including the human element as well as between safety (Delta Risk) and cost (Delta cost) in the implementation of the proposed recommendations (Goerlandt, F. & Montewka, J., 2015, Pusa et al., 2021).

This paper focuses on describing the process of assessing the risk (Aven, 2012, 2022), as well as identifying and implementing cost-effective solutions for the design of new ships or for retrofitting existing ships (Vassalos et al., 2021, 2022b) to achieve

<sup>1</sup> Maritime Safety Research Centre, Department of Naval Architecture, Ocean and Marine Engineering, University of Strathclyde, Glasgow, Scotland, UK

<sup>2</sup> Sharjah Maritime Academy, Khorfakkan, UAE

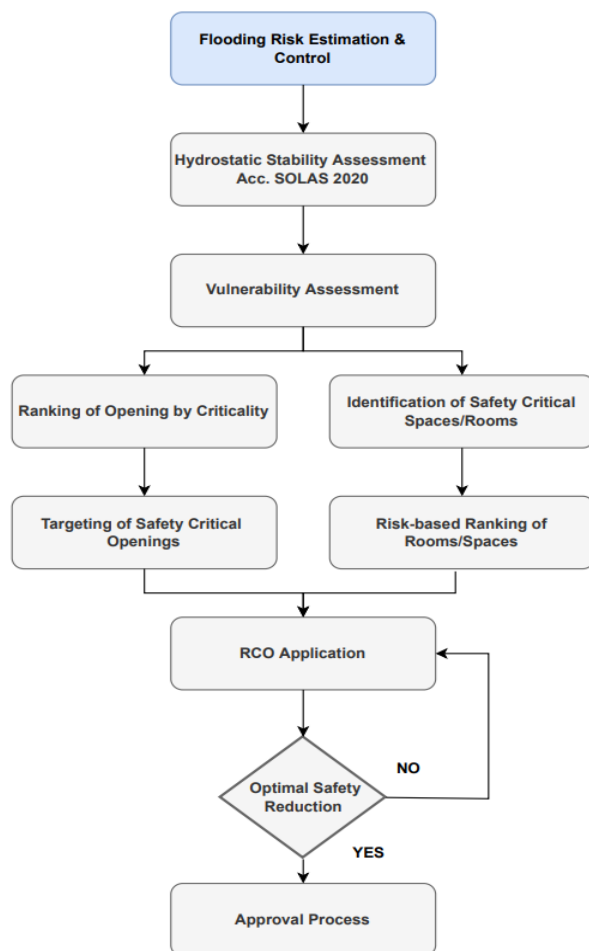

higher safety standards with focus on the highest risk contributor, as previously identified, namely inadequate damage stability and the ensuing risk to human life (Vassalos, 2012). To this end, following a ship selection process of representative ships from the whole fleet currently engaged in domestic voyages in the Philippines, three ships have been selected, namely (a) a small motor banca; (b) a medium-sized modern RoPax and (c) a large older design RoPax. In this paper, only the two latter categories are being addressed. The process of risk analysis and risk assessment is detailed, the latter providing a cost-benefit assessment to aid decision-making in the Risk Control Options (RCOs) selection, practical implementation, and impact.

## ADOPTED METHODOLOGY FOR FLOODING RISK ESTIMATION

### Survivability Assessment

The methodology adopted in the FSA Philippines project, has been tailored to cater for flooding risk estimation (using different risk metrics), pertinent to static assessment and statutory requirements, leading to risk-informed performance in relevant conditions and environments. This, in turn, facilitates the design and implementation of pertinent RCOs to prevent, mitigate and control flooding risk in domestic passenger ships and is comprised of eight distinct phases, as elaborated in the following and shown in Figure 1. The process begins by addressing damage stability assessment based upon conventional hydrostatic techniques (Bulian et al., 2016, Ruponen et al., 2019, Mauro & Vassalos, 2022). Such assessment is conducted in accordance with applicable IMO statutory instruments, which vary depending on vessel age, type, and size. When assessing new build vessels engaged in international voyage, this relates to the requirements of either SOLAS 2009 (IMO, 2009) or SOLAS 2020 (IMO, 2020), as applicable. This form of assessment enables a quantifiable baseline risk level to be established from which the impact of RCOs can then be measured and compared (Vassalos et al., 2022b). Unfortunately, a great deal of existing ships and domestic vessels are regulated based on older prescriptive regimes, with an implicit but not explicitly quantifiable safety level. This is by using the Index of Subdivision (A-Index) as the risk metric to facilitate comparisons in the attained “risk” level and for evaluation of various design options to enhance ship damage stability. This means that the choice of risk control options is somewhat shaped by the elements of assumption, generalisation and simplification that are commonplace within technical standards.

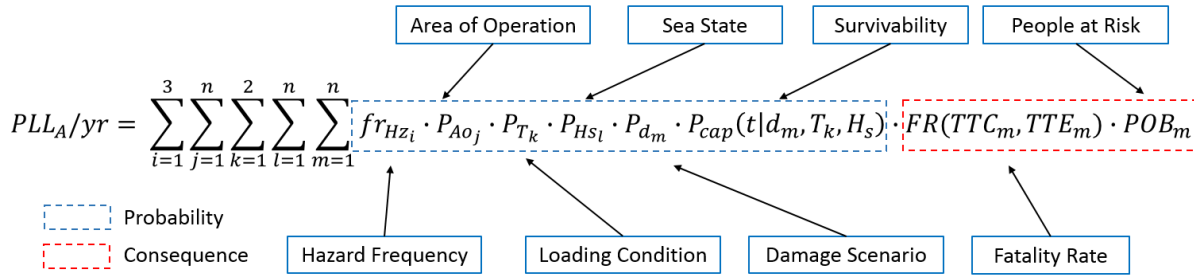

**Figure 1: Methodology Adopted**

## Risk Assessment

Building upon the developments in risk models over the past 30 years, a generic risk quantification process and modelling is presented in this section, geared towards domestic passenger ships operating in the Philippines. In this respect, a generalised way of considering flooding risk in the form of Potential Loss of Life (pertinent to design evaluation; hence PLL Attamed, PLL<sub>A</sub>) is given in equations [1] and [2], with a description in Figure 1.

[1]

$$PLL = Probability \times Consequence$$

**Figure 1: Description of Risk Estimation (PLL) Components**

$$PLL_A/yr = \sum_{i=1}^3 \sum_{j=1}^n \sum_{k=1}^2 \sum_{l=1}^n \sum_{m=1}^n fr_{Hz_i} \cdot P_{Ao_j} \cdot P_{T_k} \cdot P_{Hs_l} \cdot P_{d_m} \cdot P_{cap}(t|d_m, T_k, H_s) \cdot FR(TTC_m, TTE_m) \cdot POB_m \quad [2]$$

Where,

$i$	denotes hazard (1=collision, 2=side grounding, 3=bottom grounding from the accident database devethe undertaking of this project)
$j$	denotes area of operation (e.g., open sea, restricted, port)
$k$	denotes loading condition for the 3 SOLAS drafts (D <sub>L</sub> D <sub>S</sub> D <sub>P</sub> )
$l$	denotes the 99 <sup>th</sup> percentile of H <sub>s</sub> pertinent to the area of operation
$m$	denotes a particular damage scenario up to the nth scenario of the sample
$FR(TTC_m, TTE_m)$	denotes Fatality Rate for each loss modality (transient, progressive, failure criteria, e.g., IMO/ITTC capsizes criteria)
$POB_m$	denotes persons on board (people at risk) at each scenario
$PPL_A/yr$	denotes Potential Loss of Life per year of exposure at each scenario; hence PLL for life cycle needs to account for years, duration in service and POB in each.

For singular values of the variables  $i, j, k, l, m$ , (i.e., at scenario level) equation [2] becomes:

$$\frac{PLL_A}{yr} = hazardfrequency \times breach frequency \times capsize probability \times fatality rate \times PoB \quad [3]$$

The process itself and the various terms depicted in Eq. [2] are expanded upon in the following.

## Flooding Risk Quantification – Input Data and Parameters

### Sample ships – Initial ship data and preliminary analysis

The first item considered in analysing domestic passenger fleet data pertaining to the Philippines, has been to observe the fleet demographics in terms of ship type and age, as shown in Figure 3.

Fleet Demographic by Ship Type

Fleet Demographic by Age

Figure 2: Ship Demographics by Ship Type and Ship Age

Here, the following key observations can be made:

- 93% of the fleet is less than 100 GT;
- 98% of the fleet is less than 1,000 GT;
- 37% of the fleet is less than 10 m length;
- 83% of the fleet is less than 20 m length.

In addition, the domestic passenger vessel fleet has also been analysed in terms of PAX capacity, Gross Tonnage and Length, as shown in Figure 3, Figure 4 and Figure 5.

Figure 3: Fleet at Risk – PAX capacity Vs Gross Tonnage

**Figure 4: Fleet at Risk – Length Vs Gross Tonnage**

**Figure 5: Fleet at Risk – Pax Capacity Vs Length**

### *Sample ships selection*

Figure 7 outlines the vessels selected for the FSA study, representing the full size-range, on the basis of which quantitative risk assessment will be undertaken, in particular damage stability calculations and risk analysis in the FSA study. The red markers in the figure are the ships selected in order to provide a representative picture of the whole range of vessels comprising the fleet at risk. This, in turn, supports the argument that a weighted (based on the number of ships in each of the four selected bands) risk evaluation will suitably represent the whole fleet at risk. However, it should be noted that the vessels selected have also been influenced by the availability of requisite information on the vessels to support calculations. Instead, the nearest representative vessels have been selected in such instances.

Figure 6: Vessel selection for the FSA study

Table 1: Representative ships and associated characteristics selected for the FSA study

Name	Service	Homeport	Registry	Build Yr.	Rig	Hull	Length	Breadth	GRT	PoB
Kate Alleson	Passenger	Surigao City	Surigao City	2019	MBCA	WOOD	15.75	1.24	3.86	24
Starlite Venus	Passenger	Batangas	Batangas	2020	MV	STEEL	90.11	16.3	1616	688
ST. Pope John Paul II	Passenger/Cargo	Manila	CEBU	1984	MV	STEEL	165.31	26.8	1931	1688

#### Frequency estimation of a loss scenario

1. **Hazard frequency:** This needs to be ship and area specific as well as hazard specific. In the absence of all the requisite information, we can take frequencies from the accident database, developed in the project purposely for the Philippines Domestic Passenger Ships, pertaining to each hazard in question (collision, bottom grounding, side grounding).

Table 2: Hazard frequencies for the domestic ferries in the Philippines (only collision has been considered)

Hazard type	Domestic Ferries in the Philippines	
	Frequency 1/ship year	
	Motor Banca	RoPax
Collision	4.55E-04	1.68E-03

2. **Scenario frequency:** This is the frequency of a given scenario occurring, conditional on the hazard being addressed, as defined by the p-factor. The product of 1 and 2 gives the frequency of the loss scenario being considered.
3. **PLL calculation:** Ship level PLL can be calculated by substituting scenario specific 1-s values, with the compliment of the Attained Index as an estimation of capsizes probability.

## PLLA Quantification

### Consequence estimation of a loss scenario

As the expected number of fatalities depends on the time to capsize and static analysis does not account for time, some approximation is called for to estimate the fatality rate. This is conditional on fast or slow capsize and assumptions relating to the percentage of People On Board (POB) lost. To simplify the methodology and to account for the dependencies between survivability and fatality rate, the following simplifying assumptions are made (based on work performed in Project FLARE), Eq. [4] and Eq. [5]:

$$\text{If } 0 < \text{s-factor} < 1 \quad \rightarrow \quad \text{Fatality rate} = 5\% \quad [4]$$

$$\text{If s-factor} = 0 \quad \rightarrow \quad \text{Fatality rate} = 80\% \quad [5]$$

This simple and conservative approach is in line with the method used in the EMSA III Project for capsizing and the development of SOLAS2020. Moreover, research in Project FLARE (Cardinale et al., 2022) indicated that collated information from time-domain simulations on cruise and RoPax vessels that the majority of damage scenarios in a survivability assessment are transient capsize cases, in which case no time for evacuation is available (on average 5 minutes for RoPax). In the absence of other evidence, it is assumed that for domestic ferries this value also applies.

### Main assumptions and considerations

Drawing from Eq. [2], the following main assumptions are made for risk estimation:

i	Only collision is considered (1=collision)
j	Area of operation is considered with $H_s=4$ m, as per SOLAS
k	Three loading conditions are accounted for
$FR(s)$	Fatality Rate as a function of s-factor according to eq. [4] and eq. [5]
$POB$	Persons on board (people at risk) according for the operational profile of each selected vessel
$PLL_{A/yr}$	Attained Potential Loss of Life per year of exposure.

On the basis of the above, Eq. [2], with all the variables set to unit values, i.e., PLL for collision, per loading condition and scenario, becomes:

$$\frac{PLL_A}{yr} = \text{hazard frequency} \times \text{scenario frequency} \times \text{capsize probability} \times \text{fatality rate} \times \text{PoB} \quad [7]$$

Where,

- Hazard frequency for domestic ferries in the Philippines (
- Table 2).
- Scenario frequency is the p-factor corresponding to the breach being examined (damage scenario)
- Capsize probability is the complement of the scenario s-factor, i.e., (1-s)
- SOLAS breach distribution is used for collision.
- Calculations by software NAPA rel.2020.2

In the following sections, all three case studies are described in detail, including the initial damage stability evaluation, the process of implementing and measuring the impact of RCOs, and finally the approach adopted in judging the efficacy of each RCO.

## CASE STUDY – MEDIUM SIZE ROPAX VESSEL

### Vessel Principal Particulars

The following section details the vessel principal particulars, as outlined within Table 3. Here, it is observed that the vessel is a moderately large Ro-Pax, with a length nearing 100 m and a capacity of 688 persons.

**Table 3: Vessel Particulars**

Property	Value
Length (O.A.)	97.78 m
Length (B.P.)	89.80 m
Breadth (MLD.)	16.30 m
Depth (MLD.)	9.90 m
Design Draft	4.90 m
GM	3.40 m
Deadweight	1094.89 ton
Passenger Capacity	688 persons
No. of Crew	50 persons

## Coordinate System

A right-handed coordinate system has been used in defining the vessel stability model, as shown in Figure 7. The origin is located at frame #0, and locations in the ship are designated in accordance with a Cartesian coordinate system, where the axes are placed as follows:

- X-axis: longitudinal coordinate, positive in the direction of the bow, zero at frame #0,
- Y-axis: transverse coordinate, positive direction to port side, zero at the centre line,
- Z-axis: vertical coordinate, positive upwards, zero at the baseline.

In addition, trim is positive to stern and negative to bow.

The heeling angle is positive when the vessel heels to the port side.

**Figure 7: coordinate system**

## Stability Model

The ship model used in the damage stability calculations has been defined from the baseline up to, and including, the vessel ro-ro deck (9.9 m A.B.L.). In addition, one bow thruster has been reduced from the buoyant volume in the fore of the vessel. The resultant calculation sections of the model are shown in Figure 8 below, with the profile and body plan illustrated in Figure 9, and General Arrangement plan in Figure 10.

**Figure 8: Stability Model Calculation Sections**

**Figure 9: Stability Model Body Plan & Profile**

## Relevant Openings

When calculating the range of positive stability beyond the angle of equilibrium, the GZ curve has been truncated when an unprotected opening has been submerged. However, if an opening with a weathertight closing appliance has been temporarily submerged, it has had no effect on the range of positive stability. Instead, such openings are only accounted for if immersed in the final equilibrium floating position, resulting in  $s=0$ .

## Subdivision Arrangement

In the calculation of the Attained Subdivision Index, the vessel subdivision has been discretised into 14 zones, Figure 11.

## Permeabilities

The permeabilities used in the damage stability calculations are in accordance with the SOLAS 2020 prescribed values:

Figure 10: General Arrangement Plan

Figure 11: Subdivision Arrangement Plan

Figure 12: Wind Profile

## Compartment Connections

As the vessel does not possess any A-class boundaries liable to inhibit floodwater equalisation, nor any cross-flooding arrangements, there are no damage cases flooded in stages.

## Moments Due to Wind and Passenger Crowding

### 4.81 Wind-Induced Moment

The projected windage area of the vessel and corresponding moment lever are shown in Figure 12. The wind-induced heeling moment pertinent to damage stability calculations is estimated with the following formula:

$$M_{wind} = (P \cdot A \cdot Z) / 9.806 \text{ (tm)} \quad [8]$$

Where,

$P = 120 \text{ (N/m}^2\text{)}$

$A = \text{Windage area (m}^2\text{), measured in accordance with the projected lateral area relating to each calculation draft.}$

$Z = \text{Distance from T/2 to the centroid of windage area (m)}$

### Moment Resulting from Passenger Crowding

The moment resulting from passenger crowding has been calculated in accordance with the maximum number of persons onboard the vessel (738 persons). A conservative transverse lever of  $B/2$  (8.15m) from the centreline has been assumed and the weight attributed to each passenger is 75 Kg.

$$\text{Moment by crowding of passengers} = 451.1 \text{ tm} \quad [9]$$

## Initial Conditions

In accordance with Regulation 7, MSC.421(98), damage stability calculations shall be conducted with respect to three different drafts that define assumed upper and lower extremities of the vessel draft range, in addition to an intermediate condition. This includes the vessel deepest subdivision draft (3.41 m), the light service draft (2.89 m), and a partial subdivision draft determined by the following formula:

$$dp = dl + 0.6(ds - dl) = 3.202 \text{ m} \quad [10]$$

The damage stability calculations are performed with a typical aft trim of -1.45 m for the light service draft and with zero trim (even keel) for the partial and deepest subdivision drafts. The draft, trim, intact GM and KG values applied in the calculations are summarised in Table 5. The assessment has been conducted under limiting GM conditions relating to Regulation 7 compliance, and hence the GM/KG values assigned to the calculation loading conditions, as detailed in Table 5, differ from those attributed to the statutory loading conditions of the vessel.

**Table 4: Required Subdivision Index Acc. to MSC.421(98), Reg. 6**

<b>Persons on board</b>	<b>Required Index, R</b>
N<400	$R = 0.722$
$400 \leq N \leq 1,350$	$R = N/7,580 + 0.66923$
$1,350 < N \leq 6,000$	$R = 0.0369 \times \ln(N+89.048) + 0.579$
$N > 6,000$	$R = 1 - (852.5 + 0.03875 \times N)/(N + 5,000)$

**Table 5: Attained Subdivision Index Calculation - Limiting GM**

<b>Initial Condition</b>	<b>T [m]</b>	<b>TR [m]</b>	<b>GM [m]</b>	<b>A/R</b>	<b>COEF</b>	<b>A*COEF</b>
<b>DL</b>	2.890	-1.450	3.360	1.001	0.200	0.154
<b>DP</b>	3.202	0.000	3.195	1.021	0.400	0.313
<b>DS</b>	3.410	0.000	4.050	1.002	0.400	0.309
<b>Attained Subdivision Index A</b>						<b>0.775</b>
<b>Required Subdivision Index R</b>						<b>0.767</b>

## Required Subdivision Index R

The vessel subdivision and damage stability performance are considered satisfactory when the Attained Subdivision Index A, as calculated in accordance with Regulation 7, is not less than the Required Subdivision Index, R. The details of this calculation are provided in Table 5, leading to a Required Index value of 0.767 for the vessel under assessment.

## Attained Subdivision Index Calculation Under Limiting GM Conditions

Based on the assumptions outlined within the foregoing sections, the vessel Attained Subdivision Index has been calculated as summarised within

Table . Here, the Attained Index of the vessel has been optimised such that A=R for each of the calculation conditions, thus allowing limiting GM values to be derived.

## Derivation of the Limiting GM Curve & GM Margins

Having optimised the Attained Subdivision Index in accordance with the requirements of SOLAS 2020, it has then been made possible to derive the limiting GM curve of the vessel. This represents the minimum required GM across the vessel draft range, such that statutory requirements are met. This is a significant design property as it dictates the boundary between safe and unsafe operation of the vessel. The results of this calculation are presented firstly within Figure 13. Here, plots of both the intact and damage stability limiting GM curves are shown relative to all statutory loading conditions, indicated as blue markers. Through examination of this diagram, a number of key observations can be made. Firstly, it is clear that the vessel limiting GM is dictated to a significant degree by the damage stability requirements according to SOLAS 2020. Secondly, by looking at the relative position of each loading condition to the limiting GM curve, it is clear that a number of conditions have notably low GM margins, with others failing to comply entirely (LD11 & LD9). This indicates that there is a requirement for improvements to be made in the vessel design in order to achieve compliance.

## Vessel Risk Profile

A useful tool in identifying areas of heightened vulnerability within any vessel design, is to look upon the Risk Profile. This is a graph that maps collision risk across the vessel, allowing focus to be placed on those areas demonstrating the greatest vulnerability to flooding. Figure 14, shows the Risk Profile derived from the previously detailed calculations conducted under limiting GM conditions. Within the figure, collision risk is plotted along the vertical axis, and the damage centre is plotted along the horizontal axis. Differing damage lengths are distinguished by varying marker types, ranging up to four adjacent compartment damages.

**Figure 13: As-built Intact and Damage Limiting GM Curves**

**Figure 14: Vessel Risk Profile Under Limiting GM Conditions (High risk shown in red)**

Observation of the Risk Profile indicates peak risk around the vessel fore shoulder, which is typical for RoPax vessels and, indeed, passenger ships in general. Heightened risk is also evident in damages affecting the two machinery spaces, located towards the aft shoulder of the vessel. In this location there is also a larger concentration of loss scenarios, meaning that the cumulative risk within this area will be significantly higher than that relating to any other part of the vessel. On the basis of these findings, the implementation of RCOs, as covered in the following sections, will target these areas. Through doing so, it

can be ensured that the design receives help where it is needed most, whilst at the same time allowing risk to be reduced in the most efficient and thereby cost-effective manner.

## RCO 1 – Critical Opening Protection

### Description of RCO 1

On the basis of the results outlined within the foregoing, the first Risk Control Option explored has been to address critical openings identified within the vessel design. These are openings that have been found to adversely affect the magnitude of the Attained Subdivision Index, as a consequence of:

- Truncating the GZ curve, thus reducing GZ max,
- Truncating the GZ curve, thus reducing Range,
- Immersion in the final equilibrium condition, leading to a designation of  $S_i = 0$

Details pertaining to each of those openings showing the highest risk can be seen in a plot of the openings in Figure 15 . Here, three of the openings (OPE 44, 45 & 46), represent non-watertight openings leading from the vessel ro-ro deck to spaces below the bulkhead deck. As such, this represents a particular downflooding risk in such cases where water accumulates on deck. Given that this is a significant hazard in the case of Ro-Pax vessels, this needs addressing. Furthermore, two openings leading to the fore hydraulic pump room have been identified as considerably impacting the vessel Attained Index.

The proposed solution to this problem is to uprate these doors to watertight status, using either hinged or sliding watertight doors. The impact of this design change has then been measured through re-calculating the vessel Attained Index, accounting for these modifications, the results of which are outlined in the following section.

### Re-evaluation of Attained Subdivision Index

Table 5 outlines the results of the updated Attained Index calculations, conducted in light of uprating the watertight integrity of the openings described within the foregoing section. These calculations have been conducted with respect to the “as-built” limiting GM values of the vessel, as calculated previously, which provides a sound baseline from which to gauge improvement. The results demonstrate an impressive increase in the Attained Index from 0.775 to 0.797.

### Re-evaluation of the Vessel Risk Profile

Once again, the vessel Risk Profile has been generated, this time accounting for the implementation of RCO 1. Here we can observe that the peak risk towards the vessel fore shoulder, having previously existed within the “as-built” condition, has now been eradicated. In addition, a number of high-risk cases towards the aft shoulder of the vessel have been mitigated. However, there still remain a number of high-risk scenarios situated around the vessel machinery spaces. This results from the fact that the majority of such cases are lost due to capsizes and, as such, internal openings bear no significance on the outcome.

**Figure 16: Vessel Risk Profile Under Limiting GM Conditions, with RCO 1 Applied**

**Table 6: Attained Subdivision Index Calculation - Limiting GM with RCO 1**

Initial Condition	T [m]	TR [m]	GM [m]	A/R	COEF	A*COEF
DL	2.890	-1.450	3.355	1.000	0.200	0.153
DP	3.202	0.000	3.080	1.001	0.400	0.307
DS	3.410	0.000	3.440	1.002	0.400	0.307
<b>Attained Subdivision Index A</b>						<b>0.768</b>
<b>Required Subdivision Index R</b>						<b>0.767</b>

#### *Derivation of the Limiting GM Curve & GM Margins*

A further assessment has also been made in order to derive the updated limiting GM curve, thereby allowing the change in GM margins to be measured in light of the implemented RCO. The results of this process are provided in Table 6, including the limiting GM values.

Figure 17 contrasts the updated limiting GM curve to that of the existing vessel design. Here, it can be observed that a large improvement in limiting GM has been achieved, particularly towards the upper draft range. This is to be expected, as it is often deeper drafts having a tendency to suffer from lack of residual freeboard. As such, non-watertight openings pose a greater risk when the vessel is loaded to such conditions.

## **RCO 2 – Passive Foam Installations**

### *Description of RCO 2*

The second RCO considered has been the application of passive, high-expansion foam as a means of enhancing damage stability performance. This is achieved by strategically locating fixed-foam installations in vulnerable void spaces within the vessel design, resulting in a decrease in space permeability and leading to:

- A reduction in floodable volume, which preserves buoyancy, thus enhancing floatability, damaged freeboard, and reserve buoyancy.
- Enhanced stability in the form of increased damaged GM, as the foam installations increase waterplane area inertia and the metacentric radius.

The selected spaces for such applications are depicted in blue within Figure 18, and their location has been informed by the calculations pertaining to ship vulnerability.

The graph plots GM [m] on the Y-axis (ranging from 1.5 to 5.0) against Draft [m] on the X-axis (ranging from 2.4 to 3.6). It shows the relationship between draft and GM for various loading conditions (LD1 to LD12) and compares them with three regulatory curves: 2008 IS Code (red), SOLAS 2020 (blue), and SOLAS 2020 + Ope. Protection (green). The 2008 IS Code curve is the lowest, followed by the SOLAS 2020 + Ope. Protection curve, and then the SOLAS 2020 curve. The data points are scattered around these curves, with LD1 being the highest point at a draft of approximately 2.5m and LD11 being the lowest point at a draft of approximately 3.0m.

Loading Condition	Draft [m]	GM [m]
LD1	2.5	4.2
LD2	3.15	4.3
LD3	2.85	4.0
LD4	2.75	4.0
LD5	3.25	3.8
LD6	2.9	3.4
LD7	3.3	3.7
LD8	3.05	3.3
LD9	3.4	3.7
LD10	3.1	3.3
LD11	3.0	3.2
LD12	3.15	4.1

### *Optimisation of Foam Volume*

Having identified those spaces, which would be best served by passive foam protection, an optimisation process has been undertaken to determine the foam volume to be applied. This approach involves calculating the vessel Attained Subdivision Index for a series of incremental values of foam volume. This, in turn, allows the optimum foam volume to be determined as the point of diminishing returns in the relationship between the Attained Index and the volume of foam utilised.

The results of this process are outlined in Figure 19 in graphical form and within

Table in numerical form. Here, it can be observed that the optimal foam volume lies at approximately 500 m<sup>3</sup>, leading to an installation weight of approximately 17 tonnes.

### *Re-evaluation of Attained Subdivision Index*

Having identified the optimum foam volume solution, the damage stability performance of the vessel has been re-evaluated. Calculations have firstly been conducted with only the foam solution (RCO 2) in place, leading to the results presented within Table . Furthermore, an additional calculation has been conducted with consideration of opening protection (RCO 1) and foam protection (RCO 2) implemented simultaneously. Through doing so, it has been possible to measure the combined impact of both RCOs, as detailed within

Table . Quite remarkably, the results of this process show that with the foam solution in place the vessel has achieved an Attained Index of 0.829. Moreover, it has been possible to further raise the Attained Index to 0.850 when utilising both RCOs.

This indicates that the RCOs have been highly effective at reducing flooding risk, to the extent at which the damage stability performance of the vessel is now comparable with any modern RoPax operating today.

**Table 10: Attained Subdivision Index Calculation with Opening Protection and Passive Foam Installations (RCOs 1 & 2)**

### *Derivation of the Limiting GM Curve & GM Margins*

In this section, the impact of RCOs on the vessel GM limit curve and the scale of the GM margins has been explored. Firstly, the updated limiting GM values have been calculated for RCO 2 and then RCOs 1 & 2, as detailed within Table 11 and Table 12.

## **Risk Analysis & Calculation of RCO Cost-Effectiveness**

### *PLL Calculation*

A good measure of Societal Risk is the Potential Loss of Life (PLL), which is defined as the expected value of the number of fatalities per year. PLL is a form of risk integral, being a summation of risk as expressed by the product of consequence and frequency. The integral is generally summed up over all potential undesired events that can occur, in this case limited to collision events. In the following, PLL values are calculated for the vessel in as-built condition, as well as having implemented each of the RCOs examined. Furthermore, the cost-effectiveness of each solution has been gauged by calculating the Net Present Value of each RCO and contrasting this value to a Gross Cost of Averting a Fatality (GCAF) limit, determined by the value of statistical life within the Philippines. The latter has been determined in accordance with estimates made by the Economy and Environment Program for Southeast Asia, where an estimation of \$0.8 million per life within the Philippines is proposed.

In addressing cost, the following assumptions have been applied for each RCO:

- Watertight door - \$20,000 per door installed.
- Passive Foam - \$6/kg installed.

The results of the calculation are summarised in Table 13, where it can be observed that all RCOs are significantly cost-effective; each exceeding GCAF limits by at least a factor of two.

**Figure 20: FN-Diagram Showing the Impact of RCOs**

**Table 13: Cost Effectiveness Calculation on the Basis of PLL, NPV & NCAF**

Item	As-Built	RCO 1	RCO2	RCO1 & RCO 2
Attained Index	0.755	0.797	0.829	0.851
PLL	0.136	0.123	0.104	0.090
$\Delta$ PLL/ship-year	N/A	0.013	0.032	0.046
$\Delta$ PLL/ship-life	N/A	0.399	0.9624	1.387
Costs for financing, insurance etc (\$)	N/A	8,000	7,127.6	15,128
CAPEX (\$)	N/A	100,000	96,222.6	204,223
Net Present Value NPV (\$)	N/A	118,800	105,844.86	224,645
GCAF Limit (\$)	N/A	319,334.4	769,920	1,109,251
GCAF/NPV	N/A	2.69	7.27	4.94

#### ***Risk Acceptance Criteria – FN Diagram***

Another useful approach to gauging the effectiveness of the RCOs, is by plotting what is known as an FN Diagram. This is a means of expressing societal risk, by illustrating the relationship between the frequency of an accident and the number of fatalities. Such diagrams are generally plotted against some form of risk-acceptance criteria, in this case taken as the IMO criteria expressed in MSC-MEPC.2/Circ.12/Rev.2. With consideration of the vessel in the as-built condition and also following the implementation of the combined RCO solution, an FN-diagram has been created as shown in Figure 20. Here, the blue curve represents the existing vessel design and the black curve the modified design with the RCOs implemented. The risk-acceptance criteria are plotted with light blue dashed lines, creating three regions within the chart, defined as follows:

- **Intolerable Region:** Risk cannot be justified and must be lowered.
- **ALARP Region:** Risk is tolerable if further risk reduction is impractical.
- **Negligible Region:** Risk is negligible.

If we observed the FN diagram, we could see that the existing vessel design falls within the intolerable region, indicating that action should be taken to bring the vessel into the ALARP region. In this respect, the application of the combined RCO solution

has achieved this aim, with all events considered now lying within the ALARP region. This again is another indicator that the RCOs considered hold significant potential to reduce flooding risk in a meaningful way.

## CONCLUSIONS

### *General Conclusions*

- One way of ensuring that action is taken before a disaster occurred is by using a process known as Formal Safety Assessment (FSA, MSC-MEPC.2/Circ.12/Rev.2.). This has been described as "a rational and systematic process for assessing the risks associated with shipping activity and for evaluating the costs and benefits of options for reducing these risks." Such options have been extended to other stakeholders (Flags, Administrations, Class, Shipyards and Ship operators), aiming at identifying cost effective solutions to improve safety standards of existing ships and new buildings.
- As the nature of this undertaking is highly technical, the proposed solutions in the form of recommendations are communicated with decision makers in mind, to ensure that all stakeholders gain sufficient information at a level that is readily understood to support effective decision making. To this end, proposed changes are compared with existing standards, targeting life cycle implications (design, operation, emergencies) to enable a balance to be drawn between technical and operational issues, including the human element, by contrasting safety (Delta Risk) and cost (Delta cost) in the implementation of the proposed measures, targeting identified hazard categories individually whilst considering cross-hazards implications.
- The focus on design solutions in the project and in this paper, is on the highest risk contributor, as previously identified, namely inadequate damage stability and the risk to human life. This comprises nearly 90% of the risk for all categories of passenger ships, as manifested by accident statistics. Contributing factors for such loss comprises not only deficiencies in design but also in environmental, human, organisational, regulatory, and other unknown factors, which are also addressed by the FSA\_P team. Therefore, collectively the team covers the whole spectrum of hazards and their ensuing consequences, leading to balanced recommendations, accounting for feasibility, practical implementation, time scales, and cost.
- To this end, representative ships from the Philippines fleet currently engaged in domestic voyages are selected for risk analysis and risk assessment, the latter by using cost-benefit assessment to aid decision making in the RCOs selection, implementation, and impact. Based on this process of using representative ship designs in the risk assessment, any conclusions reached and recommendations ensuing on the basis of this sample of ships would, in principle, apply to the whole fleet of the domestic passenger ships operating in the Philippines. The selected ships include: (a) a medium size RoPax vessel; (b) a small motor banca vessel; (c) a large old design RoPax. This paper addresses ship (a).

### *Specific Conclusions*

- Deriving from the analysis performed on the selected ship design, detailed in the report, it has been possible to identify and rectify design vulnerabilities to flooding hazards, typical of the fleet of domestic passenger ships operating internationally. Specific remarks pertaining to the selected RoPax ship, which apply to the whole fleet, include the following:
- Certain features, which make the Philippines fleet more susceptible to flooding risk, include: (a) low index of subdivision, (b) low freeboard, leading to water reaching the car deck (c) low GM margins; hence susceptible to overloading or heavy weather, (d) unprotected openings, (e) inappropriate verification, thus further exacerbating the potential for catastrophic loss of life.

### *General Recommendations*

- Considering the current state of enforcement and verification of damage stability standards for domestic passenger ships operating in the Philippines (lack of fit for purpose regulations; gaps in enforcement and verification – frequency and rigor), ships must be made more robust to withstand flooding hazards by adopting risk control measures that are extremely cost-effective to incentivise the operator to meet higher standards, which in turn will fuel a virtuous cycle for continuous safety enhancement.
- Working with this incentive in mind, the most effective and practicable solutions, applicable to new and existing ships, in any time scale, have been selected and applied to the sample ships, enabling all categories of ship size to reach damage stability standards applicable to passenger ships engaged in any domestic or international voyages, including the proposed modified designs of the motor bancas.
- This is unprecedented and exciting, enabling Philippines in the short to medium term to showcase the safety of their domestic fleet against the best in the world.
- Based on this work, a clear pathway is outlined for consideration by the safety stakeholders in the Philippines, to facilitate a safety transformation for all domestic ships operating in the Philippines.

### *Specific Recommendations*

- Based on the results detailed within the foregoing, the following specific recommendations can be made:

- In order to correctly inform the process of evaluating the damage stability performance of vessels and subsequently implement effective RCOs, it is essential that accurate and up-to-date information is available on all regulated vessels.
- As the RCOs assessed have proven highly effective in reducing flooding risk across a range of ship types, sizes and ages, due consideration should be given to providing alternative routes to compliance on the basis of implementing such measures, particularly where novel forms of RCO are to be employed.
- Guidelines should be produced detailing the approach that should be adopted in order to effectively implement and judge the efficacy of approved RCOs, in line with the approach adopted within this report.

## ACKNOWLEDGEMENTS

We should like to express our appreciation to the International Maritime Organisation and the World Bank for their support in this project, financial and otherwise, as well as our collaborators from the World Maritime University, Prof Jens-Uwe Schroeder-Hinrichs, Dr Anish Hebbar and Dr Serdar Yildiz for their unfailing support and comradeship during this project. We should also like to express our gratitude to all the Authorities and maritime industry in the Philippines for making us feel at home and for their help in every phase and aspect of this project

## ABSTRACT

*The growth and development of floating solar photovoltaic (FPV) power plants is a prominent topic within renewable energy technology. One reason contributing to this desired technology design concept is the possibility of land acquisition issues, whereas the usage of the ocean provides a greater technical alternative area. The objective of the research is to present an innovative design for a floating structure, focusing on investigating and comparing the seakeeping performance of several hull configurations: catamaran, trimaran, quadrimaran and pentamaran. The final computational simulation results indicate a linear negative trend in the motion response graphs, particularly in specific significant response values for heave (Global Z), roll (Global RX), and pitch (Global RY), as the hull configuration increases.*

## INTRODUCTION

Indonesia strives to achieve a 23% renewable share of energy in the nation's overall energy composition within the next year based on the Minister of Energy and Mineral Resources of the Republic of Indonesia (2021), as depicted in Figure 1. a.

The high dependency on coal has the potential to result in a significant increase in greenhouse gas (GHG) emissions. As an example, by the end of 2021, the Institute for Essential Services Reform, IESR (2022) determined that the greenhouse gas emission profile in Indonesia was primarily comprised of CO<sub>2</sub>, with a contribution of 93.10%. Following together was CH<sub>4</sub> at roughly 5.90%, whilst the remaining 1.00% is identified as N<sub>2</sub>O following in Figure 1. b. Even though methane (CH<sub>4</sub>) contributes less to emissions than CO<sub>2</sub>, it can cause emissions which are as high as 29.80 times higher.

Furthermore, another extensive review of IEA (2022) data reveals that coal combustion, specifically in coal-fired power plants (CFPPs), is responsible for a considerable 72.10% of methane (CH<sub>4</sub>) emissions. As shown in Figure 1c, the oil and gas industry contributes 23.40% of these emissions, with the remaining 4.50% going to the bioenergy sector.

**Figure 1.** (a) The Ratio of Power Plant Conditions in Indonesia in 2022, (b) Greenhouse Gas Emissions within Indonesia's Energy Sector, (c) Annual CH<sub>4</sub> Emissions in Indonesia

Therefore, in a proactive action, the Indonesian government has issued a document Presidential Regulation 112 (2022), aiming to expedite the development of renewable energy for electricity supply. This regulation represents the gradual phase-out of coal-fired power plants (CFPPs). However, data from the Directorate General of Renewable Energy and Energy Conservation (2022), indicates that the share of Renewable Energy (RE) in the national energy mix was 12.16% in 2021, with a slight increase of 0.12% in 2022, which should be valued at 12.30%. Figure 2 illustrates the comparison of the percentage between the planned actions and the realization share mix of renewable energy implementation with a total target of 23% in the monitoring year 2022.

**Figure 2.** Realization vs Remaining Target of the Renewable Energy Plan in 2022

Approaching the year 2025, the State Electricity Company emphasizes the crucial role of expanding hydroelectric and geothermal power plants to achieve the 23% target in the national energy mix, as both sources can generate a significant energy by the Minister of Energy and Mineral Resources of the Republic of Indonesia (2021). However, these government projects have faced delays due to challenges related to land acquisition, environmental exploration, social concerns, and the high investment required. As a result, it is critical to take proactive actions toward discovering alternate renewable energy sources. An example is the deployment of solar energy converter systems.

Additionally, as highlighted by Shi et al., (2023), Solar energy is ecologically favourable, prominent, and widely distributed, warranting robust development. The solar photovoltaic (PV) system is a popular technology for directly converting solar energy into electricity using the photogenerated power effect of PV cells. Its wide range of uses includes both on-grid and off-grid power systems.

Implementing large-scale operations in photovoltaic (PV) power plants is a considerable difficulty due to the substantial land required for installation as explained by Sreenath et al., (2020). Then, as predicted by Rosa-Clot & Tina (2018), Land-based solar power facilities have an average demand of 0.50-0.70 MWp/ha. Furthermore, Pimentel & Branco (2018) explained that the forest destruction, extinction of birds due to habitat loss, erosion, runoff, and microclimate changes are some of the issues that arise throughout the installation and generation stages. Then a brief overview by Wang & Lund (2022), presents that in dealing with these challenges, researchers are actively investigating water-based PV systems, which include both fixed and floating PV (FPV) technologies from an offshore perspective. This novel technique is emerging as a promising alternative, searching to tackle the energy demand while limiting the environmental impact (Shi et al., 2023)

The fixed PV systems model, as described by Shi et al., (2023), illustrates that solar panels are secured to the seabed using pile foundations. However, the economic implications of this bottom-fixed technique reduce with increasing water depth, due to the substantially higher cost of piling. As a result, Rosa-Clot & Tina (2018) and World Bank Group (2019), give alternative solutions that are explored for deep water applications offshore, often using floating PV (FPV) systems. These FPV systems typically represent floaters or pontoons, PV modules, mooring systems, and cables as stated by Rosa-Clot et al., (2010) and Sen et al., (2015).

Over the past ten years, there has been an essential global study on floating photovoltaic (FPV) technology. The Aichi Project in Japan, with a capacity of 20 kW, represented the introduction of the first pilot FPV technology to the world in 2007, as may be noticed by Choi et al., (2016). Subsequently, the World Bank Group (2019) confirmed that in 2008, the first commercially operating FPV plant was presented in California, USA, with a capacity of 175 kW. Initially, these two initial projects are specifically designed for small-scale research projects. Trapani & Santafé (2015), confirmed that in 2015, Japan launched its first large-scale FPV plant, with a capacity of 7.55 MWp, followed by Boersma et al., (2019) revealed that a 40 – MWp plant was introduced in China in 2017. With the financial support of the African Development Bank and Clinton Foundation, Seychelles accomplished a historic milestone by establishing a 4 MW FPV plant in 2018 then becoming the first African nation to create history in FPV technology as explained by Beetz, (2018).

Proceeded into the year 2019, the Korea Energy Agency (2022) informed that the Korean rural community corporation was established to install 280 MW of FPV plants, whereas France built a 17 MW FPV system (Kenning, 2018). In the opening years of 2022, Shandong province in China delivered its largest FPV plant to the grid system, with a capacity of 320 MW (Lindholm et al., 2022). Furthermore, particularly in Indonesia, in collaboration with Masdar, is looking into a 60.00 MW FPV project to achieve 23% renewable energy by 2025 and 31% by 2030, with a significant milestone 145 MW project executed on a 250-hectare water area (Masdar, 2023). Singapore-based company "Sunseap" is developing a large 2.20 GW FPV in the Batam reservoir, expected completed by 2024 (Silalahi et al., 2021). Singapore has impressive goals to develop the world's biggest offshore FPV plant with a capacity of 2.00 GW by 2030 in its renewable energy sector (Liu et al., 2020). Additionally, the United States currently discovering the largest FPV project in progress, an 8.90 MW installation managed by New Jersey Resources Corporation (NJRC) Clean Energy Ventures in Millburn, New Jersey. (Islam et al., 2023). Table 1 which follows provides further information and details on the ten largest FPV projects undertaken globally starting in 2020.

**Table 1.** The ten most extensive floating photovoltaic (FPV) projects worldwide

No	Country	Electric Capacity	Location	Provider / Investor	Years	Ref
1	Indonesia	2200 MW	Duriangkang reservoir, Batam Island	Sunseap, BP Batam	2024-2025	(Reuters, 2021)
2	South-Korea	2100 MW	Saemangeum floating solar energy project	SK E&S, Ocean Sun Hanwa Q Cells	2025-2030	(Frost&Sullivan, 2024)
3	India	600 MW	Omkareshwar reservoir, Madhya Pradesh	Tender process on going	2023-2024	(Frost&Sullivan, 2024)
4	China	550 MW	Wenzhou, Zhejiang Province	Chint Group	2021	(Emiliano Bellini, 2022)
5	Vietnam	500 MW	Laly hydropower reservoir, Dong Nai	Blueleaf Energy Asia	2021	(Japan International Cooperation Agency (JICA), 2020)
6	China	320 MW	Changhe and Zhouxiang reservoirs in Cixi	Hangzhou Fengling Electricity Science Technology	2020	(Frost&Sullivan, 2024)
7	Laos	240 MW	Nam Theun 2 hydropower plant, Khammouane	Electricité De France - EDF	2024	(Amir Garanovic, 2021)
8	Taiwan	181 MW	Chenghua County	Chenya Energy	2020	(Enerdata, 2020)
9	Indonesia	145 MW	Cirata, West Java	Masdar Solar Energy	2022	(Frost&Sullivan, 2024)
10	Thailand	45 MW	Sirindhorn Dam, Chanin Saleechan	B.Grimm Power, Energy China	2021	(Tom Kenning, 2019)

Table 1 shows Indonesia's ability to achieve a significant position among the top ten Floating Photovoltaic (FPV) projects globally supported by the highest potential Global Horizontal Irradiation (GHI), reaching up to 4.80 kWh/m<sup>2</sup>, as reported by (Silalahi et al., 2022), and represented in the subsequent Figure 3, when contrasted with other countries. This observation suggests that the adoption of FPV technology in Indonesia presents substantial and expansive opportunities, emphasizing the need for strategic planning to harness this potential for the future.

**Figure 3.** Global Horizontal Irradiation (GHI)

During the design process of a Floating Photovoltaic (FPV) system, a critical part is the floating structural component. It plays a crucial part in ensuring the system's buoyancy and stability. Following a research study by Sahu & Sudhakar (2019), the floating structure is often made of non-hazardous, UV light-resistant, and maintenance-free plastic materials recognised for their high tensile strength, for example, High-Density Polyethylene (HDPE). Several studies from Oliveira-Pinto & Stokkermans (2020); World Bank Group (2019) and Claus & López (2022) show that applying HDPE has numerous benefits, including a simple and easily implemented construction. Its lightweight characteristic contributes to reducing tension on the overall structure in response to offshore hydrodynamic pressures, and the use of minimum metal reduces susceptibility to corrosion. Furthermore, HDPE provides cost-effective beneficial effects when compared to other materials such as concrete (Mittal et al., 2017) and steel (Cazzaniga et al., 2017).

Taking these various factors into consideration, this study proposes a novel approach for floaters by utilizing the geometric shape of High-Density Polyethylene (HDPE) hulls. This material has several advantages, including resistance to the sea environment and protection against UV degradation effects. The research focuses on innovative floater design configurations in catamaran, trimaran, quadrimaran, and pentamaran. The impact of the hull configuration, administered as an initial design parameter, will be investigated by Computational Fluid Dynamics (CFD) simulations under the JONSWAP wave spectrum, including various sea-state situations.

The paper is organized as follows: **Section 2** describes the problem characterisation for the original concept of floating hull constructions. **Section 3** provides an extensive overview of the research methodology, as well as technical details about the Computational Fluid Dynamics (CFD) numerical setup. **Section 4** advances further into the CFD numerical simulation findings, investigating the effect of hull configuration on motion characteristics. Finally, **Section 5** provides a summary of the study, emphasizing its important findings.

## PROBLEM CHARACTERIZATION

A multi-hull construction with several configurations starting from the catamaran (2 hulls), trimaran (3 hulls), quadrimaran (4 hulls), and pentamaran (5 hulls) is proposed. These hulls are identical geometric shapes and sizes, arranged in parallel to form an integrated structure (single-array) designed for energy farming. This numerical study considers several factors, including independent variables, dependent variables, and control variables. In a numerical/experimental study, the researcher manipulates or changes the independent variables to determine how they affect the dependent variables. Dependent variables are measured or observed in reaction to changes in independent variables, indicating the predicted outcomes of the numerical/experimental study. In numerical/experimental studies, control variables remain constant to ensure that changes in independent variables are the cause of observed effects on dependent variables. Table 2 describes the individual variables utilized in this numerical investigation.

**Table 2.** Utilized variables

Independent Variables	Dependent Variables	Control Variable
<ul style="list-style-type: none"> <li>Sea-State [Hs] <ul style="list-style-type: none"> <li>Sea-State 1 [0.1 m]</li> <li>Sea-State 2 [0.5 m]</li> <li>Sea-State 3 [1.25 m]</li> <li>Sea-State 4 [2.50 m]</li> </ul> </li> <li>Wave Heading <ul style="list-style-type: none"> <li>0 Degree [Head Sea]</li> <li>45 Degree [Oblique Sea]</li> <li>90 Degree [Beam Sea]</li> </ul> </li> <li>Hull Configuration <ul style="list-style-type: none"> <li>Catamaran</li> <li>Trimaran</li> <li>Quadrimaran</li> <li>Pentamaran</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>Significant heave response (<math>\zeta_{s \text{ Global } Z}</math>)</li> <li>Significant roll response (<math>\zeta_{s \text{ Global } RX}</math>)</li> <li>Significant pitch response (<math>\zeta_{s \text{ Global } RY}</math>)</li> </ul>	<ul style="list-style-type: none"> <li>LoA</li> <li>Breadth Demihull</li> <li>Spacing</li> <li>Height</li> <li>Draft</li> </ul>

The dominant pure oscillatory response motions, particularly heave, rolling, and pitching characteristics in regular waves, will be determined by evaluating the free-floating conditions for all proposed design models. The results will be shown in a graph of Response Amplitude Operators (RAOs), where the frequency parameter is indicated on the horizontal axis (X-absis) and the ratio of motion amplitude in a specific mode to the wave amplitude is represented on the vertical axis(Y-ordinate), as explained by Djatmiko (2012).

As a result, the motion quality values for each proposed design will be presented as a representation of a curve, with the x-axis representing the type or number of hull configurations for the floaters and the y-axis representing the floating structure motion quality values (heave, roll, and pitch) for a specific sea-state. The trends of the scatter graph for each simulation result point

will be represented by the equation of a line that corresponds to the validity error values - R squared (R2) within the value that comes closest to 1.

## METHODOLOGY

This numerical solution is based on a Computational Fluid Dynamics (CFD) simulation. The following subsection includes data for each proposed design with initial main principal dimensions, along with electrical capacity and weight distribution calculations then followed by a general layout. The seakeeping performance is evaluated by significant response spectra ( $\zeta_{s[Z]}$ ,  $\zeta_{s[RX]}$ ,  $\zeta_{s[RY]}$ ), using further stochastic computations to calculate the area under the spectrum curve for specific sea situations.

### Model Description & Initial Calculation

The stated numbers for floater hull dimensions are identical for each proposed design configuration, indicating that the addition of hull different forms is carried out by replicating the shape of the previous hull design laterally following Figure 4.

**Figure 4.** Novel design of hull geometry adaptation for FPV: (a) Catamaran, (b) Trimaran, (c) Quadrimaran, (d) Pentamaran

The main dimensions related to the hydrostatic properties of each design are tabulated in Table 3. It should be noted that, due to the identical values of the hull shape dimensions, this will result in hydrostatic properties of the identical FPV floating structure, except for the total width and displacement values of the FPV structure.

**Table 3.** Main principles dimension

Parameter	Catamaran	Trimaran	Quadrimaran	Pentamaran	Units
Length over All (LoA)	3.24	3.24	3.24	3.24	m
Breadth (B)	3.54	6.34	9.14	11.94	m
Height (H)	0.30	0.30	0.30	0.30	m
Draft (T)	0.12	0.12	0.12	0.12	m
Demihull Width (B1)	0.74	0.74	0.74	0.74	m
Spacing (S)	2.80	2.80	2.80	2.80	m
<b>Hydrostatic properties</b>					
Displacement ( $\Delta$ )	437.31	655.31	874.74	1094.17	kg
Block coefficient ( $C_b$ )	0.75	0.75	0.75	0.75	-
Prismatic coefficient ( $C_p$ )	0.76	0.76	0.76	0.76	-
Keel to buoyancy (KB)	0.06	0.06	0.06	0.06	m
Longitudinal Center of Buoyancy (LCB) from AP	1.62	1.62	1.62	1.62	m

Table 4 shows the total installed power capacity for each proposed model, as well as the characteristics of the solar panel technology used.

**Table 4.** PV system specification and total power generation capacity

Parameter	Value	Unit	Remarks
PV capacity	665	Watt peak (Wp)	(CSI Solar Co. Ltd, 2021)
Module efficiency	21.40	%	
Length of PV	2.38	m	
Width of PV	1.30	m	
PV module weight	34.40	kg	
Total generating capacity			
Catamaran	665	Watt peak (Wp)	These calculations are based on the maximum capacity of the considered PV system technology
Trimaran	1330	Watt peak (Wp)	
Quadrimaran	1995	Watt peak (Wp)	
Pentamaran	2660	Watt peak (Wp)	

## Governing Equations

The CFD simulation software's governing equation assumed a homogeneous, inviscid, irrotational, and incompressible fluid, as outlined by (Haug et al., 2018). This assumption aims to identify the potential velocity function, which serves as a criterion for determining fluid characteristics like velocity and pressure. The computation of Response Amplitude Operators (RAOs) within the Boundary Element Method (BEM) techniques were performed using (Ansys, 2019). The potential velocity can be expressed as equation (1), where  $i$ ,  $j$ , and  $k$  represent unit vectors along the  $x$ -,  $y$ -, and  $z$ -axes, respectively.

$$V = \nabla\phi = \frac{\partial\phi}{\partial x}i + \frac{\partial\phi}{\partial y}j + \frac{\partial\phi}{\partial z}k \quad (1)$$

Under the assumption that the fluid remains incompressible – implying a consistent mass within the flow entering and leaving a control surface – the Laplace equation is formulated by the following expression (2).

$$\nabla^2\phi = \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = 0 \quad (2)$$

Subsequently, to ensure compliance with the continuity equation, every potential velocity solution should be accompanied by the non-rotation condition outlined in equation (3). In simpler terms, an irrotational fluid is one in which the vorticity vector is uniformly zero across the entire fluid.

$$\omega_v = \nabla^2 \times V = 0 \quad (3)$$

In this scenario, fluid does not pass through the surface of a fixed body in motion. This condition indicates the impermeability of the object and is expressed in equation (4).

$$\frac{\partial\phi}{\partial n} = 0 \quad (4)$$

While equation (4) indicates the impermeability of a fixed body, such as the seabed, with  $n$  representing a normal vector pointing from the seabed and extending into the fluid, equation (5) expands this concept for a moving body with a velocity  $V$

$$\frac{\partial\phi}{\partial n} = V \cdot n \quad (5)$$

The kinematic free-surface condition states that in the presence of small waves, fluid particles at the surface are expected to remain on the free surface. Furthermore, the dynamic free-surface condition requires that the water pressure at the free surface becomes equal to a constant atmospheric pressure. The following equation (6) expresses the simplified and linearized formulations for the kinematic and dynamic free-surface conditions, which use linear theory and assume small waves, zero current, and zero forward speed of the body.

$$\frac{\partial^2 \zeta}{\partial t^2} + g \frac{\partial \phi}{\partial z} = 0 \quad \text{on } z = 0 \quad (6)$$

In the end, as the vessel interacts with the waves, the potential velocity becomes an instrument for representing the wave flow field around the hull sections. Furthermore, the potential velocity is critical in computing the fluid force applied on the hull section, as well as determining hull motion and wave force. Consequently, the potential velocity generated by external waves can be combined using the method described in (7).

$$\phi = \phi_i + \phi_r + \phi_d \quad (7)$$

$\phi_i, \phi_r, \phi_d$  representing the potential functions for the incident wave, radiation wave, and diffraction wave, respectively.  $\phi_i$  is computed using Airy linear theory, while the derivation of  $\phi_r$  and  $\phi_d$  relies on the application of diffraction theory. In diffraction theory, the potential function is determined by solving the Laplace equation, considering relevant boundary conditions, and subsequently calculating the pressure and resulting forces acting on the body. Additionally, pressure is extracted using the Bernoulli equation, and the potential function is determined. In conclusion, the integration of pressure over the entire wet surface area produces wave excitation forces, which are then utilized in the AQWA software.

## Response Amplitude Operators (RAOs)

The Response Amplitude Operator (RAO) is a function of the dynamic motion of a structure induced by waves within a specific frequency range. RAO serves as a tool to convert wave forces into the dynamic motion response of the structure. Translation and rotational RAOs are described by equations (8) – (9).

$$RAO_{(k=x,y,z)} = \frac{\zeta_{k0}}{\zeta_0} \quad (8)$$

$$RAO_{(k=\theta,\phi,\psi)} = \frac{\zeta_{k0}}{\left(\frac{\omega^2}{g}\right) \zeta_0} \quad (9)$$

## Calculation of Wave Spectral

JONSWAP's wave spectrum formulation is a modified version of the Pierson-Moskowitz spectrum with integrating parameters to accommodate the characteristics of waves in enclosed waters or island environment Djatmiko (2012) Therefore, it is suitable for application in Indonesia's archipelago with the following equation (10) – (14) based on DNV-GL recommendation Det Norske Veritas (2010)

$$S_J(\omega) = A_\gamma S_{PM}(\omega) \gamma^{\exp\left[-0.5\left(\frac{\omega-\omega_p}{\sigma\omega_p}\right)^2\right]} \quad (10)$$

$$S_{PM}(\omega) = \frac{5}{16} \cdot H_s^2 \omega_p^4 \cdot \omega^{-5} \exp\left[-\frac{5}{4}\left(\frac{\omega}{\omega_p}\right)^{-4}\right] \quad (11)$$

$$\omega_p = \frac{2\pi}{T_p} \quad (12)$$

$$A_\gamma = 1 - 0.287 \ln(\gamma) \quad (13)$$

$$\sigma = 0.07 \text{ for } \omega \leq \omega_p \text{ or } \sigma = 0.09 \text{ for } \omega > \omega_p \quad (14)$$

Where,  $S_J(\omega)$  is the JONSWAP spectrum,  $S_{PM}(\omega)$  is the Pierson-Moskowitz spectrum,  $\omega_p$  is the angular spectral peak frequency,  $T_p$  is the spectral peak period,  $H_s$  is the significant wave height,  $A_\gamma$  is the normalizing factor,  $\gamma$  is the non-dimensional peak shape parameter, and  $\sigma$  is the spectral width parameter.

## Calculation of Responses Spectral

The responses of a floating structure in irregular waves shall be obtained by correlating the RAO with the wave spectrum within transforming wave energy into response energy with the following equation (15). Subsequently, the amplitude significant response is calculated as equation (16).

$$S_{\zeta_r}(\omega) = RAO^2 \times S_\zeta(\omega) \quad (15)$$

$$\zeta_s = 2\sqrt{m_0} \quad (16)$$

Where  $S_{\zeta_r}(\omega)$  is the response spectrum,  $S_{\zeta}(\omega)$  is the waves spectrum and  $m_0$  is the area under the response spectrum curve as shown in the following equation (17).

$$m_0 = \sum_{n=1}^{\infty} S_{\zeta}(\omega) \delta\omega = \int_0^{\infty} S_{\zeta}(\omega) d\omega \quad (17)$$

### 3-D Diffraction CFD Simulation Setup

The three-dimensional (3D) models of floating structures were developed using the Maxsurf modeler by Bentley System (2022). Subsequently, the 3D model was exported in .step format through Rhinoceros software to conduct seakeeping analysis using Ansys Aqwa. The statistical validation between Ansys Aqwa and the baseline for manual calculations was required to stay within a 2% threshold for all considerations, as detailed in the results presented in Table 4 (a) – (d) as recommended by Suastika et al., (2021)

**Table 5.** Statistical validation: (a) catamaran, (b) trimaran, (c) quadrimaran, (d) pentamaran

(a)

Furthermore, the motion characteristics are the combination of the mass properties and hull surface geometry of the floating structure. The mass properties such as inertia values and center of gravity (CoG) indicate how resistant a body is to changes in its rotational state. The mass properties are defined in Ansys Aqwa as a “point mass” with automatically calculated in mass and only input in radius gyration as can be seen Table 5.

**Table 6.** Radii of gyration of floating structures

Component	Catamaran (m)	Trimaran (m)	Quadrimaran (m)	Pentamaran (m)
$K_{xx}$ (X-Axis)	1.15	2.02	2.86	3.69
$K_{yy}$ (Y-Axis)	0.68	0.67	0.70	0.70
$K_{zz}$ (Z-Axis)	1.33	2.12	2.94	3.75

The generating mesh provides to calculation of pressures and forces on each number element in hull surface geometry (Bosma et al., 2012). A finer mesh was used in interface between wet and dry surface region. Both of floating were meshed as shown in Figure 4.

**Figure 5.** Mesh visualization: (a) Catamaran, (b) Trimaran, (c) Quadrimaran, (d) Pentamaran

## RESULT AND DISCUSSION

The results and discussions in this paper are divided into subsections: a key point of the fundamental proposed design, Response Amplitude Operators (RAOs) and JONSWAP's wave spectra under various sea states, including structural response spectra within stochastic values.

The main recommended design component emphasizes the importance of selecting hull-shaped floater concepts in PV technology, covering from catamaran to pentamaran shapes. This subsection examines several of the advantages of this multi-hull design in depth.

In the RAOs subsection, all graphs related to motion analysis in heave, roll, and pitch modes for each proposed design model are explained in the frequency range of 0.05 – 3.00 rad/sec. Explanations for the heave RAO graph will be presented for headings  $\varphi = 0$ ,  $\varphi = 45$ , and  $\varphi = 90$  degrees. The roll RAO graph is subsequently clarified for headings  $\varphi = 45$  and  $\varphi = 90$  degrees. The pitch RAO graph is described at headings of  $\varphi = 0$  and  $\varphi = 45$  degrees.

The significant response value of oscillatory pure motions subsection describes various aspects, including significant wave height values under each sea-state condition, and the visualization of JONSWAP wave spectra, followed by several graphical representations of motion quality calculations for each mode and sea-state condition for each proposed model.

## A Key Point of the Fundamental Proposed Design

The floater structure, as a form of buoyant force, must be designed to withstand vertical and horizontal loads. The vertical load is less substantial than anticipated, as evidenced by the lightweight proportion of this FPV innovation design, which is just approximately 38% of the total displacement capacity, indicating that this technology was created with minimalism and lightness. Furthermore, horizontal cyclic loads such as wind, wave, and current loads must be considered because the technology will be utilized in nearshore locations (Liu et al., 2018). However, presently, HDPE blocks are commonly used in the implementation of FPV technology in lakes with generally calm water conditions – related to restricted limited wind fetch generating waves and mountains surrounded area (Allsop et al., 2018; Gudrun Sigtryggisdottir, 2022). Typically, certain designs involve only segments of the HDPE blocks, which are then arranged on the water surface to provide adequate buoyancy and serve as a platform for solar panel technology. Shifting the perspective toward nearshore areas is aimed at harnessing a significantly larger technical space compared to utilizing reservoirs – which are typically limited to only 5% of the total area as per Indonesia's Public Work and Housing regulation (IESR, 2021). Subsequently, to address the challenges of dynamic nearshore water conditions, the approach for developing a PV technology floater shape must be improved.

Many prior investigations have demonstrated the numerous advantages of multihull ship designs over monohulls. This ship with several hulls is a novel type of high-speed performance ship created in the late twentieth century (Molland et al., 2011). The multihull concept originated from their ability to handle more cargo than ordinary commercial containerships, resulting in improved capacity and lower emissions due to greatly decreased water resistance. This has a positive effect on environmental conservation (Zhao et al., 2023). Figure 6 might help demonstrate specific types of high-speed and low-resistance vessels.

**Figure 6.** High-speed and low-resistance vessels: (a) Catamaran, (b) Trimaran, (c) Quadrimaran, (d) Pentamaran  
Ref: (Dr. Hans, 2021; Schionning Designs International (Pty) Ltd, 2024; Yanuar & Waskito, 2017)

The innovative concept attempts to replicate the characteristics of high-speed boats in a stationary (non-propelled) PV floater system. However, the number of hulls utilized increases the cost component in manufacture, but this is rationalized by the size of the service deck along with the location of solar panels, where this renewable energy source is proportional to area. As explained by Bhattacharyya (1978) and (Zhao et al., 2023), the addition of lateral hulls enhances the metacenter height,

resulting in a significant reduction in excitation force due to the degree of roll motion, which is related to the natural period of the motion, lateral acceleration, and extra transverse stability.

Similar to other renewable energy technology concepts, the development of FPV technology is expected to evolve towards the concept of energy farming at sea. This involves a series of configurations, both laterally and transversally on the water surface where the incremental addition of floaters becomes inevitable. Hence, the complex and multi-analysis of CFD within fluid-structure interaction shall be conducted the key design of FPV energy farming (Wei et al., 2024).

## Response Amplitude Operators (RAOs)

The results of seakeeping numerical simulations for all designs are presented in this section. Due to the symmetrical geometry in the stern and bow of all proposed floating structures, the wave heading is considered only at  $\varphi = 0^\circ$  (following sea),  $\varphi = 45^\circ$  (quartering sea), and  $\varphi = 90^\circ$  (beam sea). From the three graphs provided, it becomes demonstrated that at a  $0^\circ$  heading, all heave response graphs, from catamaran to pentamaran, demonstrate zero differences. This is because when waves counter from the forward position (FP) or backside (AP), the FPV structural will be move (heave response mode) in a synchronized up-and-down action. This is due to the hull configuration in the design is arranged adjacent to one another.

The response degrees at  $\varphi = 45^\circ$  and  $\varphi = 90^\circ$  are significantly lower than at  $\varphi = 0^\circ$ . The trend throughout all three graphs has been described as follows: The heave response motion decreases as the wave incidence angle approaches perpendicular to the longitudinal axis of the ship's centerline ( $\varphi = 90^\circ$ ). This behavior is also consistent with the increase of hull types. At headings of  $\varphi = 45^\circ$  and  $\varphi = 90^\circ$ , the pentamaran model demonstrates the lowest heave reaction.

**Figure 7.** Heave RAO: (a)  $\varphi = 0^\circ$ , (b)  $\varphi = 45^\circ$ , (c)  $\varphi = 90^\circ$

Furthermore, the roll Response Amplitude Operator (RAO) curve of the FPV structure shows that the highest value of the peak roll response RAO occurs in the  $\varphi = 90^\circ$  of wave incidence direction, indicating that this is the dominant direction leading to the roll response when compared to the  $45^\circ$  heading. Nevertheless, further investigation shows a significant discrepancy in peak values between the two headings ( $\varphi = 45^\circ$  &  $90^\circ$ ), particularly in the catamaran model (the difference can reach over 40% - nonetheless this percentage value will decrease significantly with the addition of configurations to the FPV structure). Then the addition of the hull configuration for the floater, the area under the roll motion response curve (RAO) will decrease, indicating that with an increasing number of float structure configurations, the roll motion can be dampened.

**Figure 8.** Roll RAO: (a)  $\varphi = 45^\circ$ , (b)  $\varphi = 90^\circ$

Then, the final response considered as pure oscillatory motion is the pitch motion. The findings of this investigation are unique, considering that the pitch response at the  $\varphi = 0^\circ$  heading for all proposed designs is similar to the heave motion mode (no differences occur). When the structure is stimulated by waves from the dominant pitch motion direction ( $\varphi = 0^\circ$ ), all models will consistently provide identical response values throughout the specified wave frequency range. This also indicates that the addition of hull configuration to the FPV structure does not have a significant influence on the performance of this pitch motion mode.

However, there is a substantial difference at  $45^\circ$  heading, since the consequences of adding hull configurations to the FPV structure appear to have a significant effect. The pentamaran hull configuration has the lowest peak value of the pitch Response Amplitude Operator (RAO) response when compared to the other floater configuration.

**Figure 9.** Pitch RAO: (a)  $\varphi = 0^\circ$ , (b)  $\varphi = 45^\circ$ .

## Significant Response Value of Oscillatory Pure Motions

Analyzing the wave spectrum is the subsequent process in evaluating the effect of the hull configuration. Figure 10 illustrates JONSWAP's wave spectra for sea states 1–4 based on Table 7, which indicate sea conditions.

**Table 7.** Sea-state codes

Sea-State	Description of sea	Significant Wave Height (m)
1	Calm (rippled)	0.10
2	Smooth (wavelets)	0.50
3	Slight	1.25
4	Moderate	2.50

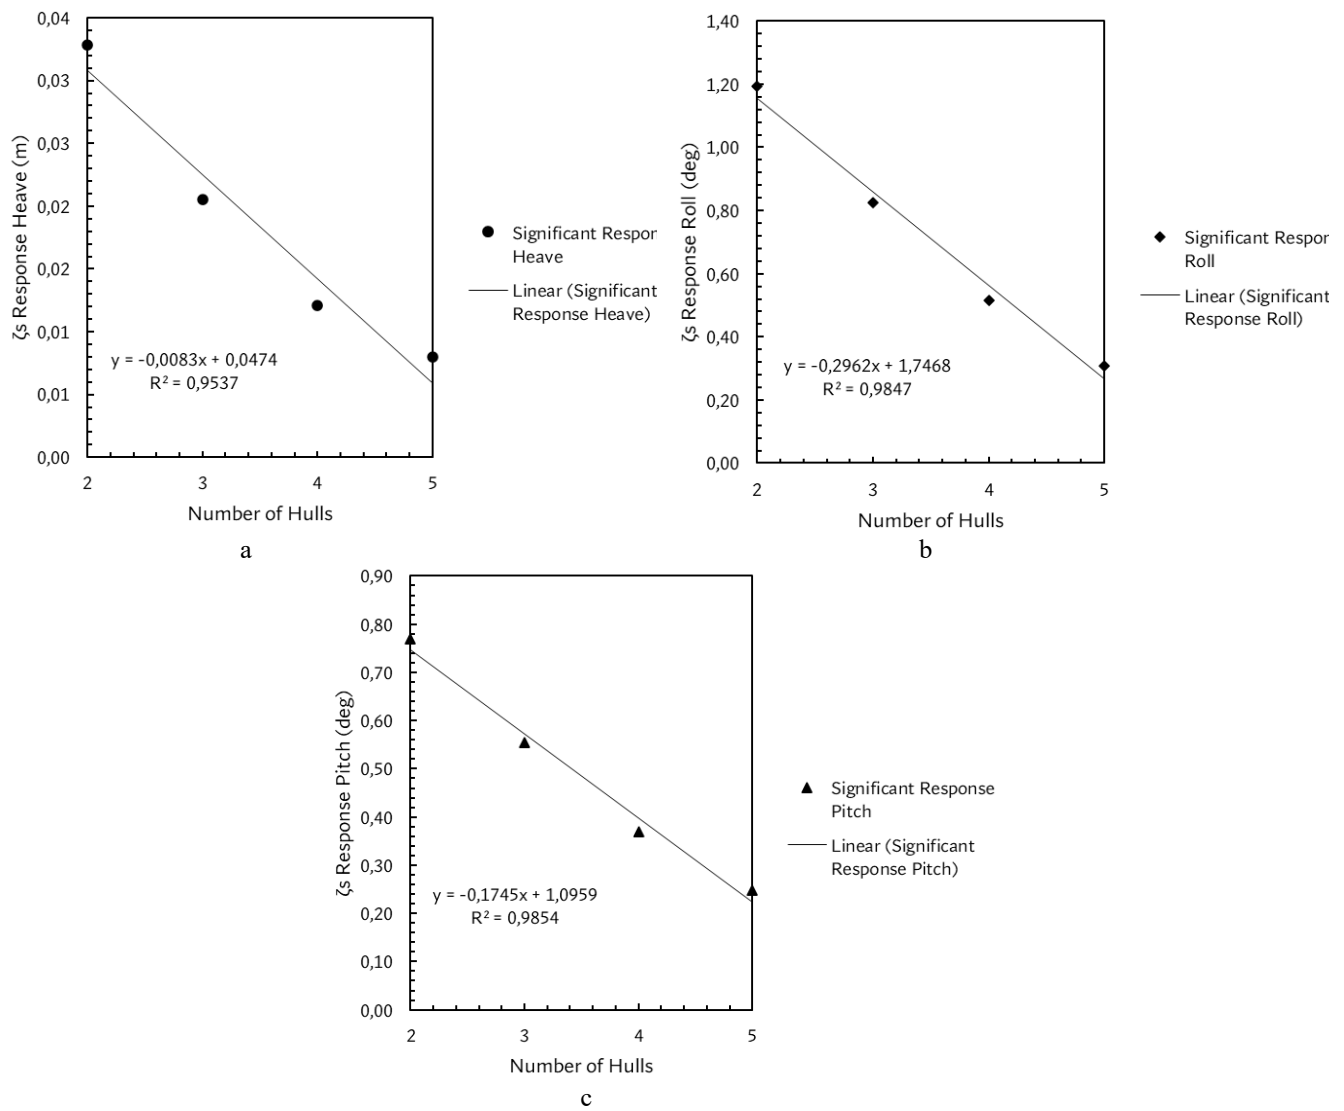

**Figure 10.** JONSWAP's wave spectra for various sea-state

Two key factors that influence the arrangement of response spectra are the wave spectrum and the RAO for specific modes. Moreover, stochastic parameters were computed based on the curves of response spectra for each mode. Nevertheless, the primary focus of this investigation will be restricted to determining significant response amplitudes, which represent an average measurement of the largest 33% of responses, within the sea-state range of 1-4.

Then, in Figures 11-14, it is shown that there is a negative linear trend in all three motion modes (pure oscillatory motion) when hull configurations have been added to the FPV floater structure under each sea-state scenario.

These graphs provide insightful data, particularly if there is an objective for developing an FPV floater structure using the single-array design concept with the addition of configurations laterally. The equation of each graph's negative linear regression line can be applied to predict the qualitative value of floating structure motion for an FPV structure with more than 5 hulls (pentamaran).

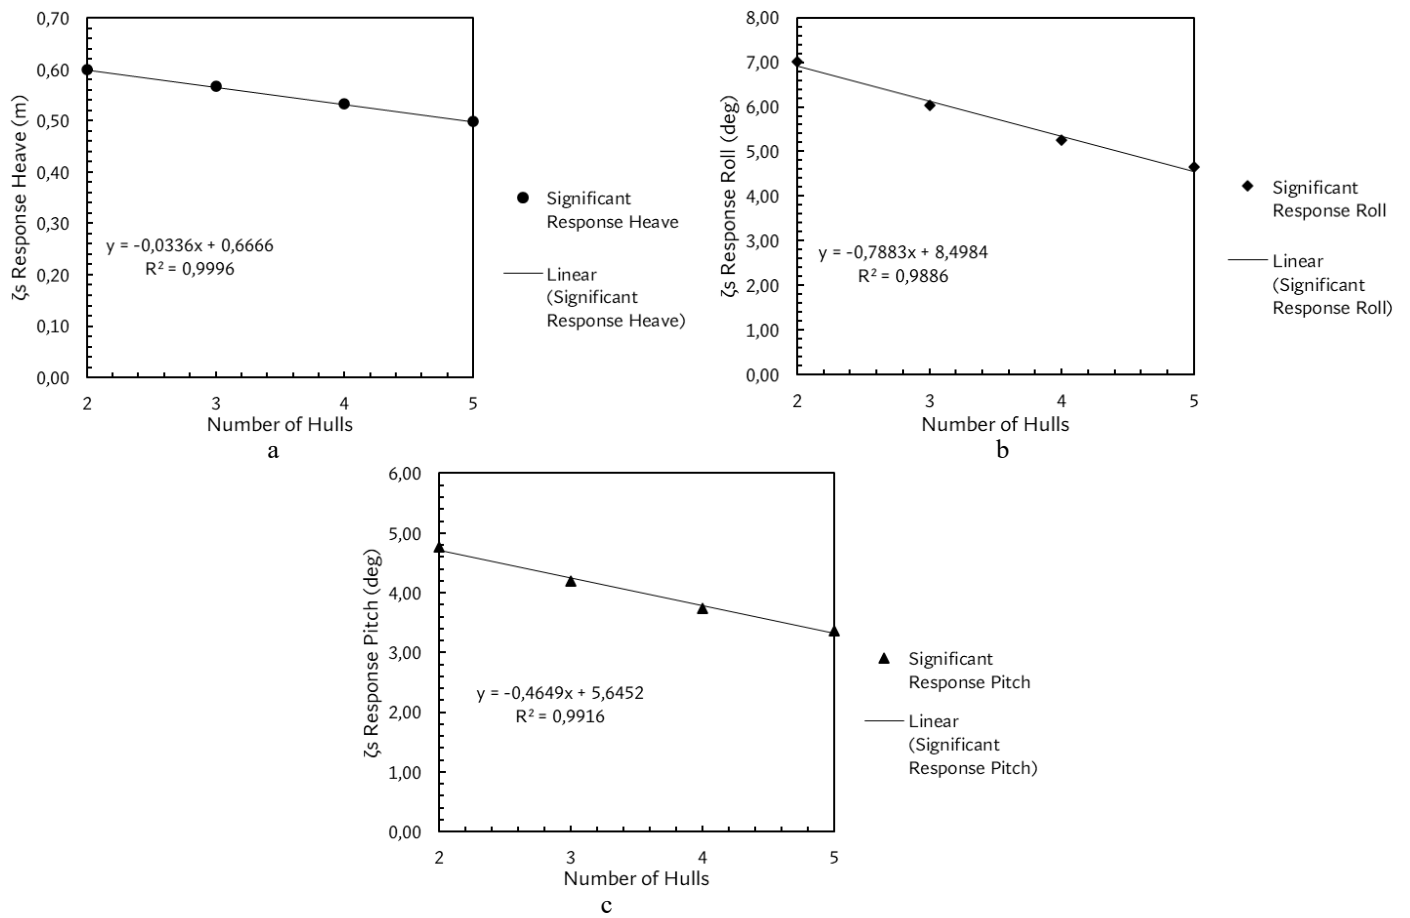

**Figure 11.**  $\zeta_s$  Respons FPV – Sea-State 1: (a) Global Z, (b) Global RX, (c) Global RY

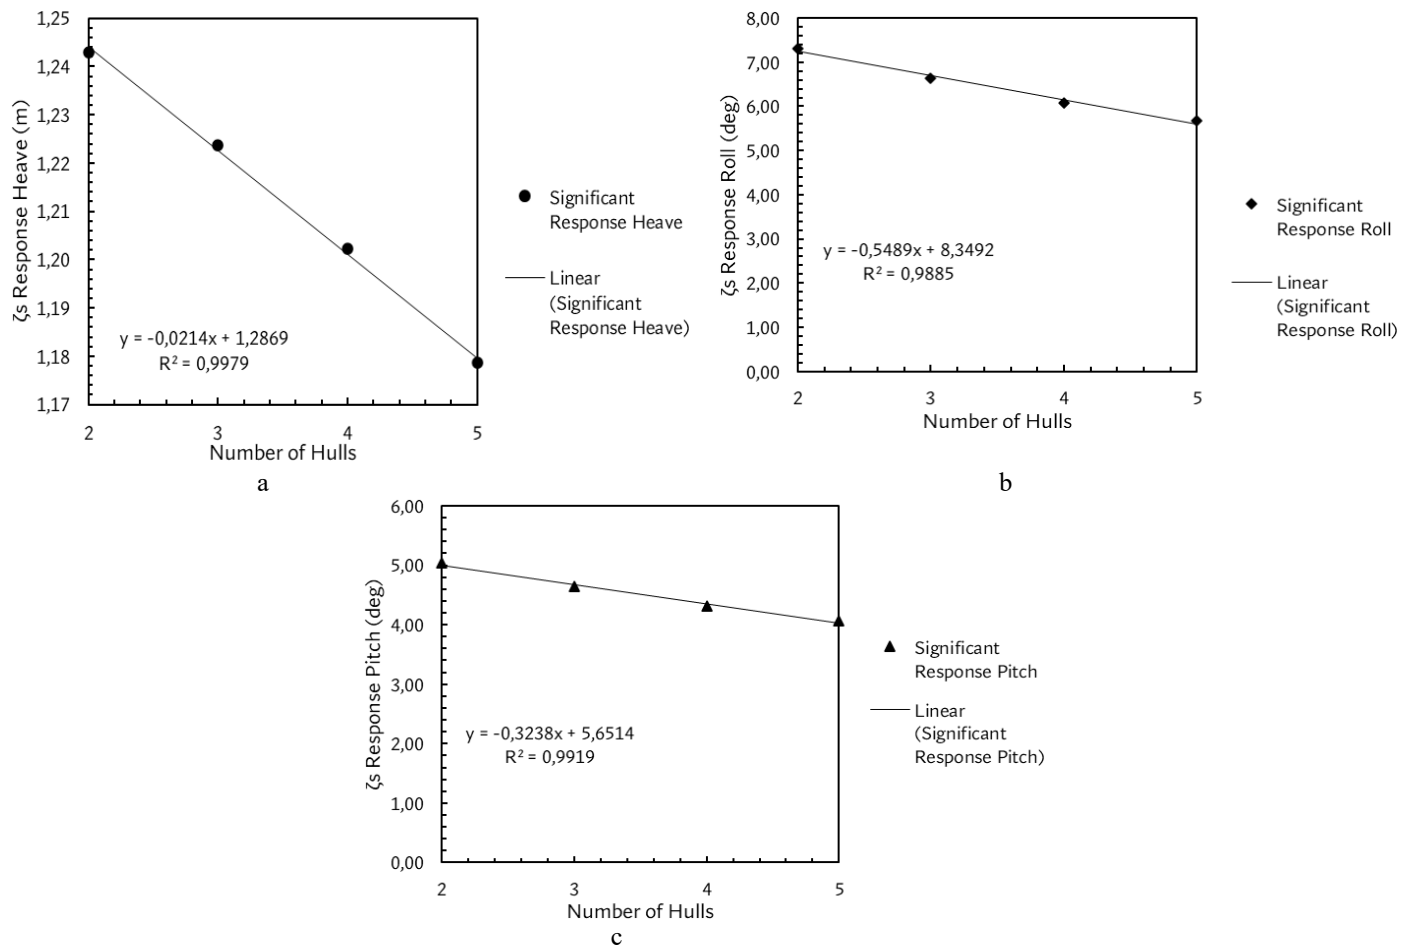

**Figure 12.**  $\zeta_s$  Responses FPV – Sea-State 2: (a) Global Z, (b) Global RX, (c) Global RY

**Figure 13.**  $\zeta_s$  Responses FPV – Sea-State 3: (a) Global Z, (b) Global RX, (c) Global RY

**Figure 14.**  $\zeta_s$  Responses FPV – Sea-State 4: (a) Global Z, (b) Global RX, (c) Global RY

Table 8 illustrates the relationship between the variable reflecting the quantity of proposed floating structure configurations along the X-axis and its impact on the quality of each motion mode generated along the Y-axis under predefined sea-state conditions.

**Table 8.** Regression equation for each motion mode

Sea-State	Significant Responses	Equation	Curve Form	R <sup>2</sup>
Sea-State 1	Heave	$y = -0.0083x + 0.0474$	Linear Negative	0.954
	Roll	$y = -0.2962x + 1.7468$		0.985
	Pitch	$y = -0.1745x + 1.0959$		0.985
Sea-State 2	Heave	$y = -0.0326x + 0.2768$		0.999
	Roll	$y = -0.7823x + 6.1139$		0.988
	Pitch	$y = -0.4599x + 3.9561$		0.990
Sea-State 3	Heave	$y = -0.0336x + 0.6666$		1.000
	Roll	$y = -0.7883x + 8.4984$		0.989
	Pitch	$y = -0.4649x + 5.6452$		0.992
Sea-State 4	Heave	$y = -0.0214x + 1.2869$		0.998
	Roll	$y = -0.5489x + 8.3492$		0.989
	Pitch	$y = -0.3238x + 5.6514$		0.992

## CONCLUSIONS

A study was conducted to investigate the impact of platform configurations and environmental conditions on the performance of floating solar photovoltaic (FPV) structures. Numerical Computational Fluid Dynamics (CFD) simulations based on 3-D

diffraction were carried out to identify pure oscillatory motions in heave, pitch, and roll for all proposed designs. The numerical findings show that the FPV structure with 5 (five) floater hulls has the lowest motion response (pure oscillatory motion) compared to other configurations under each sea-state scenario. Furthermore, there is a negative linear trend in the motion response of the FPV structure from the catamaran configuration to the pentamaran. It is essential to note that if subsequent studies desire for a concept with several hull configurations exceeding 5 hulls, the negative linear regression equations for each motion under different sea-state conditions can be predicted, provided that the design concept, geometric shape, configuration arrangement, and several control variables remain similar to this study.

Furthermore, , The future works should consider the selection of mooring configurations and various types for the FPV structure's mooring system. The hydrodynamics responses of mooring lines and FPV structures could be investigated in the time domain analysis.

# A Fundamental Study on Inter-Array Cabling Methods Between Two Floating Offshore Wind Turbines in Shallow Waters

Kangho Kim<sup>1</sup>, Chunsik Shim<sup>1</sup>, Min Suk Kim<sup>2</sup>, Daseul Jeong<sup>1,\*</sup>

## ABSTRACT

*As the transition to renewable energy accelerates, interest in wind farms is heightening. There is a need to safely and economically transport energy produced from Floating Offshore Wind Turbines (FOWTs) to the shore. Consequently, this study conducted an analysis of inter-array cabling methods between two FOWTs in shallow waters, targeting the southwestern sea of South Korea. This research targeted four shapes of dynamic power cables: free hanging catenary, lazy wave shape, suspended and W-configuration type. To verify the economy of the dynamic power cable, the total lengths were compared, and to check safety, curvature and tension were examined. Insights obtained through this study indicate that among the four shapes of dynamic power cables, the lazy wave shape has substantial advantages in shallow waters.*

## KEY WORDS

Inter-array cable; Dynamic power cable; Motion analysis; Excursion.

## INTRODUCTION

As interest in renewable energy grows, there is increasing attention to the production of eco-friendly electricity that can be mass-produced. Among these, the production efficiency of wind energy is relatively high compared to other green energy sources, making the construction of wind farms an essential role in decarbonization. The electricity from a wind farm, which comprises several wind turbines, is transmitted to a substation through power cables after each wind turbine generates it, as shows in Figure 1(Moon et al., 2014). In this study, we conducted a fundamental study on the methods of transmitting electricity from each wind turbine before it converges at the substation.

Li et al. (2023) developed a dynamic response analysis model for ultra-deepwater cables with double-stepped configurations, focusing on the dynamic responses and robustness to moving boundaries during deep-sea mining operations. The study utilized finite element simulations combined with hydrodynamic models to analyze the cable's behavior under environmental excitations. It concluded that the double-stepped cable design offers improved compliance and effectiveness in buffering responses caused by moving boundaries, contributing to safer and more efficient deep-sea mining operations.

Chen et al. (2021) investigated the structural configurations and dynamic performances of flexible risers with distributed buoyancy modules, using Finite Element Method (FEM) simulations. Their study focused on assessing the influences of buoyancy module positioning and ratio on riser performance, especially under deep-sea mining conditions. The research concluded that the installation positions and buoyancy ratios significantly impact the riser's configuration, tension, and dynamic performance, contributing to the understanding of riser design for safe and effective deep-sea mining operations.

Okpokparoro and Sriramula (2023) conducted a reliability analysis of floating wind turbine dynamic cables under realistic environmental loads. Their research utilized an analytical model to evaluate the fatigue damage and reliability of these cables, considering environmental uncertainties and cable-soil interactions. The study offers significant insights into the structural reliability of dynamic power cables in offshore wind applications, highlighting the importance of considering realistic environmental loads in cable design and reliability assessment.

Poirette et al. (2017) presented a novel optimization methodology for the configuration of inter-array cables in floating offshore wind farms. This study utilizes FEM hydrodynamic simulations in conjunction with a derivative-free Sequential Quadratic Approximation (SQA) optimization algorithm. The research focuses on optimizing the cable layout for minimizing material costs while considering constraints to ensure cable integrity. This approach offers a new perspective on enhancing the efficiency and cost-effectiveness of cable configurations in floating offshore wind farm projects.

Zhao et al. (2021) conducted a study comparing two dynamic power cable configurations for floating offshore wind turbines in shallow water. Their research compared the hydrostatic and hydrodynamic performance of lazy wave and double wave configurations, utilizing a comprehensive numerical simulation approach. The study found that the double wave configuration exhibited superior performance, offering advantages in terms of reduced fatigue damage and better handling of high curvature tension.

Ahmad et al. (2023) explored an optimization methodology for suspended inter-array power cable configurations between two floating offshore wind turbines. Their research focused on the dynamic response of these configurations using a novel setup involving subsea buoys. The study demonstrated the feasibility of the suspended inter-array power cable concept, highlighting those smaller buoys yield more efficient designs and the copper cable configurations result in smaller horizontal excursions compared to aluminum cables.

Rentschler et al. (2019) focused on the design optimization of dynamic inter-array cable systems for floating offshore wind turbines. Utilizing a genetic algorithm, they analyzed cable configurations to improve fatigue life performance under extreme weather conditions. The research highlights the importance of considering dynamic behaviors and offers design recommendations for different water depths, contributing significantly to the development of efficient and reliable floating offshore wind technologies.

Schnepf et al. (2023) conducted a feasibility study on suspended inter-array power cables between two spar-type offshore wind turbines. This research involved exploring various cable configurations and their impact on structural behavior, focusing on buoyancy module placements. The study concluded that certain configurations, particularly those with strategically placed buoyancy modules, can lead to significant improvements in cable performance and cost-effectiveness in offshore wind turbine applications.

Jason Lavis (2021) argued that while shallow water was previously described as having depths of up to 91-121m, today, depths of less than 305m are now considered shallow. Tong (1998) identified the economic depth range for floating offshore wind turbines as typically between 100m and 300m. This study focuses on an area located in the Southwest Sea, with a water depth of 150m, falling well within Tong's suggested economic depth range. This placement offers optimal conditions for installing FOWTs, suggesting a strategic fit for this renewable energy technology in areas previously deemed challenging.

This study builds upon the 12MW FOWT model by SINTEF Norway and, to conduct a fully coupled dynamic analysis, using OrcaFlex to adapt to the ocean data measured from Uido island located in southwestern of Korea. The pivotal research endeavor involves the integration of a dynamic power cable into a 12 MW FOWT, thus considering the mooring system's intricate design. By adhering to the IEC 61400 regulations and realistic maritime conditions found in South Korea's southwestern sea, the study

carries out both Serviceability Limit State (SLS) and Ultimate Limit State (ULS) analyses, ensuring its findings' accuracy and practical relevance. The study focused on four types of power cables: free hanging catenary, lazy wave shape, suspended and W-configuration type.

## METHOD

### Three-column FOWT layout for optimal mooring and cable integration

Figure 2 shows the 12MW substructure model of SINTEF. The model consists of three columns and six pontoons. The main properties of the 12MW FOWT are summarized in Table 1 (SINTEF, 2022).

Figure 2: SINTEF 12MW substructure

The coordinate system of the analytical model is designed to align with the global coordinates of the substructure provided by SINTEF, as shown in Figure 3.

Figure 3: Coordinate system of SINTEF's 12MW offshore wind turbine substructure

To construct a wind farm using a substructure with three columns, the layout presented in Figure 4 by Aker Solutions (2019) is referenced. The model modeled using OrcaFlex is as shown in Figure 5. This configuration is an arrangement of a floater with three columns that shares anchors and ensures there is no interference between power cables and mooring lines. An advantage of using such an arrangement is that it facilitates the expansion for the construction of a wind farm, as illustrated in Figure 6.

Figure 4: Inter array cable layout

**Table 1: Main properties of the 12MW wind turbine**

Parameter	Properties
Turbine rating	NREL 12MW
Blade length (m)	105.4
Hub diameter (m)	6
Hub Height (m)	131.7
Draft (m)	15.5
Nacelle mass (kg)	600,000
tower mass (kg)	1,161,600
Blade mass (kg)	3 * 63024
Hub mass (kg)	60,000
Total mass (kg)	14,176,000
Cut-in/rated/cut-out wind speed (m/s)	4.0 / 10.6 / 25.0
Cut-in/ rated rotor speed (rpm)	5.5 / 7.8
Generator efficiency (%)	94

**Figure 5: Layout of analysis model (top view)**

**Figure 6: Expanding the floating substructure with three columns**

The analysis model and the coordinate system used in this process are presented in Figure 7, and the specifications of the designed mooring line are detailed in Table 2. Additionally, Table 3 describes the positions of crucial points such as the fairleads and anchor points for each mooring line in their static state to understand the mooring system.

**Figure 7: Overview of the analytical model for offshore wind farm cabling**

### Design of the dynamic power cable configurations

**Figure 8: Typical dynamic cable cross section**

The cross-section of the cable is composed of three conductor cores wrapped in insulation and two steel armour. In addition, it has four helical layers (circular helix type) including a copper shield and an outer sheath to protect the cores. The typical shape of a three-core power cable's cross-section is as shown in Figure 8 (CIGRE, 2022). The capacity of the power cable used in this study is 66kV.

**Figure 9: Cable configurations. From top, (a) free hanging catenary (b) lazy wave shape (c) suspended (d) W-configuration**

Rentschler et al. (2020) conducted a parametric study on the inter-array cable systems of FOWTs. The optimal total cable lengths relative to water depth and buoy placements obtained through the parametric study are referenced for the design of the catenary and lazy wave shapes.

In this study, as shown in Figure 9, simulations are conducted for four types of power cables: (a) free hanging catenary, (b) lazy wave shape, (c) suspended and (d) W-configuration. The depth is set to 150 meters to determine which inter-array cable method is most suitable for shallow water depths.

The total length of the cable is 1681.9 meters, and different types of buoys are used to implement the lazy wave shape, suspended and W-configurations. For the lazy wave shape, relatively small buoys are attached, numbering 62 in total, while

for the suspended configuration, 7 large-capacity buoys are attached. In the W-configuration, 5 buoys are installed in each of the 7 sections, making a total of 35 buoys installed. Detailed specifications of the buoys are as presented in Table 4.

**Table 4: Power cable attachment buoy specification**

	Mass (te)	Volume (m <sup>3</sup> )	Drag coefficient (x)	Drag coefficient (z)	Added mass coefficient (x)	Added mass coefficient (z)
Lazy wave shape buoy	0.069	0.197	1.100	1.100	1.000	1.000
Suspended buoy	2.700	8.615	0.209	1.000	0.459	0.600
W-configuration buoy	0.55	1.72	1.2	1.000	0.459	0.600

Figure 10 displays a detailed comparison between the suspended and W-configuration, zooming in on their structural differences. In the suspended configuration, a single buoy is installed in each section, resulting in a pointed appearance, whereas in the W-configuration, five buoys are installed in a single section, creating a smoother curve. The number and arrangement of buoys have been adjusted to prevent excessive curvature.

**Figure 10: Detailed comparison between suspended and W-configuration**

## Environmental load case

### Wave

To conduct simulations that closely resemble actual conditions at sea, numerous variables such as significant wave height ( $H_s$ ), zero-crossing period ( $T_z$ ), wave direction, tidal speed, and wind speed/direction are identified to establish comprehensive load cases. These variables are not arbitrarily chosen, but meticulously selected and optimized based on an extensive collection and processing of maritime environmental data. The data, harvested from Uido, Sinan, Jeollanam-do, South Korea, spans an entire year in 2021 and comprises 7,853 data points observed at hourly intervals, as shown in Table 5. (KHOA, 2022) waves are implemented using the JONSWAP spectrum with the obtained values for  $T_z$  and  $H_s$ . (Hasselmann, K. et al.)

**Table 5: Wave scatter diagram for Sinan Uido**

$T_z$ (s)	$H_s$ (m)							sum
	0.5	1.5	2.5	3.5	4.5	5.5	6.5	
3.5	834	3	0	0	0	0	0	837
4.5	1,766	121	0	0	0	0	0	1,887
5.5	1,719	600	8	0	0	0	0	2,327
6.5	824	684	101	0	0	0	0	1,609
7.5	370	252	239	9	0	0	0	870
8.5	88	36	40	71	1	0	0	236
9.5	73	24	5	11	4	0	0	87
sum	5,644	1,720	393	91	5	0	0	7,853

## Current

Current is calculated through wind-generated, tidal, and power law methods. (DNV, 2019) The current generated by the wind is determined by multiplying the average wind speed at an altitude of 10m by a coefficient  $k$ , as in Equation 1. The wind speed for the SLS is 18m/s, and for the ULS is 42.5m/s. Precise values of the coefficient  $k$  can be obtained from field measurements or detailed fluid dynamics models, but in this study, an intermediate value of 0.02 was used.

$$v_{c,wind}(0) = kU_{1\text{ hour},10m} \text{ where } k = 0.015 \text{ to } 0.03 \quad [1]$$

For the current, the power law method, as detailed in Equation 2, was used to establish varying speeds at the 50m depth and the seabed.  $S_f$  and  $S_b$  denote the current speeds at the surface and seabed, respectively.  $Z_f$  and  $Z_b$  represent the  $Z$  coordinate of the 50m depth and seabed directly below the (X, Y) coordinates. This study set the power law exponent, denoted as  $p$ , to 7 (Orcina, 2023). The current profile used in this study is as depicted in Figure 11.

$$S = S_b + (S_f - S_b) \left[ \frac{Z - Z_b}{Z_f - Z_b} \right]^{\frac{1}{p}} \quad [2]$$

**Figure 11: Current profiles in SLS and ULS**

## Environmental load in a 50-year cycle

The SLS analysis utilizes maximum values, such as significant wave height ( $H_s$  4.5m), zero-crossing period ( $T_z$  9.5s), and wind speed (18m/s). To recognize the potential impact of wave and wind directions on the mooring lines, these elements are set at 180 degrees, 300 degrees, and 60 degrees, resulting in a total of 9 SLS load cases. For the ULS analysis, assumptions are made based on Det Norske Veritas DLC 1.3 (DNV, 2016), with an understanding that the wind and wave directions are aligned.

Table 6 presents the wind speed, derived by examining the standard parameters that classify wind turbine stages in accordance with International Electrotechnical Commission 61400-1 (IEC, 2005). This research utilizes the wind speed recorded at the wind turbine class II stage.  $V_{ref}$  symbolizes the reference wind speed measured over 10 minutes, and A, B, C denote category designation values for high, medium, and low turbulence characteristics, respectively. Additionally,  $I_{ref}$  denotes the anticipated turbulence intensity value at a wind speed of 15m/s.

**Table 6: Basic parameters for wind turbine classes**

Wind turbine class	I	II	III	S
V <sub>ref</sub> (m/s)	50	42.5	37.5	Values specified by the designer
A I <sub>ref</sub>	0.16			
B I <sub>ref</sub>	0.14			
C I <sub>ref</sub>	0.12			

The extreme wind speeds corresponding to a 50-year return period are determined by referencing the IEC 61400-1 standard, which prescribes the standard wind speeds for three distinct turbine classes. The reference wind speed of 42.5m/s, associated with Class II, is employed in our analysis. For the evaluation of the significant wave height and the zero-crossing period under extreme wind scenarios, the American Petroleum Institute's (API, 2007) 2INT-MET guidelines are consulted. With a considered wind speed of 41.12m/s, the significant wave height is found to be 12.9m, and the zero-crossing period is recorded at 14 seconds. Hence, one ULS load case has been established in this research. The crucial details and visualizations for these load cases, vital for an all-encompassing understanding of the system's behavior, are shown in Table 7 and Figure 12.

**Table 7: Environmental load case**

	Load case	Waves			Wind	
		H <sub>s</sub>	T <sub>z</sub>	Dir.	Speed	Dir
		m	s	degree	m/s	degree
SLS	1	4.5	9.5	180	18.0	180
	2			180		300
	3			180		60
	4			300		180
	5			300		300
	6			300		60
	7			60		180
	8			60		300
	9			60		60
ULS	10	12.9	14.0	180	42.5	180

In this study, ten Environmental load cases are established, and the analysis is conducted targeting the shapes of four power cables. The names for the analysis cases are configured as C-LC1 (Catenary-Load Case1), L-LC1 (Lazy wave-Load Case1), S-LC1 (Suspended-Load Case1) and W-LC1(W-configuration-Load Case1).

**Figure 12: Load case diagram**

# RESULTS

## Assessing cable configuration performance in LC10

In shallow water depth, a dynamic analysis is conducted using two FOWTs to determine the best method among four cable configurations. The simulation time is 10,800s (3 hours), with a start-up time of 300s, totaling 11,100s of dynamic analysis. Figure 13 shows the maximum elevation state at LC10 after completing the dynamic analysis for each shape. In the case of catenary and lazy wave, the cables lay on the seabed, while in suspended and W-configuration, they float in the middle. The suspended and W-configuration are designed to minimize the impact of wind-generated forces in the maximum elevation state, being set lower than 50 meters in depth.

Figures 14 and 15 illustrate the profiles of maximum effective tension and maximum curvature according to arc length, respectively. The maximum tensions and curvatures for each configuration are summarized in Table 8. The tension of the lazy wave is 19.00% lower than that of the catenary, 25.01% lower compared to the suspended and 26.28% lower compared to the W-configuration. Additionally, the lazy wave demonstrates superior performance in curvature as well, being 30.52% lower than the catenary, 77.42% lower than the suspended and 60.16% lower than the W-configuration. Overall, the performance of the lazy wave shape is confirmed to be superior, and it is advisable to use the lazy wave shape for ensuring long-term fatigue performance of dynamically behaving cables.

The W-configuration is a form designed to prevent the excessive curvature observed in the suspended configuration by installing five buoys in one section. While this significantly reduced the curvature, it was found to offer no substantial advantage in terms of tension. Considering installation and maintenance costs, it becomes evident that the lazy wave shape offers greater benefits.

**Table 8: The rate of increase in tension and curvature for each configuration compared to the lazy wave**

DLC	Maximum tension (kN)	Rate of increase compared to lazy wave (%)	Maximum curvature (m/m)	Rate of increase compared to lazy wave (%)
L-LC10	60.18	0.00	0.1218	0.00
C-LC10	74.29	19.00	0.1753	30.52
S-LC10	80.25	25.01	0.5393	77.42
W-LC10	81.57	26.28	0.3055	60.16

**Figure 13: Cable configuration of maximum elevation state per arc length in LC10**

**Figure 14: Maximum effective tension profile for each shape in LC10**

**Figure 15: Maximum curvature profile for each shape in LC10**

## Evaluating all design load cases

Figures 16 and 17 respectively display the values of maximum effective tension and maximum curvature for all load cases. The points of highest tension and curvature in the cable occur at the hang-off connected to the substructure and the touch down point affected by the bottom drag. For the suspended case, since there is no touch down point, the tension and curvature at the buoy nearest to the hang-off are observed, denoted as the ‘1<sup>st</sup> buoy’.

In the case of C-LC10, the curvature and tension at the touch down point show significant differences between the SLS and ULS. This is deemed a characteristic of the free-hanging shape, where movements at the upper part of the power cable induce excessive motion at the lower part. For lazy wave and suspended, the difference between SLS and ULS is not substantial, indicating that the buoys placed in-between prevent excessive transfer of movements from the upper part of the power cable. However, considering the much higher curvature of the suspended compared to the catenary and lazy wave, the lazy wave method appears most suitable for inter-array cabling of power cables in shallow waters.

Figure 16: Maximum effective tension for all design load case

Figure 17: Maximum curvature for all design load case

### Bird caging effect in helical cable

According to the study by Lu et al. (2017), the bird cage buckling phenomenon is likely to occur when the armor wires are subjected to high axial compression that exceeds their critical load, especially if there is damage to the cover sheath and strength tapes, as shows Figure 18.

Figure 18: Bird caging failure mode of tension armor wires

The bird caging phenomenon can occur in steel armor cables that are twisted in one direction and can manifest when excessive compressive loads are applied. Among the four analytical models performed in this study, it was observed that a negative tension occurred at the touch down point of the catenary. As shown in Figure 19, the maximum compressive load was calculated to be 10.71 kN, which is not an absolute large value, but it suggests that caution is needed when designing FOWTs.

**Figure 19: Minimum tension distribution on configuration profile in C-LC10**

## CONCLUSIONS

This study conducted research on inter-array cabling methods in shallow waters. A substructure with three columns was used to minimize interference between mooring lines and power cables. The power cables are analyzed in four types: catenary, lazy wave, suspended and W-configuration. To simulate a realistic environment, observational data and relevant standards are referenced. The obtained results are as follows.

1. Under ULS conditions, the lazy wave is found to have the best performance among the four shapes. It exhibited 19.00% lower tension compared to the catenary, 25.01% lower compared to the suspended and 26.28% lower compared to the W-configuration, along with 30.52% lower curvature than the catenary, 77.42% lower than the suspended and 60.16% lower than the W-configuration. The selection of the lazy wave is beneficial for ensuring long-term safety.
2. Additionally, the lazy wave shape showed low tension and curvature, with minimal difference in the impact on power cables between the SLS and ULS. Even in rapidly changing environmental conditions, it maintained low tension and curvature, proving superior in terms of shock load as well.
3. When a dynamic power cable has a catenary shape without any means to prevent direct contact with the seabed, it is observed that compressive loads can occur at the touch-down point. Although the values identified in this study are small compared to tensile loads, significant compressive loads may arise due to the cable's configuration deep water depth accompanied by heavy cable weight, and severe environmental conditions, potentially leading to bird caging. Careful consideration during design is necessary to prevent this phenomenon.
4. In this study, an analysis was conducted on four different cabling methods in terms of tension and curvature. However, the results of this study are to be considered preliminary, pending calibration with experimental data. Future research will involve comparative analyses with the free-decay test and regular wave test provided by SINTEF to enhance the reliability of the results.
5. Real ocean environment data obtained from the study will be utilized for fatigue analysis of mooring lines and dynamic power cables. Fatigue Limit State (FLS) will be generated using data observed in the targeted marine area to perform fatigue analysis. Moreover, an essential aspect to be addressed in further research is the cost-effectiveness. A comparative analysis between the installation costs and power production of the four different dynamic power cable configurations will be conducted to determine the payback period and profit based on fatigue life calculations.

# Using a Design Exploration Model to Assess the Global Techno-Economic Feasibility of Far Offshore Green Hydrogen Production Towards 2050

T. Melles<sup>1,2,\*</sup>, J.F.J. Pruyn<sup>1</sup>, J.L. Gelling<sup>1</sup> and J.J. de Wilde<sup>2</sup>

## ABSTRACT

*With space constraints onshore, strong renewable resources available far offshore and growing green hydrogen demand, far offshore green hydrogen production may be an attractive option. To assess this potential, a mixed integer quadratically constraint programming (MIQCP) optimization model was developed to find the cost per kilogram of far offshore green hydrogen in specific scenarios. The design of the far offshore green hydrogen supply chain was optimized with this model for six high potential scenarios in varying locations and the results were analyzed. It was found that far offshore green hydrogen costs are in the same order of magnitude as the costs of its alternatives. Far offshore green hydrogen may be considered marginally competitive with these alternatives from 2035 onwards in the analyzed scenarios when taking into account the considerable advantages of far offshore production, such as avoidance of scarce land usage in crowded areas and certain geopolitical considerations.*

Far offshore; Green hydrogen; Green FPSO; LCoH; Optimization

## INTRODUCTION

As the world attempts to slow down and eventually stop climate change, sustainability becomes increasingly important. According to Lapidés et al. (2020), around 80% of the economy is relatively easy to decarbonize by electrification, with costs being reasonable and technologies already (widely) available. The other 20% consists of peak power generation, heavy duty transport (buses, trucks and ships) and industrial processes requiring combustion of a fuel to create high temperatures. For this last 20%, also referred to as the ‘last mile’ of decarbonization or hard-to-abate, hydrogen may play a key role in the path towards sustainability.

Hydrogen produced without any emissions using renewable energy is called green hydrogen. The production of green hydrogen occurs in a process called electrolysis, where electricity and water are used to produce hydrogen and oxygen. When renewable energy is used in this process, the hydrogen can be regarded as zero-emission and green. Since the production of green hydrogen will require large amounts of energy, a lot of additional renewable energy is needed. (Hague, 2021)

The demand for hydrogen is expected to rise strongly towards 2050 in many parts of the world (The Hydrogen Council & McKinsey & Company, 2021). Looking at the net-zero goals set by various countries (United Nations, n.d.), the demand

for green hydrogen and renewable energy in general will grow significantly, which means space restrictions onshore and near offshore may present problems. In addition, the development of floating energy generation, and the strong and steady wind resources available in many (far) offshore locations may make far offshore renewable energy generation attractive. To transport large amounts of energy over long distances, transport in the form of hydrogen is more economic than transport through electrical cables (d'Amore-Domenech et al., 2021). Therefore, far offshore green hydrogen production could be even more beneficial, as it will make long distance transport to shore more economic and therefore the distance to shore of the production location less important.

The actual techno-economic feasibility of far offshore green hydrogen production is however still largely unknown. Therefore, the main objective of this research is to create a first idea of the worldwide technological and economic feasibility of far offshore green hydrogen production over time, identifying the technologies to be used in its supply chains, looking at which factors influence its price, comparing it to its alternatives and showing the role it may play in a net-zero economy in and towards 2050. In this research, 'far offshore production' is defined as production in areas with water depths over 50 meters, where floating production is necessary (ESMAP, 2019).

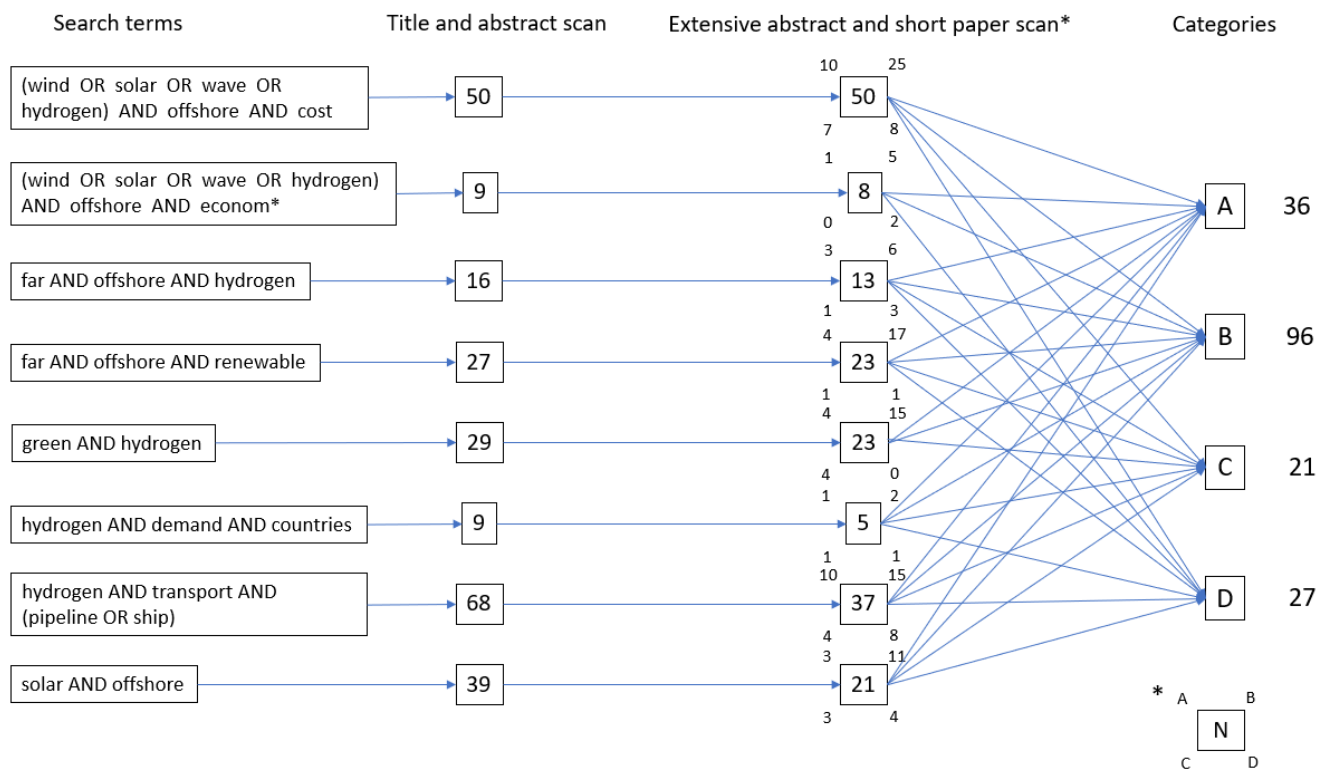

Many factors can influence the far offshore green hydrogen supply chain and therefore the costs of far offshore green hydrogen. The right combination of energy generation devices, electrolyzers, conversion devices, storage size, FPSO size and hydrogen carrier must be determined in every scenario. In order to solve this design challenge and find the optimal combination of all these aspects leading to the lowest far offshore green hydrogen costs, an optimization model is needed when analyzing the scenarios to be considered. How to best set up the model for this research will be discussed in the literature review. In this literature review, the method of the literature retrieval and the technologies that were considered in this research will be discussed as well. Next, the methodology will show the model developed in this research and the scenarios that were analyzed. After this, the results will be analyzed, followed by a short discussion and the conclusions.

## LITERATURE REVIEW

An extensive literature review was conducted to map the available knowledge regarding far offshore green hydrogen production and related topics. In this section, it will be discussed how the relevant literature was retrieved, how a suitable modelling method was found and which technologies were included in the model.

### Literature Retrieval

For the literature retrieval, mainly SCOPUS was used. Eight combinations of search terms were used, which are shown in Figure 1. On the search results, a title scan and subsequently a quick abstract scan were performed which resulted in a list of possibly interesting references. Next, the selected references were analysed further by doing an extensive abstract scan and a quick scan of the rest of the paper. This led to a further selection and structuring of the papers. In Figure 1, the literature retrieval process is shown visually and the amount of references is indicated for each part of the process. As can be seen, the initial scan resulted in a total of 247 references, which was brought down to 180 after the second scan. These references were then placed in four different categories (A, B, C and D), with categories A and B containing the literature with relevant general information on the various topics of interest (for example on the techno-economic feasibility of possibly interesting technologies) and categories C and D containing the literature describing possibly relevant methods. Furthermore, categories A and C contain the references that were expected to be relevant in their entirety, whereas categories B and D contain the references that are not relevant in their entirety, but contain relevant aspects, such as one or several specific input data values or a method for a specific (small) part of the model. Eventually, a total of 57 references were identified as most relevant (categories A and C). The literature review has been set up primarily based on these references. In all of the reviewed literature, only one reference was found describing a solution approach with a similar scope, which was used as a base for the modelling approach developed in this research, as will be explained below.

**Figure 1:** Flow chart literature retrieval (please note that the small numbers in the third column indicate how many references were placed into each category, as shown in the legend in the bottom right corner of the figure)

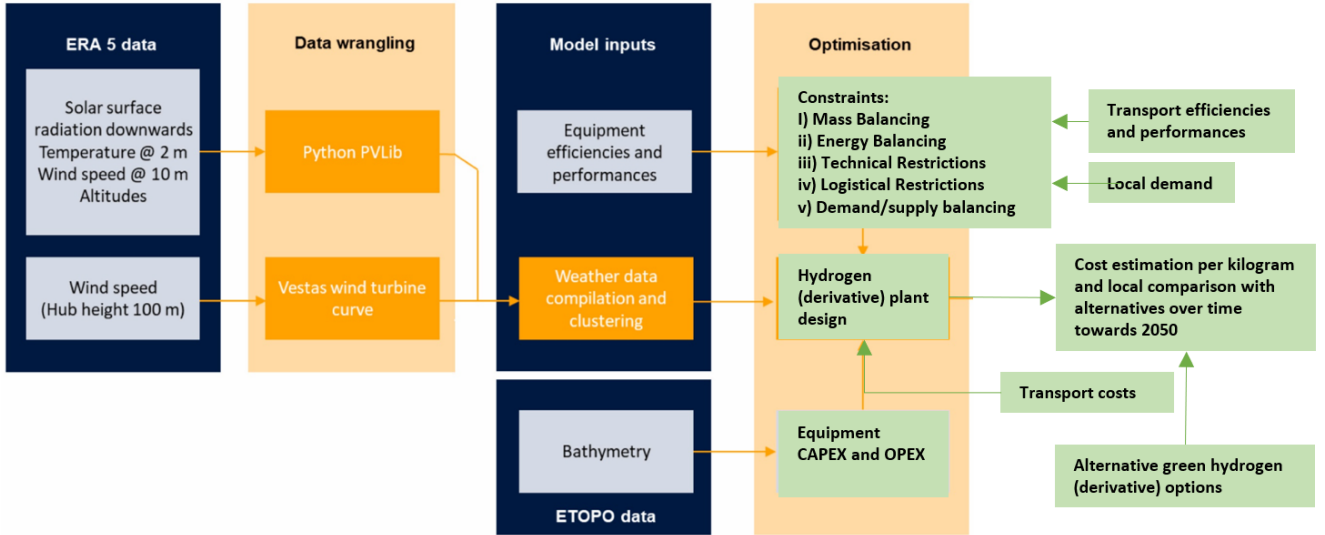

### Suitable Modelling Method

During the reviewing, only one reference describing a solution approach with a similar scope to this research has been found. In this paper, Salmon and Bañares-Alcántara (2022) look at the worldwide feasibility of (far) offshore green ammonia production in 2030. Their main analysis is done on a global level, directly comparing the best onshore with the best offshore locations. This may however not show the full potential of far offshore production of green hydrogen and its derivatives. For example, if we directly compare an onshore production location in Morocco and an offshore production location off the coast of New Zealand to each other, the production costs of the onshore location in Morocco might be lower. However, if the demand is located in New Zealand, the delivered costs of the green hydrogen may still be lower from the offshore location when taking into account the conversion and transport costs. For this reason, comparing green ammonia production costs on a global level directly as done by Salmon and Bañares-Alcántara (2022) in their main analysis does not lead to a realistic comparison and approaches the potential of far offshore green ammonia from a very conservative side. This is a major limitation to their research and was therefore taken into account when setting up the modelling method for this research.

In order to assess the effect of infrastructure costs on the potential of far offshore green ammonia, Salmon and Bañares-Alcántara (2022) shortly look at its potential in two scenarios with usage in Germany and Japan (including transport). They conclude that far offshore green ammonia will be beneficial in Japan and not in Germany, with which they illustrate themselves that the specific scenario is highly important, which means an analysis based on specific scenarios is needed to make a realistic analysis. Therefore, the global potential of far offshore green hydrogen should be assessed ‘bottom-up’, where a representative set of specific scenarios is analyzed, from which conclusions are drawn about the global potential of far offshore green hydrogen. This means the main gap in literature to be filled by this research is an evaluation of the global potential of far offshore green hydrogen over time using local comparisons with specific scenarios. In addition to this, Salmon and Bañares-Alcántara (2022) only made predictions for 2030 and only considered ammonia. These shortcomings were ad-

addressed in this research as well. When defining the scenarios to be analyzed in this research, the highest potential scenarios were selected first, as it was still unknown whether far offshore green hydrogen production will become feasible at all. In the methodology, the scenarios considered in this research will be discussed in more detail.

In Figure 2, the modelling approach used by Salmon and Bañares-Alcántara (2022) is shown with the main adjustments as described in the previous paragraph (green blocks). This was used as a base for the model developed in this research. As can be seen, transport costs and technical data, several hydrogen carriers, and the period until 2050 are included. Also, the potential of far offshore green hydrogen is evaluated with local comparisons, shown by the fact that local demand and green hydrogen alternatives are used.

**Figure 2:** Basis for the modelling approach as adjusted from Salmon and Bañares-Alcántara (2022) (only main adjustments)

When following a modelling approach similar to the one shown in Figure 2, the focus is put on the optimization of the far offshore green hydrogen supply chain. The alternative would be to put the focus on a higher level supply/demand interaction in a global network of production and usage locations, and simplify the far offshore green hydrogen supply chain modelling. It is expected that putting the focus on the optimization of the far offshore green hydrogen supply chain will have a more direct practical relevance for the choices to be made in the development of far offshore green hydrogen production at this moment in time. In addition, it is expected that it will result in more complete and reliable insights into what technologies may become part of far offshore green hydrogen supply chains and how the potential will develop. Furthermore, when focusing on the optimization of the supply and demand interaction, too large uncertainties are expected to be introduced. More research must be performed to be used as a base for a research with such a focus. Therefore, the focus was put on the optimization of the far offshore green hydrogen supply chain in this research. Within this supply chain, the main optimization challenges included in the model developed in this research are (1) the optimization of the combination of various renewable energy generation devices with the electrolyzers, and (2) the choice between several hydrogen carriers as transport medium. Both of these optimizations integrate various parts of the far offshore green hydrogen supply chain. The outcome therefore depends on many different factors and the two optimizations are connected as well when solved simultaneously. How the model was set up to solve the two main optimization challenges and design the rest of the supply chain too will be discussed in more detail in the methodology.

Next to the focus of the model, the method to be used is of great importance. Salmon and Bañares-Alcántara (2022) applied an optimization model with mixed integer linear programming (MILP). MILP is preferred over genetic algorithms as it guarantees the optimality of the solution (EMD International, 2020). In addition, optimization is preferred over simulation, because the optimal supply chain must be designed by the model to assess the full potential of far offshore green

hydrogen and it is expected to be difficult to predefine a set of simulations due to the limited knowledge available on far offshore green hydrogen supply chains. So far, the approach of Salmon and Bañares-Alcántara (2022) is followed. However, because several hydrogen carriers were considered in this research, it was expected that not all constraints would be linear, since the value of certain variables would depend on which hydrogen carrier is used, which is defined in the model through a constraint. When those variables are then used in other constraints, quadratic constraints can arise. For the same reason, quadratic objective terms could also arise. Therefore, MILP cannot be applied in this research and mixed integer quadratically constraint programming (MIQCP) is used instead to deal with the quadratic constraints and objective terms. Lastly, the model is implemented in Python and the Gurobi optimization solver is used, which is freely available through an academic license.

### Technologies to Be Included

The next step was to decide what exactly to include in the model, which was needed to be able to expand the general modelling approach presented in Figure 2 to a more detailed one. To do this, the retrieved literature was reviewed to assess what is already known about the techno-economic feasibility of the various aspects of a far offshore green hydrogen supply chain. An overview of the technologies included in the model is given in Table 1.

For the far offshore renewable energy generation, moored floating wind and solar energy production seem to be coming close to techno-economic feasibility (De Vries et al., 2021; Jan De Nul, 2023; SolarDuck, n.d.) and are therefore considered. The technological and especially cost development of wave energy converters is deemed too uncertain (Kasiulis et al., 2022; Rehman et al., 2022) and therefore, wave energy is left outside of the scope of the intended research.

With regards to the hydrogen production, it was found that PEM electrolyzers are expected to be most suitable for far offshore green hydrogen production due to their compact stacking possibilities and ability to handle the dynamic power input associated with renewable energy production (Jang et al., 2022). Furthermore, the focus of this research was put on centralized hydrogen production in an FPSO, leaving the option of decentralized hydrogen production out of the scope. Offshore hydrogen production with PEM electrolyzers will require a desalination plant as well (Jang et al., 2022).

Looking at the transport of hydrogen produced far offshore, the transport over sea seems most feasible from a techno-economic perspective if it is done by ship in the form of ammonia or liquid hydrogen. Whether ammonia or liquid hydrogen is more beneficial depends on the distance to be traveled and the quantity of hydrogen to be transported (International Renewable Energy Agency, 2022). Both options have therefore been included in the model. Methanol and compressed hydrogen are not considered in the model, since their costs are expected to be higher for most far offshore green hydrogen production scenarios (Cebolla et al., 2022). Other liquid organic hydrogen carriers (LOHCs) are also left out of the scope because there are multiple challenges that can limit their potential role in the global hydrogen trade, including limited availability, high costs, low hydrogen density, losses during recycling and high energy usage to recover the hydrogen from the carrier (International Renewable Energy Agency, 2022). Transport over land is assumed to be done with pipelines as gaseous hydrogen, since this seems to receive most attention at the moment. Long term storage onshore is not included in the model, but storage in the FPSO is. This storage may be done in the form of ammonia or liquid hydrogen, depending on which medium is used for transport.

**Table 1:** Technologies included in the model for each step of the far offshore green hydrogen supply chain

Step	Technologies included in the model
Power generation	Floating wind turbines Floating solar platforms
Electrolysis	PEM electrolyzers (with desalination) Centralized production on FPSO
Conversion and storage on FPSO	Ammonia Liquid hydrogen
Sea transport	Ammonia (by ship) Liquid hydrogen (by ship)
Land transport	Gaseous hydrogen (through pipelines)

## METHODOLOGY

In this section, the model will be shown and its general outline will be discussed. In addition, the scenarios to be analyzed will be presented. In the report this paper was based on, a more detailed explanation of the model is given.

### Model Overview

A schematic overview of the calculations belonging to an optimization of a far offshore green hydrogen supply chain, which forms the core of the developed model, is shown in Figure 3. It should be noted that only one optimization is visualized here, while a normal run of the model will include several optimizations for the chosen scenario in different years, meaning the visualized optimization will be run multiple times with changing input data. When looking at the input data for these optimizations belonging to different years, only the cost data will change, which is represented by the cell in the bottom right of Figure 3. This could lead to a different optimal far offshore green hydrogen supply chain for every considered year.

Next to the time domain included in the model by simulating several years, a second time domain is included within each optimization. From ERA5, hourly weather data is imported for a reference period of 10 months, which enters the model at the very left of Figure 3. From this hourly weather data, the hourly power production, the hourly power available for and used by the electrolyzers, and the hourly hydrogen production are determined over the reference period. Using these hourly production figures, the supply chain is optimized for production over a longer period of time, leading to more realistic results.

In Figure 3, the cells with yellow background color are ‘normal’, numeric input data or based on calculations with solely numeric data. The cells with red background color are variables, which are to be varied directly by the used optimization solver when finding the optimum. The cells with blue background color are based on calculations including other variables, meaning their value also changes while the optimization runs. Furthermore, the black arrows connecting cells represent ‘regular’ calculations, whereas the orange arrows represent constraints. Finally, the colors of the borders of the cells show to which part of the model they belong, as discussed further later in this section.

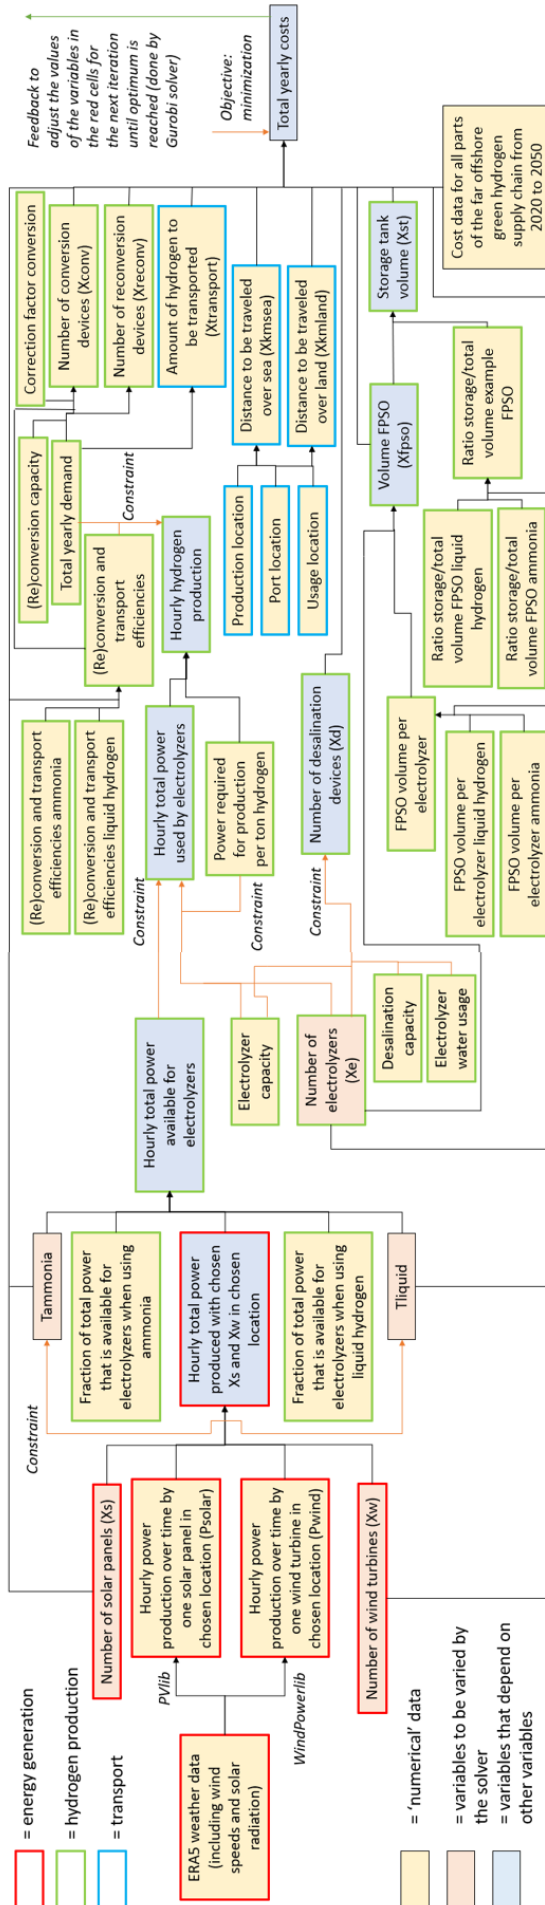

Figure 3: Model visualization

As can be seen in the figures, most calculations in the model eventually lead back to the calculation of the total yearly costs. As the yearly hydrogen production is given as a (constant) input to the optimization, these total yearly costs are directly related to the costs per kg of hydrogen. This means minimizing the total yearly costs is equal to minimizing the costs per kg of hydrogen for the analyzed supply chain. Therefore, the objective function to be minimized in the model is formulated as shown in Equation (1), where ‘i’ indicates the components of vectors x and C. Vectors x and C represent the number of units and the cost per unit respectively.

$$MIN(\sum_i x[i] * C[i]) \quad (1)$$

This means the sum that is minimized in the objective function is equal to the total costs for the far offshore green hydrogen supply chain in the defined scenario in the selected year. The elements of vectors x and C can be split up into three different groups: energy generation ( $X_{\text{energy}}$  and  $C_{\text{energy}}$ ), hydrogen production ( $X_{\text{production}}$  and  $C_{\text{production}}$ ) and transport ( $X_{\text{transport}}$  and  $C_{\text{transport}}$ ). This gives the split shown in Equation (2). In Figure 3, it has been indicated which part of the model belongs to each group through the color of the borders of the cells. The meaning of these colors is given in the legend. The cells with  $T_{\text{ammonia}}$ ,  $T_{\text{liquid}}$  and the cost data do not have a colored border, because the calculations in which they are used belong to multiple groups.

$$x * C = X_{\text{energy}} * C_{\text{energy}} + X_{\text{production}} * C_{\text{production}} + X_{\text{transport}} * C_{\text{transport}} \quad (2)$$

The three categories shown in Equation (2) can each be split up further, as shown in Equations (3) to (5). In Table 2, the variables and parameters used in these equations are explained. As indicated in the table, most of the equipment types are restricted to integer values.

$$X_{\text{energy}} * C_{\text{energy}} = X_w * C_w + X_s * C_s \quad (3)$$

$$\begin{aligned} X_{\text{production}} * C_{\text{production}} = & X_e * C_e + X_d * C_d + X_{\text{st}} * C_{\text{st}} + X_{\text{fpso}} * C_{\text{fpso}} \\ & + T_{\text{ammonia}} * X_{\text{convammonia}} * C_{\text{convammonia}} + T_{\text{liquid}} * X_{\text{convliquid}} * C_{\text{convliquid}} \\ & + T_{\text{ammonia}} * X_{\text{reconvammonia}} * C_{\text{reconvammonia}} + T_{\text{liquid}} * X_{\text{reconvliquid}} * C_{\text{reconvliquid}} \end{aligned} \quad (4)$$

$$X_{\text{transport}} * C_{\text{transport}} = X_{\text{basetransport}} * C_{\text{basetransport}} + X_{\text{kmsea}} * C_{\text{kmsea}} + X_{\text{kmland}} * C_{\text{kmland}} \quad (5)$$

**Table 2:** Meaning variables and parameters

Component	Meaning	Unit
$X_w$	Number of wind turbines (integer)	<i>dmnl</i>
$X_s$	Number of solar platforms (integer)	<i>dmnl</i>
$X_e$	Number of electrolyzers (integer)	<i>dmnl</i>
$X_d$	Number of desalination devices (integer)	<i>dmnl</i>
$X_{st}$	Volume of the storage tank on the FPSO	$m^3$
$X_{fpso}$	Volume of the FPSO	$m^3$
$X_{kmsea}$	Distance to be traveled over sea	<i>km</i>
$X_{basetransport}$	Amount of hydrogen to be transported	<i>tons</i>
$X_{kmland}$	Distance to be traveled over land	<i>km</i>
$X_{convammonia}$	Amount of conversion devices in case of transport as ammonia (integer)	<i>dmnl</i>
$X_{convliquid}$	Amount of conversion devices in case of transport as liquid hydrogen (integer)	<i>dmnl</i>
$X_{reconvammonia}$	Amount of reconversion devices in case of transport as ammonia (integer)	<i>dmnl</i>
$X_{reconvliquid}$	Amount of reconversion devices in case of transport as liquid hydrogen (integer)	<i>dmnl</i>
$T_{ammonia}$	Binary variable that indicates transport is done with ammonia when equal to 1	<i>dmnl</i>
$T_{liquid}$	Binary variable that indicates transport is done with liquid hydrogen when equal to 1	<i>dmnl</i>
$C_w$	Yearly costs of one wind turbine	<i>euros/year/unit</i>
$C_s$	Yearly costs of one solar platform	<i>euros/year/unit</i>
$C_e$	Yearly costs of one electrolyzer	<i>euros/year/unit</i>
$C_d$	Yearly costs of one desalination device	<i>euros/year/unit</i>
$C_{st}$	Yearly costs of one $m^3$ of storage tank	<i>euros/year/m3</i>
$C_{fpso}$	Yearly costs of one $m^3$ of FPSO	<i>euros/year/m3</i>
$C_{kmsea}$	Costs of ammonia or liquid hydrogen transport over sea for one tonkm hydrogen	<i>euros/ton of hydrogen/km</i>
$C_{basetransport}$	Base sea transport costs of ammonia or liquid hydrogen for one ton of hydrogen	<i>euros/ton of hydrogen</i>
$C_{kmland}$	Costs of gaseous hydrogen transport over land through pipelines per tonkm hydrogen	<i>euros/ton of hydrogen/km</i>
$C_{convammonia}$	Yearly costs of one ammonia conversion device	<i>euros/year/unit</i>
$C_{convliquid}$	Yearly costs of one liquid hydrogen conversion device	<i>euros/year/unit</i>
$C_{reconvammonia}$	Yearly costs of one ammonia reconversion device	<i>euros/year/unit</i>
$C_{reconvliquid}$	Yearly costs of one liquid hydrogen reconversion device	<i>euros/year/unit</i>

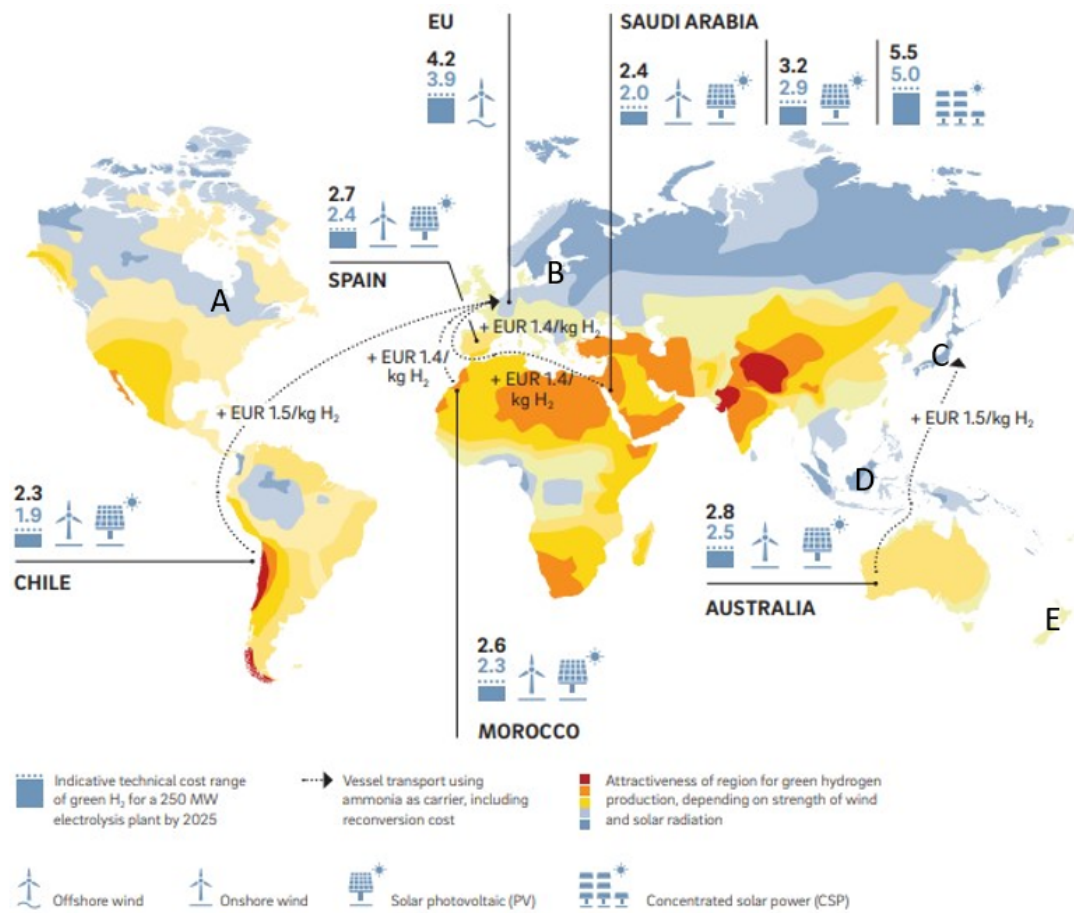

In Equations (3) to (5) and in some of the other calculations in the developed model,  $T_{ammonia}$  and  $T_{liquid}$  are used, which are also mentioned in Table 2.  $T_{ammonia}$  and  $T_{liquid}$  are binary variables used to include the choice between transporting with ammonia or liquid hydrogen in the optimization. To force the optimization solver to choose between the two, the constraint in Equation (6) has been implemented, which is also shown in Figure 3.

$$T_{ammonia} + T_{liquid} = 1 \quad (6)$$

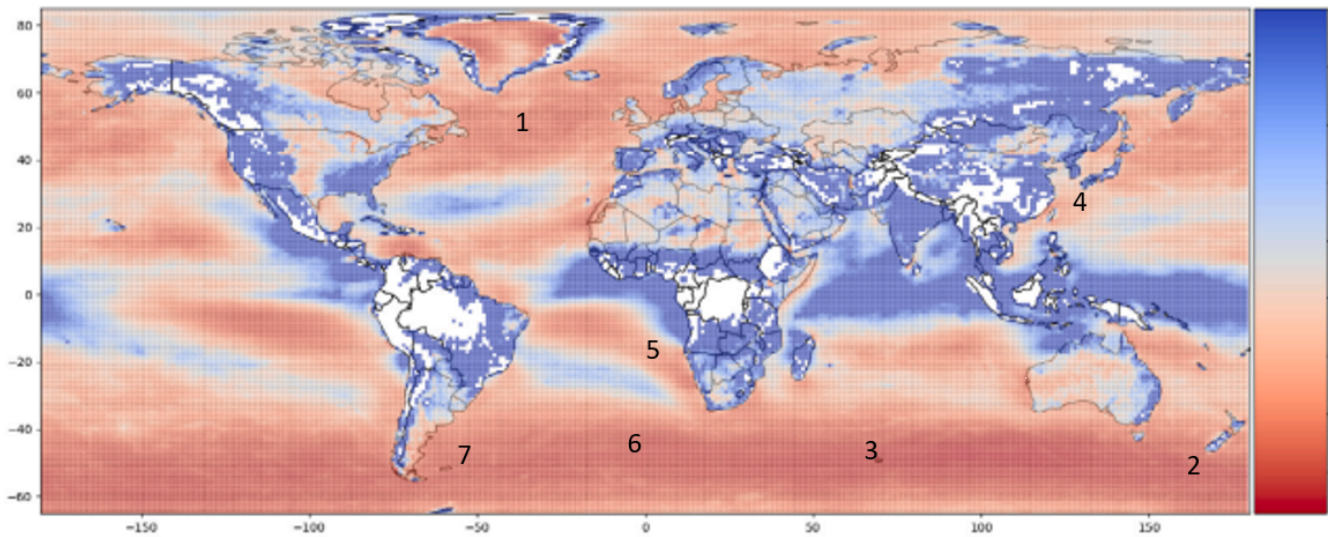

In this section, the central cost calculation for the objective function as done by the developed model was shown. However, many related calculations and constraints are included in the model as well. As mentioned before, those are discussed in more detail in the report this paper was based on.

### Scenario Definition

As explained before, the global potential of far offshore green hydrogen was assessed through the analysis of a representative set of high potential scenarios. To find these scenarios, usage locations were identified with high local production costs, as shown in Figure 4. In addition production locations were selected with strong wind resources and limited water depths, as shown in Figure 5.

**Figure 4:** High potential far offshore green hydrogen usage locations A to E (modified from (De Vries et al., 2021))

**Figure 5:** High potential far offshore production locations 1 to 7 (modified from (Salmon & Bañares-Alcántara, 2022))

The potential usage locations were combined with the closest production location to create the scenarios to be analyzed. For usage location D (Singapore), this could have been production location 2 (in the Southern Pacific Ocean), 3 (in the Indian Ocean) or 4 (in the East Chinese Sea). In this case, location 2 was chosen due to the strong renewable resource potential and relatively large area with limited water depth. The selection as described here lead to the selected scenarios shown in Table 3.

**Table 3:** High potential far offshore green hydrogen scenarios to be analyzed further in this research

	Production location	Usage location
Scenario 1	East Chinese Sea (4)	Tokyo, Japan (C)
Scenario 2	East Chinese Sea (4)	Seoul, South Korea (C)
Scenario 3	Northern Atlantic Ocean (1)	Cologne, Germany (B)
Scenario 4	Northern Atlantic Ocean (1)	New York, USA (A)
Scenario 5	Southern Pacific Ocean (2)	Singapore (D)
Scenario 6	Southern Pacific Ocean (2)	Christchurch, New Zealand (E)

## RESULTS

After having formulated the model and defined a representative set of scenarios, the chosen scenarios could now be analyzed. The far offshore green hydrogen supply chain was optimized for all scenarios using the developed model and the accompanying costs per kilogram of hydrogen produced far offshore were compared to the costs of local green hydrogen production and green hydrogen import. The latter were determined primarily with the model made publicly available by Brändle et al. (2021). In the report this paper was based on, the general input data for the model (which stays the same across scenarios) and the scenario-specific input data can be found. In Figures 6 to 11, the results of the scenarios are presented, where the orange lines represent the far offshore green hydrogen costs.

**Figure 6:** Results scenario 1

**Figure 7:** Results scenario 2

**Figure 8:** Results scenario 3

**Figure 9:** Results scenario 4

**Figure 10:** Results scenario 5

**Figure 11:** Results scenario 6

The results differ greatly between scenarios. In scenarios 1 and 2 (Figures 6 and 7), the far offshore green hydrogen costs are similar to the highest local production costs between 2035 and 2050. Green hydrogen import costs are clearly lower, which means far offshore green hydrogen does not have the preference from a purely techno-economic standpoint in these scenarios. However, since the cheap green hydrogen import options for Japan are mostly represented by China, Russia, Iran, Saudi Arabia and Oman, geopolitical factors may play in favour of far offshore green hydrogen. Based on the local production capacity of Japan (Brändle et al., 2021) and the expected demand in 2050 (The Hydrogen Council & McKinsey & Company, 2021), Japan is not expected to be able to be self-sufficient with onshore production, which means far offshore production will be necessary if Japan aims to be self-sufficient. The situation for South Korea is similar, although the on-shore production capacity is higher there (Brändle et al., 2021).

When looking at scenario 3 (Figure 8), it can be seen that far offshore green hydrogen is less economic than its alternatives over the entire period, but especially before 2035. The import options for Germany in this scenario include Spain, Italy, France, Norway and Morocco. It is therefore expected that the influence of geopolitical factors will be limited here. For scenario 4 (Figure 9), the far offshore green hydrogen costs are lower than the highest local production costs and similar to the import costs. However, the onshore green hydrogen production capacity in the USA is very large (Brändle et al., 2021), which means the local demand can be filled without any import. In scenarios 3 and 4, far offshore green hydrogen is not expected to be feasible from a purely techno-economic perspective based on these results. Societal factors such as the willingness to install renewable energy production onshore may however have an influence.

Finally, scenarios 5 and 6 (Figures 10 and 11) show relatively low far offshore green hydrogen costs, which can be attributed to the production location in the Southern Pacific Ocean, where very strong and steady winds can be found. From 2032 to

2050, the far offshore green hydrogen costs are similar to the import costs and also before 2032, the difference is relatively small. In Singapore (scenario 5), the local production costs are very high and the capacity is very small, so import is expected to be essential, either from a different country (in this case China) or from far offshore. Both options could share the market or the Singaporean government could choose between the two. In New Zealand, local onshore production is also relatively economic. It may depend on the capacity of this onshore production whether import from China or far offshore production is necessary. If one of these is necessary, again no strong preference can be given based on the costs.

Next to the scenario analysis based on the final costs, some additional analysis was done. It was found that combining wind turbines and solar platforms to create a more steady energy production is beneficial in most scenarios and that in every scenario, a different combination of wind turbines, solar platforms and electrolyzers is optimal. Figure 12 shows the installed wind and solar power generation capacity over the years for scenario 1 to illustrate this. In scenarios 1 and 2, a relatively large amount of solar power is used in the beginning, but this decreases over the years since the floating wind costs develop faster than the floating solar costs under the assumptions taken. After 2035, the model still uses some solar power in most years, but the capacity is small compared to the installed wind power capacity. The latter is the case for the entire period between 2020 and 2050 in scenarios 3 and 4. In scenarios 5 and 6, no solar power is used, indicating a relatively strong wind resource in the production location used in those scenarios.

Next, it was found that energy generation represents the biggest share of the total far offshore green hydrogen costs in 2020, but this decreases over the years. The percentage taken up by ammonia conversion, ammonia transport and the FPSO on the other hand grow because their costs stay constant while all other costs are decreasing over the years. This can be seen in Figure 13, which shows the development over the years of the far offshore green hydrogen costs and its distribution for scenario 1 as an example. In 2050, the ammonia (re)conversion costs are expected to be the biggest cost contributor, closely followed by the energy generation

Furthermore, ammonia is found to be the preferred transport medium for far offshore green hydrogen until at least 2050 in the analyzed scenarios. The choice between ammonia and liquid hydrogen based on the distance to be traveled over sea and the storage volume on the FPSO is illustrated in Figure 14 for scenario 1 in 2050. In this figure, it can be seen clearly that lower transport distances and lower storage volumes favor liquid hydrogen. The effect of reducing the liquid hydrogen transport, storage and (re)conversion costs by 10% is also shown.

Finally, in order to gain further insight in the influence of different input parameters on the costs per kilogram of far offshore green hydrogen, a sensitivity analysis was performed. In this analysis, it was found that the interest rate, floating wind costs, floating solar costs, ammonia (re)conversion costs, FPSO costs and large changes in water depth can have significant influence on the costs per kilogram of hydrogen. In addition, it was found that dampening and enhancing effects can be seen when changing the costs of floating wind, floating solar and the electrolyzers. Furthermore, it was found that the desalination costs, liquid hydrogen and ammonia transport costs, electrolyzer costs, distance to shore and size of the hydrogen demand have a relatively small influence within the variations performed. The small influence of the last one was however attributed to model simplifications.

**Figure 12:** Total installed wind and solar power generation capacity from 2020 to 2050 in supply chains as optimized by the model for scenario 1

**Figure 13:** Cost distributions scenario 1 in 2020, 2035 and 2050

**Figure 14:** Visualization of preference for liquid hydrogen or ammonia based on distance to be traveled over sea and storage volume on the FPSO for scenario 1 in 2050

## DISCUSSION

In the previous section, the results have been presented. Some side notes should however be placed with these results. First of all, as the field of far offshore green hydrogen is relatively new, data availability is limited. Therefore, the input data as used in this research should continuously be developed in follow-up research once more data becomes available.

Furthermore, follow-up research could look into further extending the model to make sure it becomes even more complete and accurate. The model could be extended by including size limitations of offshore locations, the effects of economy of scale, the costs of longer electricity cables for bigger wind parks (increasing the attractiveness of adding solar platforms),

differences in OPEX worldwide, and a more accurate estimation of the distance to be traveled over sea. These points are discussed in more detail in the report this paper was based on. Next to the model developed in this research, the model used to determine the green hydrogen local production and import costs also has several limitations, as discussed by Brändle et al. (2021).

Lastly, it should be mentioned that this research mostly looks at the techno-economic potential of far offshore green hydrogen, while geopolitical and social factors may also greatly influence its feasibility. Despite the comments mentioned in this section, valuable insights were created into what the global potential is of far offshore green hydrogen towards 2050 and what influences this potential. The conclusions drawn will be discussed further in the next section.

## CONCLUSION

The techno-economic analysis of the selected scenarios in the present study shows a levelized cost of delivered green hydrogen from far offshore production locations of 3.5 to 5 euro/kg in 2050, coming from a cost of 7.5 to 12 euro/kg in 2020. A clear decreasing trend of the levelized cost of hydrogen (LCoH) can be observed for the coming decades up to 2050 across all scenarios. For two out of the six scenarios analyzed in our study (combination of far offshore production location and final delivery destination onshore), an LCoH below 5 euro/kg seems feasible from 2030 onwards, and from 2035 this is expected to be the case for another two scenarios. This cost may be considered as marginally competitive with alternatives such as local production of green hydrogen onshore or import of green hydrogen from other places in the world. Although the far offshore production costs are (slightly) higher in most scenarios, the considerable advantages of far offshore production, such as avoidance of scarce land usage in crowded areas and certain geopolitical considerations, should be taken into account when considering the competitiveness of the far offshore green hydrogen option and increase its feasibility. It should also be noted that techno-economic analysis of far offshore green hydrogen is still a relatively new research topic and that many aspects have not yet been thoroughly explored. Estimated cost may therefore still be lower or higher in certain specific scenarios, making or breaking the far offshore green hydrogen option. The most important uncertainty seems to be the development of the cost (CAPEX and OPEX) of critical components such as floating offshore wind, floating offshore solar and large size electrolyzers for installation on a central floating production unit.

When going into a bit more detail, it was concluded that PEM electrolyzers would be most suitable for far offshore green hydrogen production. Furthermore, it was confirmed that combining wind and solar energy generation in far offshore hydrogen production can be beneficial, but it was also found that this not the case in every scenario. In addition, it was concluded that the optimal combination of wind turbines, solar platforms and electrolyzers strongly depends on the production location and the year considered. Furthermore, it was found that until at least 2050, ammonia appears to be the most suitable transport medium for green hydrogen produced far offshore under the current assumptions. In addition, it was found that the cost distribution of far offshore green hydrogen will develop strongly over the years. In 2050, the simulations predict the ammonia (re)conversion costs to account for the biggest part of the total costs, closely followed by the energy generation. Finally, it was found that the interest rate, floating wind costs, floating solar costs, ammonia (re)conversion costs, FPSO costs and large changes in water depth can have significant influence on the costs per kilogram of hydrogen.

Having come to these conclusions, a tangible outlook on the worldwide potential of far offshore green hydrogen towards 2050 has been created. This outlook, together with the developed model and gathered input data, will form a base from which future research will be able to explore this new and exciting research field in various directions. This research may be one of the first bricks in the wall for the development of a future where far offshore green hydrogen is a part of our energy mix. However, much research is still to be done, including further analysis with the existing model, expanding the model in different directions, and related research such as in depth technical studies of floating wind turbines and social studies to create insight into less tangible factors influencing the potential of far offshore green hydrogen production.

# **ENERGY TRANSITION**

# A review of the state-of-the-art Sustainable and Climate-resilient inland waterway vessels

Richmond Anku<sup>1,\*</sup>, Jeroen Pruyn<sup>1,2</sup> and Cornel Thill<sup>1</sup>

## ABSTRACT

*Inland water vessels are impacted by climate change in two respects. First of all, they will need to convert to low-impact power propulsion and energy (PPE) systems. Secondly, they will need to deal with the impact of climate change, especially longer periods of very low and high water. This paper reviews the multi facet impacts of climate change on inland waterway vessel performance and problems associated with the choice of alternative power energy and propulsion (PPE) system on the vessel's performance*

## KEY WORDS

climate-change, decarbonisation, inland waterway vessels, shallow-water

## INTRODUCTION

Inland waterways play an important role in transportation, presenting a sustainable and energy-efficient means with better environmental performance than other transport modes in terms of CO<sub>2</sub> emissions by transport work (gCO<sub>2</sub>e/tkm) (Doll et al., 2020). In the Netherlands, inland waterway transport accounts for approximately 41 % of the total freight transport among the main hinterland transport modalities according to ("Eurostat", 2023), contributing to the decongestion of road and rail networks (Vinke et al., 2022), and presents an economically competitive alternative in terms of cost and tonnage. Inland waterway vessels are affected by climate change in dual dimensions. First, there is an ambition to mitigate climate change by abating greenhouse gas (GHG) emissions, which, according to the European Environmental Agency (Doll et al., 2020), as of 2018, inland water transport emits 33 gCO<sub>2</sub>/tkm, making up a share of about 17 % of CO<sub>2</sub> emissions from the transport sector. However, these vessels need to adapt to the predominant effects of climate change on waterways, ensuring sufficient cargo transport and navigation during prolonged periods of severe drought and flood, resulting in high and low water levels. To achieve a significant emission reduction, the use of low-impact energy carriers complemented by suitable energy converters is required (Zwaginga & Pruyn, 2022), and the adoption of alternative energy carriers poses inherent challenges owing to their lower energy densities. Meeting propulsion and power energy demands necessitate additional space and weight for storage, directly affecting vessel performance (Wang & Wright, 2021). In addition, the adverse effects of climate change influence vessel performance (Jonkeren et al., 2013).

Inland waterway vessels differ significantly from ocean-going vessels; given that they are much smaller in size and the environment in which they operate. Inland waterway vessels are designed to navigate and manoeuvre through confined and restricted waterways such as rivers with bridges and locks (Radojčić et al., 2021). Although ocean-going vessels sail under adverse weather conditions, they do not have the limitations of inland water vessels. The physical interaction between the hull and waterway, and thus the flow around the hull, influences the hull form design and maximum dimensions of inland

water vessels to suit the respective waterway classifications in which they operate (Zeng, 2019). The length is restricted by the lock length, the breadth is restricted by the lock width, the air draught (vessel height above the water line) is limited by the bridge vertical clearance, and the vessel draught is limited by the water depth (Guesnet et al., 2014). These distinguish inland waterway vessels from ocean-going vessels, which underpins the fact that their efficient operations are affected more by the effects of climate change. When this is not addressed, inland water transport would become a less reliable transport mode and could lead to a modal shift that is undesirable because the other transport modes do not have the capacity to compensate for the loss of capacity by inland water transport (IWT) (Vinke et al., 2022), whereas IWT has underexploited reserves. This would lead to a disruption of the supply chain, as well as an increase in environmental pollution from road transport. A fundamental element for ensuring the effective and safe transport of cargo along these routes involves a comprehensive understanding of ship hydrodynamics (Gebraad et al., 2021), actions required to adapt fleets, ensuring transportation reliability (Kempmann et al., 2023), and reducing the environmental footprint. The challenge however faced by ship designers and naval architects is finding the "sweet spot", an ideal balance between achieving zero-emission, adapting to climate change and vessel performance; thus, the trade-offs between adapting short-term measures and flexibility to meet uncertain future requirements are imperative, and hence careful consideration from the design point of view (Andrews & Erikstad, 2015).

This literature review focuses on current state-of-the-art research on the decarbonisation of inland water transportation and adaptation of inland water transport to climate change. The main research question for this literature review is:

*“What is the current state of climate-resilient and sustainable inland water vessel design?”*

The rest of this paper is structured as follows. In the next section, the [Methodology](#) is outlined, providing insight into the literature exploration approach. Following this, [Results and Discussions](#) presents and discusses the outcomes derived from the reviewed literature. Finally, in [Conclusion and Future Study](#), a concise summary of the entire paper is provided, encapsulating the essential findings from the literature outcomes and the author’s reflection on future research directions from identified gaps.

## METHODOLOGY

To comprehensively organise and evaluate findings from past research, we conducted a methodological exploration of the literature utilising specific search terms to answer the main research question highlighted in the previous section. The search strategy for this study stems from two concepts derived from the main research question: one concerns the climate change adaptation of inland waterway vessels and the decarbonisation of inland waterway vessels. For the first concept, the search terms included “climate change” OR “low water” OR “shallow water” AND “inland navigation” OR “IWT” OR “inland water\*”. Whereas for the second concept, the search terms included “sustainability” OR “decarbonisation” OR “emission reduction” OR “GHG emissions” AND “inland navigation” OR “IWT” OR “inland water\*”. The snowball technique was also used in the literature search, involving the examination and assessment of references cited in the selected primary literature for relevance and potential inclusion in this study. The initial search for resources was conducted using databases connected to the TU Delft library, as summarised in Table 1. The articles selected for this literature review provide a back-

**Table 1: Search resources and types of documents**

Information resources or database for preliminary search	Types of documents
Web of Science, Google Scholar, and TU Delft repository	Journal articles, conference papers, books
Secondary resources	Types of documents
Cited references of primary resources	Journal articles, conference papers

ground to answer the research questions. Selection and exclusion were performed first by scanning the titles and keywords, after which a detailed perusal of the abstracts, introductions, and conclusions of articles was performed to assess their relevance for this work.

## RESULTS AND DISCUSSIONS

The search terms led to a selection of 392 papers, and after reviewing the titles, approximately 150 remained. Based on their abstracts, a further 65 were dismissed, as these primarily addressed logistics, policy management, or hydrology. The state-of-the-art review began by exploring the remaining 51 papers.

Figure 1: Literature clustering from database

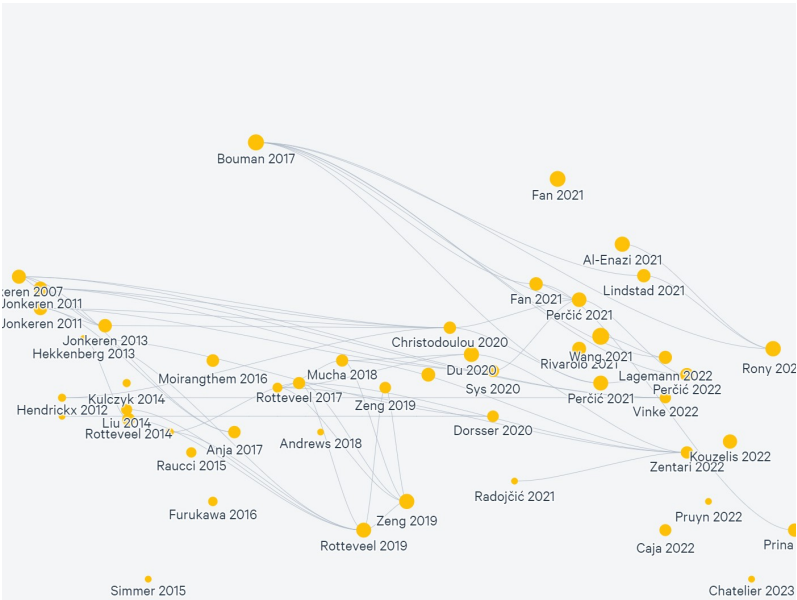

Figure 2: Map of reviewed literature

For the final review, 63 papers were studied in depth to arrive at the current state of the art, which will be presented next. The review is divided into two sections: the first section, which is covered in [Climate Change and Inland Waterway Vessels](#), presents the impact of climate change on inland waterway vessels and the state-of-the-art options for adaptation, whereas [Decarbonising Inland Waterway Vessels](#) discusses the state-of-the-art decarbonisation of inland waterway vessels.

## Climate Change and Inland Waterway Vessels

Climate change threatens the competitiveness and reliability of inland navigation, which also challenges the realisation of one of the objectives of the EU project NAIADES III action plan (Sys et al., 2020), which is to shift the significant share of freight transport from roads to more sustainable modes, such as inland waterways and rail transport. Several investigations have been conducted on the impact of climate change on inland water transport, and it is also interesting to note that many of these studies focused on the impact of low water depth on navigable fairways, because prolonged periods of droughts are expected to occur more often in the future and have even more severe consequences on efficiency, safety, and reliability than problems associated with high water levels or discharge on the fairways (Jonkeren, 2009). In many of these studies, various models were developed to predict the fairway conditions, estimate the hydrodynamic performance in shallow water, economic models to estimate revenue loss due to loss of payload capacity, and estimate the potential of modal shift from inland water transport to roads. In this section, we discuss the most prevailing impact of climate change on inland waterway vessels covered by current and past literature.

### Resistance and Power Demand

Water depth severely impacts the resistance and power demands as this increases with decreasing water depth according to (Radojčić et al., 2021). ITTC, 2017 outlined that the shallow water effect on ship resistance must be taken into account when one or the combination of the following thresholds are met;

- Finite water depth to vessel draught ratio  $h/T < 4$ .
- Froude number of water depth  $F_{nh} > 0.5$ .

According to (Radojčić et al., 2021), total ship resistance of inland waterway vessels can be decomposed into two categories; the viscous resistance and the wave-making resistance (see equation 1). Zentari et al., 2022 did highlight that, when  $F_{nh} < 0.6$ , which characterises a subcritical flow regime, the wave-making resistance of a vessel in shallow water is comparable to deep water conditions. However, shallow water effect on wave-making resistance becomes more pronounced when the vessel approaches a critical flow regime of  $F_{nh} = 1$ . Nevertheless, this is not the case for inland waterway vessels given that most of these vessels operate within a speed range below the critical regime (Zentari et al., 2022). As such, viscous resistance emerges as the most dominant resistance component of inland waterway vessels, where the influencing factors are the friction coefficient and hull form factor.

In shallow water navigation, the keel clearance, which is the safety distance between the hull bottom and waterway bed is considerably reduced. This consequently causes ship squat, also known as dynamic sinkage, which as a result of increased water flow around the hull, leads to reduced pressure below the hull, a phenomenon based on Bernoulli principle (Radojčić et al., 2021; Zeng, 2019). The squat further amplifies the frictional resistance (Zeng et al., 2017), due to thinner boundary layer resulting from accelerated under-keel flow. The power required to propel the vessel depends on the total resistance and the ship's speed (see equation 2). As such given an increase in ship resistance as a result of shallow water, for the same sailing speed, the ship would require more propulsion power to perform its functions, and this translates into more energy consumption. Alternatively, for a given installed power, the speed may have to be reduced, and as a result, more time may be required to transport cargo over a distance (Schweighofer et al., 2022), which also translates into more energy consumption.

$$R_T = R_V + R_W \quad (1)$$

$$P_E = R_T \cdot V_s \quad (2)$$

In recent years, numerical methods using computational fluid dynamics (CFD) simulation tools have been used for both predictions and optimisation of ship resistance [9]. The traditional, model scale tests and use of empirical models such as the Holtrop & Mennen have been used for resistance estimations with some correction factors, applied to ship speed and form factor (Pompée, 2015), to account for shallow water effects. However, the Holtrop & Mennen empirical model was fundamentally obtained from datasets of ocean-going ships and hence applying this to inland water vessels may lead to inaccurate predictions. Moreover, the Schlichting (1934) empirical method was based on speed correction to account for the deviation of residual resistance in shallow water compared to the deep-water case (Pompée, 2015; Raven, 2012). The Schlichting speed correction method was further improved by Lackenby (1963) by extending its application to extreme shallow water conditions (Raven, 2012; Zeng et al., 2017). Jiang (2001) proposed another approach to estimate the shallow-water effect, based on effective Froude number influenced by dynamic sinkage (ship squat) to predict a new effective speed of the vessel. The weakness of these empirical methods is that they rely on correcting the resistance curve in deep water for shallow-water scenarios of ocean-going vessels.

Given that the presence of channel walls and the shallow nature of inland waterways significantly impact the hydrodynamic resistance of inland water vessels at a given speed. Rotteveel (Rotteveel & Hekkenberg, 2015) stated that the limited breadth of the waterway leads to backflow around the vessel, increasing the water speed around the hull and thereby amplifying frictional resistance, which is termed as the hydraulic effect. Additionally, the restricted water depth limits the wave speed, causing increased resistance from wave formation at the ship's specified speed, which is termed the undulatory effect (Pompée, 2015). For the reasons identified above, the empirical methods with shallow water corrections derived from seagoing vessels are characterised by higher speed and lower block coefficients, adding to the fact that the environment in which they operate differ considerably not only in terms of depth but also breadth and the presence of canals and locks. These methods may not be sufficient for application in inland waterway vessels. Hence, using CFD methods, recent studies (Zeng et al., 2019) and (Raven, 2012) focused on predicting the shallow-water effect on the frictional coefficient. While Furukawa et al., 2016 focused on predicting the hull form variation and shallow water on the viscous component of the total resistance of inland waterway vessels. Table 2 summarises recent studies performed to accurately estimate the resistance components of inland waterway vessels, accounting for shallow water effects.

**Table 2: Summary of recent literature on shallow water effects on resistance of inland vessels**

Reference	Method	Key findings
Zeng et al., 2019	Regression numerical friction line for shallow water correction obtained from CFD simulations.	Authors find that this method can be used to better estimate the frictional resistance of the ship's flat bottom (parallel middle body), however, should be combined with the ITTC57 correlation line for other wetted surfaces for accurate estimation of overall frictional resistance in shallow water conditions
Rotteveel and Hekkenberg (2015)	CFD approach to investigate the effect of hull form variation (block coefficient) and shallow water on resistance.	The authors' viscous pressure resistance component increases faster in shallow water than frictional resistance. Also, the water depth effect is larger than the hull form variation on the total ship's resistance as an effect of the hull for variation rather becomes smaller in shallow water.
Zeng et al., 2017	Numerical and experimental methods to investigate dynamic sinkage and ship resistance in extreme shallow water.	The authors found that flow under the keel accelerated as keel clearance reduced leading to a thinner boundary layer which increased the frictional resistance component. And this is further amplified by trim and squat effects. The trim correlation line was not linear or monotonic, and a piecewise function might best be used to represent the relation between trim and ship speed.

**Table 2** continued

Furukawa et al., 2016	Captive model test to estimate the longitudinal hydrodynamic forces acting on bare hull in sufficient and shallow water conditions, to measure the shallow water effects on the longitudinal components of hydrodynamic derivatives.	Based on the results from the database of test cases performed on multiple types of vessels. The authors derived an empirical formula for estimating longitudinal hydrodynamic forces acting on a vessel.
Raven, 2012	CFD approach Using PARNAS-SOS, a RANS solver developed by MARIN to estimate the viscous resistance of 4 different ships accounting for shallow water effects.	The variations of viscous resistance against water depth were determined by the computational model. The authors also found a correction for model-to-full ship extrapolation of the viscous resistance in shallow water. It was mentioned the Froude extrapolation and form factor extrapolation can be applied for full-scale frictional resistance prediction, however, may lead to overestimation of residual resistance at full scale.
Raven, 2022	Numerical computation approach by MARIN to establish correction factors independently for viscous resistance, a wave-making resistance and an overall added resistance due to squat effect for extremely shallow water conditions. The results were then validated with full-scale ship trials and empirical estimates.	The author found a limiting Froude number $Fr_h < 0.65$ for which there is no influence of water depth on wave-making resistance. It was also observed that overall resistance increased as a result of sinkage, which is present due to low pressure underneath the hull in shallow water. Although this sinkage effect was somewhat uncertainty, stating that the estimated increase in sinkage was too large, and therefore may lead to inaccurate prediction of the overall resistance.
Mucha et al., 2018	An experimental study of the effects of water depth, separation distance and bank effects on resistance of inland waterway vessels.	Result of this study revealed that sinkage was more pronounced with increasing ship speed and decreasing water depth. Also, lateral restrictions (proximity of vessel to the sides of the fairway) further lead to increase in lateral forces and moment (hydrodynamic sway and yaw motions). The magnitude of these lateral force and moment as noted by the authors can even exceed that of the longitudinal force required to move the vessel forward.
Zentari et al., 2022	An experimental and numerical investigation of shallow water effects on resistance and propulsion of coupled convoys.	Although authors recorded some deviation 15 % when comparing the numerical results of resistance to the experimental result in shallow water. It was found that in deep water, the boundary layer is fully developed, and flow separation zones are smaller, and less vortex shedding occurs, however, that is not the case in shallow water. In shallow water it was observed that the under-keel clearance influenced the boundary layer, thereby altering the velocity pressure field, causing flow separation.

Table 2 continued

Du et al., 2020	Numerical simulation of confined waterway effect on resistance and ship-generated waves of two inland waterway vessels.	It was observed from the simulations results that stronger confinements characterised by smaller cross-section area ratio between channel and ship, increase the ship resistance. This effect becomes even more evident with higher values of ship speed and higher loaded draft. Also investigating the wave pattern, it was noted that the wave propagation is limited by the channel banks and bottom, causing reflection and refraction. This effect was also seen to amplify with larger loaded draught.
--------------------	---	---

### Propulsive Efficiency and Manoeuvring Capability

The heightened power demand is further exacerbated by the reduced propulsive efficiency, which is a result of increased thrust loading on the propellers when operating in extremely shallow water (Radojčić et al., 2021). With reduced keel clearance, the inflow to propellers considerably differs from deep-water conditions, and as a result, affects the open-water efficiency coefficients (Radojčić et al., 2021). In addition to the reduced propulsive efficiency caused by high thrust loading owing to increased resistance when operating under low water conditions, the risk of propeller emergence or ventilation is also higher when sailing on reduced draught owing to the limited water depth, resulting in the loss of thrust and low propulsive efficiency (Hagesteijn et al., 2015). The hydrodynamic propulsive efficiency applied to ocean-going ships is fundamentally the ratio of effective power ( $P_E$ ) and the power delivered to the propeller through the shaft ( $P_D$ ), as defined by (Radojčić et al., 2021) in equation 3:

$$\eta_d = \frac{P_E}{P_D} = \eta_H \cdot \eta_o \cdot \eta_R \quad (3)$$

$$\eta_H = \frac{1 - t}{1 - w} \quad (4)$$

$$\eta_o = \frac{J}{2\pi} \cdot \frac{K_T}{K_Q} \quad (5)$$

The hull efficiency  $\eta_H$  and the relative rotative efficiency  $\eta_R$ , both describe the overall hull and propeller interactions. The action of the propellers behind the hull induces additional resistance to the entire ship resistance. Consequently, an additional thrust force is required to overcome the ship towing resistance, and the added resistance is measured by the thrust deduction factor  $t$ . Also, for IW vessels navigating in restricted water, the changes in the inflow to the propeller tend to increase the wake fraction  $w$ . And if the wake fraction  $w$  becomes larger than the thrust deduction coefficient  $t$ , the hull efficiency increases according to (Rotteveel et al., 2017) and confirmed by research results of MARIN in (Mucha et al., 2018). However, this phenomenon is a complex one, given that, an increase in wake fraction means a reduction in advanced speed ( $V_A$ ), translating into a reduction in open water efficiency  $\eta_o$  and relative rotative efficiency  $\eta_R$ , which could ultimately even lead to an overall reduction in propulsive efficiency  $\eta_d$  (Radojčić et al., 2021). An interesting observation by (Rotteveel et al., 2017) of the wakefield, is that the nominal wake fraction  $w$  which is usually estimated without the presence of propeller may lead to low power estimation, given that the presence of propeller suppresses the growth of wake and flow separation. Therefore, an effective wake fraction  $w_e$ , accounting for propeller action is rather accurate for estimating power.

Pompée, 2015 highlighted that, given the high block coefficient of inland vessels around 0.85 and 0.95, the wake fraction could easily be twice as high as that of ocean-going vessels. The high wake fraction value which is characterised by low inflow speed to the propeller is very difficult to measure as noted by (Rotteveel et al., 2014), that simply approximating with empirical formulas may give misleading results. Howbeit, according to (Pompée, 2015; Rotteveel et al., 2014), methods like the Holtrop & Mennen and Pappel commonly utilised in naval architecture for predicting propulsion efficiencies through thrust and wake fractions, primarily cater to ocean-faring ships, overlooking considerations for IW vessels. The

extended version of the Papmel formula was modified by A.M.Basin & Miniovich for inland vessels and pushers to accommodate inland vessels and pushers has been observed by (Pompée, 2015) and (Raven, 2022) to lack the incorporation of water depth effects. Most recently Rotteveel in (Rotteveel, 2019) analysed the influence of stern shape under varying waterway conditions on the propulsion performance of inland waterway vessels, this and other recent research have been summarised in Table 3 below.

**Table 3: Summary of most recent literature on shallow water effect on inland waterway vessels propulsion**

Reference	Method	Key findings
Rotteveel, 2019	In his thesis, Rotteveel used the CFD computation approach to analyse, the influence of stern shape variation of IWV on propulsion performance under different operating conditions. Further surrogate models were used to find trends and patterns for optimal design from the CFD results.	The author introduced novel design guidelines aimed at achieving an optimal stern design for efficient propulsion in low water conditions. This optimization process entailed balancing trade-offs between the ship's displacement and its propulsive performance across varying water depths. Through iterative adjustments of variables to attain the optimal design, the study identified the pivotal significance of stern length and the athwartship propeller position in enhancing propulsion efficiency.
Rotteveel et al. (2017)	Inland ship stern optimisation in shallow water. Optimising propulsion power based on aft-ship hull parameters which include; the lateral position of the propeller, stern bottom shape (V-shape and S-shape), stern bilge radius, and tunnel curvature.	It was observed the lateral propellers' position closer to the centerline, moves the propellers in a stronger wake field yielding increased hull efficiency. The V bottom shape showed stronger effect (increase) in thrust deduction compared to the S bottom shape in shallow water. The effect of the tunnel curvature was observed to be small and negligible with changing water depth. Also, the influence of the bilge radius was observed to decrease in shallow water, owing to the fact that in shallow water, the flow comes from the sides instead of the bottom.
Kulczyk and Tabaczek, 2014	Analysis of results of model tests, and numerical computation of the influence of ship loading, water depth, ship speed and stern height on thrust and wake coefficient for inland waterway motor cargo vessels and pushboats with stern tunnel	The authors found that both increase in ship speed and reduced h/T leads to decrease in wake fraction and corresponding increase in thrust deduction, owing to the reduction in under-keel clearance.
Hagesteijn et al., 2015	Model scale test in a Depressurized Wave Basin, to assess the performance reduction due to propeller ventilation.	Authors found from the experiment, speed reduction of 0.5knot due to ventilation. It was observed that, when propellers suck in air, the achievable thrust and torque required drop for a given advance coefficient. The resulting reduced thrust is sufficient to propel the vessel such that speed loss is inevitable.

The ideal design of propellers for IW vessels, especially to adapt to low-water conditions, as emphasised by (Hekkenberg, 2013), should be determined on a case-by-case basis. This involves finding a “sweet spot” such that, the propeller is small enough to remain fully immersed in water on the ballast draft, and also large enough to deliver sufficient thrust at the laden draft. This could also mean adopting the tunnel aft-ship to mitigate ventilation in ballast conditions or reduced draught im-

posed by low water depths; this was investigated by in (Rotteveel et al., 2017). However, (Hagesteijn et al., 2015) found that tunnel aft-ship does have added adverse effect on the hull resistance.

The manoeuvring and stopping capabilities of inland water vessels are also negatively impacted by shallow water effects. The change in hydrodynamic forces and moments acting on the hull and lifting surfaces influences the turning, stopping, and course-keeping performance, thereby compromising the safe operation of the vessel (Liu et al., 2014).

### ***Cargo Capacity Utilisation***

The loading capacity of inland water vessels is constrained by the available water depth. For a given ship size and dimension, the only variable that determines how much tonnes of cargo can be transported at a given time is the loaded draft, as the displacement in such instances depends on the depth of the vessel immersed in water. Total ship displacement can be decomposed into lightweight and deadweight; the deadweight tonnage is the component that determines the carrying capacity of the ship correlating directly to the loaded draft as investigated by (Hekkenberg, 2013) in a parametric inland ship design model. Given the draught restrictions imposed on vessels when navigating shallow water, the corresponding volume of cargo that can be transported is limited. The consequence of low water levels on the load factor differs for each ship type and size, depends on the vessel's empty and loaded draft (van Dorsser et al., 2020). The research findings from the EU joint research centre (JRC) in (Rothstein & Scholten, 2016), where they estimate the bearing capacity for different ship sizes and types, suggests that ships characterised by greater empty drafts are more prone to experiencing a reduction in their loading capacity at low level of water on the Danube river. In this work, for the lowest recorded water level of 177cm, the load factor of smaller vessels was about 50 %, whereas that of larger vessels ranged between 20 % and 30 %. Although not same quantified values of load factors were found by (van Dorsser et al., 2020) on the Rhine river, he also came to a similar finding that larger vessels experienced higher reduction and deadweight and payload capacity at low water levels.

Furthermore, a sensitivity analysis was conducted by (Al-Enazi et al., 2021), to deepen the understanding of the impact of capacity utilisation on the quantity of emissions produced. The findings revealed that an increase in capacity utilisation leads to a consistent decrease in CO<sub>2</sub> emissions (Al-Enazi et al., 2021) per tonne-km. This is more related to the energy efficiency indices; an important operational performance metric, that quantifies carbon emission per transport work. Table 4 summarises recent literature on shallow water effects on cargo capacity utilisation

**Table 4: Summary of the most recent literature on the effects of shallow water on cargo capacity utilisation**

Reference	Method	Key findings
van Dorsser et al., 2020	Empirical model based on regression analysis of loading certificates of 157 ships, to analyse the relative effect of reduced or increased draft on loading capacity index	The model which was based on the operational loading of vessels during the extreme drought season of 2018, authors observed that vessels with higher empty draught are more vulnerable to low water conditions relative to vessels with low empty draft.
Rothstein and Scholten (2016)	Multi-regression analysis of the relation between water level and degree of capacity utilisation, transport volume per ship, total transport volumes and number of ships for transport on Danube river.	It was found from the analysis that, for every reduction in water depth by 10cm, the degree of capacity reduction was between (0.51 % and 0.66 %), for same water level reduction also, the transported cargo reduced by between (10t and 14t) for different ship types. Finally, also the total transported cargo on the corridor was observed to reduce in the range of (1188t and 3760t). For the lowest water condition recorded, they found from their model that smaller vessels could load about 50 % of their maximum capacity, whereas larger vessels only use up about 20 % to 30 %.

Vinke et al., <a href="#">2022</a>	Agent-Based and Discrete Event simulation using OpenCLSim; integrating hydrology data of corridor to estimate the cascading effects on navigation, transport performance, and economic impact	The authors observed a change in fleet composition with changing water levels, and also the number of trips required to make up for the volumes in normal conditions, although the simulation shows a loss of total transported volume
---------------------------------------	---	--

### ***Transport Cost***

The cost, among other factors, determines the competitiveness of inland water transportation. The restriction in the load factor, which results in reduced transport capacity caused by low water levels, leads to escalated transport expenses for the ship owner or operator. Moreover, (Jonkeren & Rietveld, [2007](#)) says under certain demands, some negative relation between prices and water level is expected. These additional costs stem from the amplified voyage frequency, heightened handling expenses, prolonged waiting periods, and increased energy consumption. Consequently, these factors collectively account for a significant portion of operational expenditures (Jonkeren et al., [2013](#)). Jonkeren, [2009](#) even found that the cost per ton could increase by as much as 75 % for vessels plying serious bottlenecks of the Rhine fairway at extreme water levels, noting that these additional costs are usually not borne by the operators or ship owners themselves, but the economic burden of low water periods is shifted to shippers and finally the consumers. As such shippers may consider alternative modes of transportation, potentially resulting in a decline in demand for inland water transport, and further worsening its competitive position (Krekt & van der Laan, [2011](#)).

In a study conducted by (Jonkeren et al., [2011](#)), the impact of prolonged drought on the cost of inland transport operations in Northwest Europe was evaluated. Their findings indicated that, in an extreme climate scenario, inland water transport could potentially experience a reduction in capacity of approximately 5.4 %. Furthermore, it was highlighted that road transport is likely to absorb a significant portion of this reduced capacity. Although (Krekt & van der Laan, [2011](#)) also highlighted the potential loss of capacity to other transport modes due to climate change, they asserted that the majority of the shift would be towards rail transport, which contrasts the findings of (Jonkeren et al., [2011](#)). Table 5 summarises recent literature on shallow water effect on the cost of cargo transport.

**Table 5: Summary of most recent literature on shallow water effects on transport cost**

Reference	Method	Key findings
Jonkeren and Rietveld, <a href="#">2007</a>	Multi-regression analysis to assess the impact of water level on the logarithms of load factor, freight rate per ton and freight rate per trip.	From the analysis of data on inland water transport activities on the Rhine River, authors found an empirical formula to estimate the welfare loss (economic implications) due to low water conditions between 2003 and 2005.
Jonkeren et al., <a href="#">2011</a>	Multimodal freight transport modelling with NODUS, a GIS-based software to assess the cost of transport operations for IWT over the Rhine River under varying climate scenarios	Authors discovered that the impact of extremely low water conditions extends beyond influencing the transportation prices of Inland Waterway Transport (IWT). These conditions may induce modal shifts, thereby compromising the competitive position of IWT in comparison to other modes of transportation.

## Options for Technical Adaptation

To sustain competitiveness, cost-effectiveness, and reliability, it is imperative for inland water transport (IWT) to become less susceptible or more resilient to low-water periods, which are expected to become more frequent owing to climate change according to (Jonkeren, 2009). This necessitates a re-evaluation of vessel design trends, particularly for larger vessels that are inherently more vulnerable to low-water conditions (Radojčić et al., 2021; Rothstein & Scholten, 2016). From a design perspective, several research and development projects have been conducted to address the resilience of inland navigation to climate change. These projects consider technical adaptation measures aimed at efficient operation at a reduced draught, enabling flexible year-round navigation in both sufficient and shallow waters. Notable among them are concepts to achieve increased cargo capacity utilisation at reduced draught, by means of added buoyancy without altering the principal dimensions of the vessels. One of these concepts is the floatable side blisters investigated in the ECCONET project as referenced in (Zigic et al., 2012). The investigation of the concept of added buoyancy was further expounded and validated in the NOVIMOVE project (B. Ramne, 2021). In addition, measures to increase cargo transport on low draught by means of weight reduction, making use of lightweight materials for hull construction, were investigated in the INBAT project referenced by (Radojčić et al., 2021). Other options for maximising the capacity of a vessel by altering the principal dimensions of the ship have been investigated by (Bačkalov et al., 2016) and (Guesnet et al., 2014). To compensate for the loss of dead-weight owing to shallow draught, it is possible to increase either the length or breadth of the ship. Bačkalov et al., 2016 noted that ‘beamy’ container vessels are more favourable than “lengthy” ones on restricted waterways, although the extent of beam increase is limited by canal and locks spaces on the fairway.

In a general context, it can be inferred from the previous subsection that operating under conditions of low water levels results in an increase in the thrust loading coefficient. Consequently, the open water efficiency is reduced, and when the draught is extremely low, the risk of propeller ventilation is high, impeding the generation of the thrust necessary to propel the vessel in water. The reduction in propulsive efficiency can be addressed by the concept of distributed thrust which was investigated by the notable STREAMLINE research project (Hagesteijn et al., 2015). Within this project, a novel design with six (6) thrusters was developed to attain higher efficiency at low propeller loading. The configuration of these propellers is such that forward propellers accelerate the flow to the trailing ones; at the same time, these propellers generate thrust instead of adding to the total ship resistance, as is the case with tunnels. The stern design is also such that the forward propellers again avoid flow separation and hence reduce the risk of propeller ventilation. In this research, for lower draughts, a new concept is proposed for streamlined cover plates to be fitted to prevent propeller ventilation which was originally investigated by DST. Given the relatively long lifespans of inland water vessels, climate change predictions must be factored into their design and planning. The careful design of the hull and propulsion, power, and energy (PPE) system configuration is imperative when accounting for low-water conditions in the early design phase (Kempmann et al., 2023). Table 6 summarises some notable adaptation measures and their application scenarios, as found in the state-of-the-art research projects and literature.

**Table 6: Summary of Notable EU projects on Inland Waterway Vessels shallow-water adaptation**

Reference	Adaptability Measures				Application Scenarios	Key findings
	Payload increase					
	<i>Suitable Propulsion</i>	<i>Additional buoyancy device</i>	<i>Lightweight construction</i>	<i>Beamy</i>		
ECCONET - Zigic et al., 2012	✓	✓	✓		Self-propelled cargo vessels	Retractable side blisters to increase buoyancy enabling improved cargo load factor at a reduced draught. Also, the use of high-tensile steel and aluminum was proposed to reduce the ship’s weight

Table 6 continued

NOVIMOVE - B. Ramne, <a href="#">2021</a>	✓		Self propelled dry cargo vessel	Innovative Vessel concept, with added buoyancy to transport more cargo in shallow water conditions. Modular inflatable airpads which can be couple to the vessel's sides when needed to provide additional buoyancy during periods of low water levels.
VERBIS - Radojčić et al., <a href="#">2021</a>	✓	✓	Self-propelled cargo vessel and pushboats	Optimal hull form design for maximum payload at draughts. Also, a pump-jet propulsion was developed for push boats with draught (0.8-1.7m) to allow for shallow water operations
INBAT - Radojčić et al., <a href="#">2021</a>	✓		Push boats and barge train	The application of lightweight construction materials and structural design was developed, realising weight saving of around 40 % if steel sandwich panels were used for small barge. Complimented with an innovative retractable middle propeller for additional thrust and manoeuvring during low draughts.
STREAMLINE - Hagesteijn et al., <a href="#">2015</a>	✓		Self-propelled Rhine class cargo vessel	A novel concept of distributed propulsion systems, offering efficient navigation advantage in extreme conditions. Although this comes with higher cost of investment, it offers the advantage of cheaper and smaller engines (usually road truck engines), which are also easier to maintain and replace. With the new stern design for 6 rudder propellers, it was also found that the cargo carrying capacity of the vessel could increase up to 3 %. In comparison with the reference vessel, an open water efficiency improvement of 21.5 % was recorded
IDV - Guesnet et al., <a href="#">2014</a>	✓	✓	Self-propelled container vessels for the Danube River	For the container vessel, the proposed concept is to increase the breadth of a standard 4-row container vessel from 11.4m to 11.65m to allow loading of 2.5 -2.55m wide domestic containers beside ISO containers, stowing up 2 tiers of container at 1.7 low draught. Also, for this concept, the author proposed an azimuth propeller for excellent manoeuvring optimised for low draught.
X-type - Bačkalov et al., <a href="#">2016</a>		✓	Self-propelled container vessels for the Danube River	The unconventional X-Type container vessel design. Increasing the breadth of a standard Class Va inland vessel carrying 4-row containers from 11.4 to 13.9 to stow an additional row. Increasing the beam was chosen over lengthening, for structural and cost considerations

### Summary of Climate-Change Impact on Inland Waterway Vessels

The subsections [Resistance and Power Demand](#) to [Transport Cost](#) discussed the thematic literature on the state-of-art impacts of low water levels due to climate change on inland waterway vessels. The cascading effects could lead to a delay in the supply of goods, increased sailing time owing to reduced speed, and high transport costs for the given voyage, This culminating in an overall loss in transport efficiency and compounded by the undesirable modal shift to other transport modes with implications on the competitiveness of IWT. Identifying the main challenges, [Options for Technical Adaptation](#), summarises some notable research projects and studies on adaptation measures to make inland waterway vessels more resilient to climate change. These projects primarily sought to address the issue of loss of cargo capacity utilisation with novel con-

cepts to transport sufficient cargo even at low draughts. Additionally, they explored the concepts of suitable propulsion systems to ensure navigation at both low draught and normal laden draught conditions. Moving on, the next section discusses the state-of-the-art decarbonisation of inland waterway transport and the current state-of-the-art report on greening pilot projects within the European region.

## Decarbonising Inland Waterway Vessels

The EU stage V emission limits, which are sets of regulatory requirements established by the European Union, are considered the world's strictest emission standards for non-road mobile machinery (NRMM). These standards, outlined in Regulation (EU) 2016/1628 (Shao et al., 2016), set specific limits for the levels of local pollutants, including particulate matter (PM), nitrogen oxides (NO<sub>x</sub>), hydrocarbons (HC), and carbon monoxide (CO), emitted by new IWV engines higher than 300 kW. The current approach to curb the environmental footprint of inland water fleets is achieved through internal combustion engines fitted with exhaust filtering systems. Nevertheless, the most challenging aspect is reducing GHG emissions, which have global warming potential (GWP) and ozone depletion potential, by way of absorbing infrared radiation. The main anthropogenic GHG gases, according to, are;

- Carbon dioxide (CO<sub>2</sub>) accounts for approximately 76 % of the total GHG emissions.
- Methane (CH<sub>4</sub>) accounts for approximately 16 % of all GHG.
- Nitrous oxide (N<sub>2</sub>O) accounts for approximately 6 % of all GHG.

Greenhouse gas (GHG) emissions emanating from ships primarily stem from conventional fossil-based fuels that are extensively employed as the primary energy source for ship propulsion, with carbon dioxide (CO<sub>2</sub>) being the predominant gas. Nevertheless, the use of liquefied natural gas (LNG) as a fuel introduces emissions of methane (CH<sub>4</sub>), whose environmental impact is significantly more potent than that of CO<sub>2</sub>. It has been observed that there is a wide range of technical and operational measures with significant emission abatement potentials. Independent options and combinations of options may provide enormous benefits. The feasibility of the options, as highlighted by (Finney et al., 2022), is dependent on the vessel types and their operations. A typical example is an optimal hull design combined with the use of hull air lubrication, primarily focusing on reducing ship resistance during operation, which in essence reduces power demands and, hence, energy consumption. This can contribute to improving energy efficiency and CO<sub>2</sub> emission reduction, but (Bouman et al., 2017)[48] illustrates that its potential as a single measure may be limited. Although many abatement options are mutually exclusive, such that they are not practically and economically feasible to be adopted in combination with other options, others may need to be combined with other options to significantly contribute to emission reduction (Bouman et al., 2017). According to life-cycle (LCA) studies, the primary source of adverse environmental outcomes throughout a ship's life cycle is identified as the operating phase (Al-Enazi et al., 2021), with energy consumption emerging as its largest contributor. Consequently, the transition to greener alternative energy sources is regarded as a viable approach to attain environmental sustainability objectives, offering up to 100 % emission reduction.

### *State-of-the-art of IWV Greening Projects*

The SYNERGETICS <sup>1</sup> project has been tracking and compiling a database of pilot projects and developments of inland water transport decarbonisation within Europe, and so far, a total of 115 diverse types and classes of inland waterway vessels are being retrofitted or newly built. Throughout these projects, the main sustainable alternatives considered of interest for the IWT are LNG, biofuels (FAME, HVO), methanol, hydrogen, and batteries (see Figures 3 and 4).

---

<sup>1</sup><https://www.synergetics-project.eu/downloads/>

**Figure 3: Shares Greening of IWV pilots in Europe**

**Figure 4: Classification of vessels and types of energy adopted for greening pilots.**

Evidently, there are no ammonia-related projects, fundamentally because of toxicity and associated risks for IWT. A larger share of these projects is electrification, as shown in Figure 4, and the types of vessels that adopt batteries are those for short trips, such as day trip vessels and ferry boats.

The power train of a vessel is a system carefully designed to propel the vessel in water, primarily consisting of fuels as an energy source, internal combustion engines as convertors, and propellers as the device that produces thrust. Recognising the importance of tailoring newbuilds and retrofit solutions to specific vessels based on their operational profiles and power demands, it is necessary to explore viable options for alternative energy and power systems. Several studies have compared alternative propulsion, power, and energy (PPE) options based on their, environmental performance and economic viability, as well as the technology maturity. Table 7 summarises key literature on alternative fuels for inland navigation.

**Table 7: Some key literature on Inland Water Vessels decarbonisation**

Reference	Study	Alternative energy carrier	Key findings
Perčić, Vladimir, and Koričan, 2021	Electrification of Inland Waterway Ships Considering Power System Lifetime Emissions and Costs	Batteries	From the LCCA study on a cargo vessel, although electrification offered low environmental impact, it was found by the authors that reducing battery capacity onboard due to limited available space required reduction of sailing distance consequently extending the voyage duration by about 6 times hence the life cycle cost does not favour electrification for a cargo vessel. On the other hand, due to the lower required endurance of passenger ships, PV battery was found as most economical for passenger vessel, suggesting that electrification was more feasible for sustainable transition of passenger fleets.
Simmer et al., 2015	Multi criteria assessment of LNG as fuel for Inland Navigation	LNG	In considering the technical, logistic, financial, and environmental influence of adopting LNG as alternative fuel for inland navigation. Authors suggested that, the main factors influencing the adoption of LNG is the cost of investment, and regulatory barriers, although it was pointed out that the environmental gain are minimal and that because of methane slip.
Perčić, Vladimir, and Fan, 2021	Techno-economic assessment of alternative marine fuels for inland shipping in Croatia	LNG / Methanol / B20/ Hydrogen / Ammonia	The LCA revealed that the most environmentally friendly option is an electric powered vessel, however from the LCCA resulted in methanol as the most cost-effective option. A sensitivity analysis also showed that the not only does speed reduction influences the environmental performance of the alternatives, but also it influences the total cost of ownership. Indicating that although battery is the most expensive solution, reducing the speed by 30 % would result in 51 % reduction in net present value (NPV).
Rivarolo et al., 2021	Multi-criteria comparison of power generation and fuel storage solutions for maritime application	Hydrogen / Ammonia / Methanol / LNG	Comparative analysis based on weight, volume, cost, and emissions revealed, that the weight and volume limitations are more pronounce in the choice of alternative power and energy system than the emission reductions, given that this significantly reduced cargo loading and hence the revenue stream of the vessel.
Taccani et al., 2020	High energy density storage of gaseous marine fuels	Hydrogen	Efficient onboard storage containment for hydrogen fuel. The newly design storage “GASVESSEL” cylinders, requires volume of about 15.2m3 and total weight of 2.5 ton to store 140kg of hydrogen, compared to the type 1 cylinder which would have require 28m3 and 12.3 tons. This was a significant saving of about 2 time and 5 time in terms of space and weight respectively.

Table 7 continued

Prina et al., 2023	Optimal fleet transition modelling for sustainable inland waterways	Batteries	Analysing the fleet composition of small electric passenger boats required to replace diesel powered passenger boats on the Orta lake. Authors found that the number of charging stations and the capacity of these station play a critical role in determining the fleet composition required to replace existing fleet. It was concluded that with higher charging capacities of the stations, the entire diesel fleet can be replaced with equal number of new electric fleet without changes to the routes and travel scheduling, however with lesser charging capacity along the fairway, more vessels were required to replace the diesel fleet
Perčić et al., 2023	Holistic energy efficiency and environmental friendliness analysis of inland ships with alternative power systems	LNG / Batteries / Methanol / Hydrogen / Ammonia	Assessing the life cycle GHG and local pollutant (NOx and Sox) emission performance of cleaner fuels for inland navigation, it was established that batteries offer better GHG footprint, however batteries contribute significantly to SOx emission during its manufacturing phase. Although the NH3 and H2 do not produce tail pipe emissions, their current production from fossil fuel results in significant GHG pollutions.
Moirangthem and Baxter, 2016	Alternative Fuels for Marine and Inland Waterways	Biofuels / Hydrogen / Methanol / Batteries	This study suggests that LNG and Methanol could serve as transition fuels for mid-term, before making a major shift to cleaner fuels such as biofuels.

### Challenges with Choice of Alternatives

Transitioning to cleaner energy and power systems for inland navigation is not devoid of challenges. The subsequent subsections shed light on the key hurdles associated with opting for alternative energy sources in inland navigation.

#### • Space and weight requirements

A challenge related to the choice of alternative power and energy systems for inland vessels is related to onboard storage and integration. As mentioned earlier, compared with conventional diesel fuel as a baseline, the low energy densities of these alternatives necessitate an additional volume or deadweight to accommodate the equivalent capacity of diesel fuel. The storage of gaseous alternative fuels presents challenges because of their considerable space and weight requirements. This issue is exacerbated by specific storage containment methods, especially for naturally occurring gaseous fuels, such as hydrogen and ammonia, which necessitate the use of cylinders. Taccani (Taccani et al., 2020)[53] in the GASVESSEL project illustrated this challenge, revealing that a 1.8-ton storage system is required to contain 140 kg of hydrogen at 25°C and 250 bar in a type I pressure vessel. Additionally, adapting cylindrically shaped tanks to fit existing rectangular spaces leads to the suboptimal use of space. Furthermore, safety considerations for handling and storing Methanol and ammonia impose non-negotiable constraints on where these fuels can be stored, further limiting the use of available space. Indeed, in an investigation by (Rivarolo et al., 2021), a comparative analysis was undertaken to assess various alternative energy carriers and their respective converters for a small river passenger boat. The evaluation criteria encompassed volume, weight, cost, and emissions. The results of their scoring revealed that the limitations associated with weight, volume, and opportunity cost exerted a more substantial influence on the choice of greening technology than emissions.

In a similar study conducted by (Lagemann et al., 2022) on retrofitting a deep-sea bulk carrier, accounting for the loss of payload, was expressed as opportunity cost within the total cost of ownership (TCO). In this situation the loss of revenue due to payload reduction when hydrogen is adopted was more pronounced. These observations arise from the impracticality of achieving zero emission when the utilization of zero-emission technology significantly takes up

cargo space and adds to the deadweight of the vessel. This limits the cargo carrying capacity of the vessel, which is the primary function of the vessel and thus the revenue stream of the owner.

- **Range and endurance (bunkering frequency)**

Ship range and endurance are defined in terms of the maximum distance a ship can travel on its loaded fuel capacity and the maximum time of continuous operation without refilling respectively. When the cargo capacity in terms of volume and deadweight is maintained, the energy capacity is then constrained to the available space and deadweight. Consequently, given the low volumetric and gravimetric energy densities of the alternative energy carriers, the quantities that can be carried onboard may not suffice the required range and endurance. As such, the ideal distance that the vessel may cover is considerably reduced, requiring intermittent bunkering to complete a voyage. An important performance metric that measures the transport efficiency of a vessel is the voyage time, which would be inevitably influenced by bunkering time and the frequency of bunkering required to complete a voyage. An example of this inefficiency was analysed by (Perčić, Vladimir, & Koričan, 2021), where it was found that reducing battery capacity due to limited available space, required a reduction of sailing distance consequently extending the voyage duration by about 6 times for an inland cargo vessel. Lower range and endurance become more challenging, particularly in situations where bunkering infrastructures are limited on a specific operating corridor.

### ***Summary of Inland Waterway Vessels Decarbonisation***

The subsection [State-of-the-art of IWV Greening Projects](#) highlighted the state-of-art green pilot projects within Europe, whereas [Alternative Energy for Inland Waterway Vessels](#) summarises recent studies on alternative energy carriers for inland waterway vessels. The subsection [Challenges with Choice of Alternatives](#) also underscored some pivotal challenges impacting vessel performance as a result of opting for alternative energy and power systems.

## **CONCLUSION AND FUTURE STUDY**

### **Conclusions**

In this study, we conducted a scoping literature review, summarising the state-art-of-the-art “sustainable and climate-resilient inland waterway vessels”. This study examines the multiple influences of climate change on vessels, as well as the problems associated with the choice of alternative energy on the performance of vessels. Altogether, this review first highlighted the most challenging impact of extreme shallow water conditions on the efficient operations of inland waterway vessels in terms of hydrodynamic performance and cargo transport performance, which threatens the ambitions to increase the modal share of inland water transport, that is already underutilised. Secondly, this work highlighted, the applicability of different alternative energy and power systems configurations on inland waterway vessels and how they also influence the performance of the vessel also in terms of cargo carrying capacity and voyage distance or endurance.

Fundamentally, there is yet to be found literature or study that takes into account, the dual facet problems of energy transition and climate-resilience of inland waterway vessel. These two have traditionally been tackled independently. While it is important to understand that the properties of the alternative energy carriers pose challenge to the overall transport efficiency of vessels, the impact of climate change on the conditions of the fairway also poses challenges to the transport efficiency of inland waterway vessels, and hence the need for both influences to be considered holistically. Having identified the gaps in the state-of-the-art, this presents an opportunity for further investigation, towards future-ready and climate-resilient inland waterway vessels.

## Future work

To address the complexity of these challenges, a holistic approach in assessing the intricate interplay between these problems is crucial for consideration in early design stage. This comprehensive approach is important to find optimal design parameters for inland waterway vessels. The objectives of optimal design parameters are to ensure minimum energy consumption and maximise propulsive efficiency under different fairway conditions. Simultaneously, achieving maximum payload capacity, while maintaining a balance with the vessel's energy requirement and allowing cargo transport over longer range and endurance. Integral to this would be to concurrently ensure minimal environmental impact associated with the choice of alternative energy and power systems. This overall would ensure a harmonious balance between vessel performance and sustainability.

## CONTRIBUTION STATEMENT

# Simulation-based evaluation of concepts for short sea shipping of green hydrogen

M. Bergström<sup>1,\*</sup>, A. Niemi<sup>2</sup>, B. Skobieć<sup>3</sup>, Y. Dave<sup>4</sup>, M. Begum<sup>5</sup>, F. Schmid<sup>6</sup>, F. Roland<sup>7</sup>, M. Braun<sup>8</sup>, and S. Ehlers<sup>9</sup>

## ABSTRACT

*In this study, a simulation-based approach is applied to develop concepts for short sea shipping of green hydrogen and to assess their overall energy efficiency. The study is conducted as a case study involving production of green hydrogen at an offshore site in the North Sea. Hydrogen produced at the site is first transported by pipeline to a port-based intermediate storage facility, from where it is transported onwards by ship. For the onward transport, four different hydrogen carriers are considered, namely compressed hydrogen, liquid hydrogen, ammonia, and a liquid organic hydrogen carrier.*

## KEY WORDS

Maritime transport; Short-sea shipping; Green hydrogen; North Sea; Discrete-event simulation

## INTRODUCTION

In Europe, green hydrogen is expected to play an important role in the energy transition, in particular as a tool to decarbonize energy-intensive industries, such as heavy industry, shipping and aviation. To ensure a sufficient supply, the European Union (EU), as part of its plan REPowerEU, has set a target of reaching 10 million tons of domestic production of green hydrogen by 2030 (Notteboom & Haralambides, 2023). As many parts of the EU are densely populated, and thus have limited opportunities for increased local onshore production of green hydrogen, new offshore production facilities will be needed to reach the production target. Consequently, new transport infrastructure is also needed, and due to the general lack of hydrogen pipelines as well as challenges related to building new ones, especially through densely populated areas, we expect a growing demand for non-pipeline-based transport options. In this context, the aim of this study is to define and evaluate concepts for short sea shipping of green hydrogen.

The study is conducted as a case study involving the production of green hydrogen at an offshore site in the North Sea. Hydrogen produced at the site is first transported by pipeline to an intermediate port-based terminal, from where it is further transported by ship. For the onward transport, four different hydrogen carriers are considered, namely, compressed hydrogen ( $\text{CH}_2$ ), liquid hydrogen ( $\text{LH}_2$ ), ammonia ( $\text{NH}_3$ ), and a liquid organic hydrogen carrier (LOHC) (Notteboom & Haralambides, 2023). Each considered concept is defined in terms of fleet characteristics (e.g. number of ships, ship type, ship size, and ship design speed), as well as the required intermediate port-based storage capacity. The study is limited to defining requirements for the fleet and port-based infrastructure considering energy efficiency and technical feasibility. Issues concerning safety, cost-efficiency, and regulations are not considered.

## Related studies

Johnston et al. (2022) present a model developed to assist stakeholders in assessing the costs of maritime transport of hydrogen in various forms over different distances. In total five different options are considered, namely, transport of hydrogen in the form of  $\text{LH}_2$ ,  $\text{NH}_3$ , liquified natural gas (LNG), methanol ( $\text{CH}_3\text{OH}$ ), and LOHCs. Both fixed and variable costs, including port fees, canal usage charges, fuel costs, capital and operating costs, boil-off losses and expected future environmental taxes, are considered. For distances between 4 500 NM and 10 900 NM the study found that it is most cost-efficient to transport hydrogen in the form of  $\text{NH}_3$  or  $\text{CH}_3\text{OH}$ . The study also analyzed the impact of using hydrogen, or the hydrogen carrier, as a low or zero carbon emission fuel for ships involved. However, it found that this would result in lower costs only in case hydrogen is transported in the form of LNG.

d'Amore-Domenech et al. (2023) compares the cost-efficiency of six different options for transport of hydrogen over sea including transport of  $\text{LH}_2$  by ship with or without port-based storage facilities, transport of  $\text{CH}_2$  by ship with or without port-based storage facilities, and transport of gaseous hydrogen by pipeline with or without intermediate compression stations. Each alternative was assessed for different transport distances and transport volumes. They found that for a transport distance of 100 km the most cost-efficient alternative is pipeline regardless of transport volume. For a distance of 2 500 km and an annual production volume of  $1.0 \times 10^5$  ton, the most cost-efficient alternative was found to be shipping of  $\text{CH}_2$  without port-based storage facilities. For a distance of 2 500 and an annual production volume of  $1.0 \times 10^6$  ton, as well as for a distance of 5 000 km and an annual production volume of  $1.0 \times 10^5$  ton, the most cost-efficient alternative was found to be shipping of either  $\text{CH}_2$  or  $\text{LH}_2$ . For all other cases they found that the most cost-efficient alternative is shipping of  $\text{LH}_2$ .

EU Science Hub (2022) assessed the costs of different hydrogen transport options including  $\text{CH}_2$ ,  $\text{LH}_2$ ,  $\text{NH}_3$ , and LOHC. In brief, they found that for distances up to 3,000 km, the most cost-efficient option is the transport of compressed hydrogen by pipeline. For distances between 3,000-16,000 km, transport of  $\text{LH}_2$  by ship was found to be the most cost-efficient options. For very long distances above 16,000 km, the most cost-efficient option was found to be transport of hydrogen in the form of LOHC or  $\text{NH}_3$ .

Based on the above studies it is evident that for distances up to 1,000 km, pipeline is generally the most cost-efficient option. However, none of the above-mentioned studies account for the fact that building a pipeline between two specific locations may not always be feasible for political, geographical, or other reasons. This study aims to assess what sea transport option is best for such cases.

## CASE STUDY

### Overview and design approach

In the case study, hydrogen is produced at an assumed offshore wind farm located in the North Sea within the exclusive economic zone of Germany at N54°26, E6°06. The location is indicated by a triangle in Figure 1. Hydrogen produced at the site is first transported along a 190 km long pipeline, whose approximate route is marked by a dotted line in Figure 1, to an intermediate port-based terminal storage located in Bremerhaven. From there all hydrogen is transported forward by ship to Kiel along an approximately 130 NM sea route marked by a dashed line in Figure 1. As per the figure, the sea route goes through Kiel Canal. If the intermediate port-based hydrogen storage in Bremerhaven becomes full, the  $\text{H}_2$  production has to be limited or stopped. To avoid this, the capacity of the transport system must be sufficient. Moreover, the transport system must be energy- and resource-efficient.

The case study design process is carried out as follows. First, we define the hydrogen production rate based on a previous study. Second, we analyze the sea route, e.g., in terms of operational constraints, and make a preliminary assessment of the voyage time. Third, considering the hydrogen production rate and assessed voyage time, we define a preliminary conservative solution for each considered hydrogen carrier. Fourth, using the technique of discrete event simulation together with engineering

judgement, we derive a refined conceptual solution for each considered hydrogen carrier. Fifth, we assess the overall energy efficiency of each solution.

### Hydrogen production

Following Eden et al. (2024), our considered assumed offshore wind farm consists of 42 Vestas V164 turbines with a total installed power capacity of 399 MW, which is reduced by 15 % due to wake effects. All electricity produced at the wind farm is used for producing hydrogen by electrolyzers requiring 3 kWh per produced kg of hydrogen. Following Eden et al. (2024), we simulate future hourly hydrogen production rates and volumes based on historical hourly wind speed data from the Copernicus ERA5 dataset specified for an altitude of 100 m covering the 11-year period 01.01.2012 – 31.12.2022 (Hersbach, et al., 2023). Accordingly, we assume that the wind conditions in the area will be similar as during the period represented by the data.

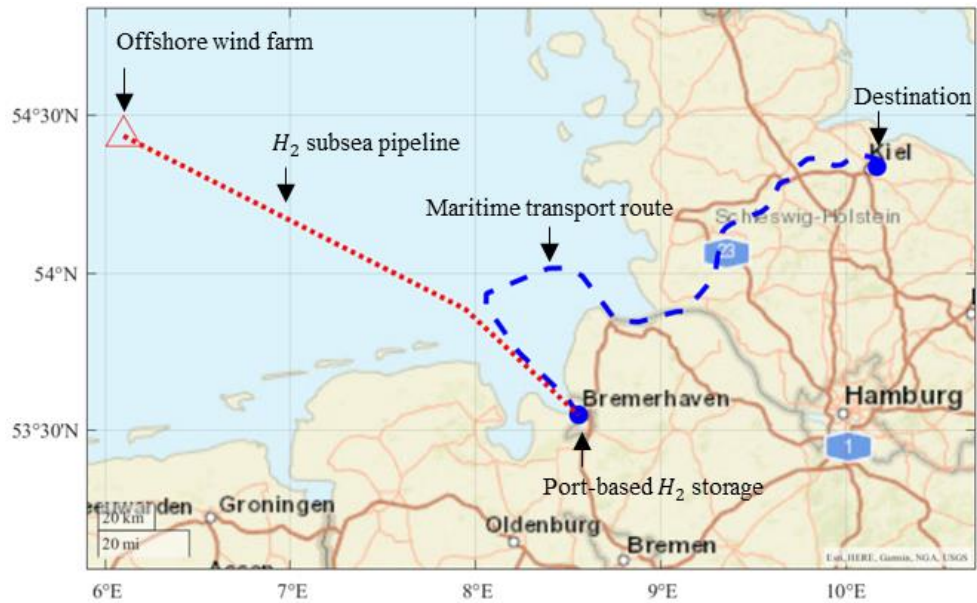

Figure 1: Production site and transport routes.

Over the considered 11-year period we simulated a total hydrogen production of around 244 000 ton. The corresponding annual, monthly, and daily averages are 22 182, 1 848, and 62 ton, respectively. However, due to variations in the prevailing wind conditions at the offshore site there are significant annual and interannual variations in the production rate. Specifically, as per Figure 2, the monthly production volume is estimated to vary between 780 and 3 050 ton.

Figure 2: Annual and interannual variations in the production rate.

### Sea route and operational constraints

The total distance of the sea route is 128.8 NM. Ship size and operational constraints are set primarily by the Kiel Canal as per Table 1. Following these constraints, ships are permitted to operate independently in all wind conditions without tug assistance

(UCA, 2023). The maximum allowed speed in and near Port of Bremerhaven and Port of Kiel is assumed to be 5 knots. In Elbe the maximum allowed speed is assumed to be 12 knots.

**Table 1: Ship size and operational constraints set by the route (UCA, 2023).**

Parameter	Maximum allowed value
Ship length	200 m
Ship beam	27 m
Ship draft	8 m
Ship speed, Kiel Canal	6.5 knots
Ship speed, port areas	5 knots
Ship speed, Elbe	12 knots

Considering the ship size and operational constraints determined as per Table 1, we choose to divide the route into 5 legs as per Table 2. Accordingly, some 40 % of the route is along Kiel Canal. As per the table, Kiel Canal has a lock at each end, i.e., in Brunsbüttel and Kiel-Holtenau, where the average locking times are assumed 45 and 25 minutes, respectively (WSV, 2022). As per WSV (2022), there are typically no additional waiting or queuing times. Assuming an open water speed of 14 knots, the total voyage time is estimated at 15.74 hour.

**Table 2: Preliminary voyage time estimation.**

Leg nr	Description	Distance [NM]	Speed [knots]	Time [hours]
1	Bremerhaven port area	3.8	5	0.77
2	Open sea (Bremerhaven - Elbe Estuary)	52.8	14	3.77
3	Elbe	16.5	12	1.37
	Lock 1 - Brunsbüttel	n/a	n/a	0.75
4	Kiel canal	53.4	6.5	8.22
	Lock 2 - Kiel-Holtenau	n/a	n/a	0.42
5	Kiel port area	2.2	5	0.43
SUM		128.8		15.74

## Elaboration of transport solutions

Assuming that the voyage time does not depend on the type of energy carrier, the voyage time for each option is preliminary estimated as per Table 2 to 15.74 hours. Assuming that the port-turn-around time in both Bremerhaven and Kiel is around 12 hours and independent of the type of energy carrier, the total duration of a round trip is estimated at  $2 \times 15.7 \text{ hours} + 2 \times 12 \text{ hours} = 55.4 \text{ hours}$ . Thus, assuming zero down time, the maximum number of round trips per month is 13. In order to meet the transport demand during a month of peak production (3 050 ton) using a single ship, the ship's required net transport capacity is estimated at  $\frac{3\,050 \text{ ton}}{13} \approx 235 \text{ ton}$  of hydrogen.

To meet this transport demand, we derive a preliminary solution for each considered energy carrier (CH<sub>2</sub>, LH<sub>2</sub>, NH<sub>3</sub>, and LOHC) considering the operational constraints as follows:

1. Gas carrier ship carrying CH<sub>2</sub> at 350 bar. Assuming as per Table 3 a density of 23.2 kg/m<sup>3</sup>, the required volumetric cargo capacity of the ship is estimate at  $\frac{235 \text{ ton} \cdot \text{m}^3}{0.0232 \text{ ton}} \approx 10\,129 \text{ m}^3$ . Because we are not aware of any reference CH<sub>2</sub> carriers, we use an LNG tanker as reference instead. Based on Clarksons Research (2024), a typical LNG tanker with a capacity of around 10 000 m<sup>3</sup> do not exceed any of the route constraints defined as per Table 1.
2. Container feeder ship carrying LH<sub>2</sub> in 40 feet cryogenic tank containers, each with a LH<sub>2</sub> capacity of 3 ton (Decker, 2019). If a single ship is used, the required FEU capacity of the ship is estimated at  $\frac{235 \text{ ton} \cdot \text{FEU}}{3 \text{ ton}} = 79 \text{ FEU}$  (158 TEU). Based on Clarksons Research (2024), a typical 160 TEU container ship do not exceed any of the route constraints defined as per Table 1.
3. Ammonia tanker ship. As per Table 3, a tone of NH<sub>3</sub> carries around 0.178 ton of hydrogen. Hence, in order to carry 235 ton of hydrogen, the ammonia tanker needs to carry  $235 \text{ ton} \cdot (1/0.178) \approx 1320 \text{ ton}$  of NH<sub>3</sub>. Based on Clarksons

Research (2024), a typical 1300 DWT LPG/Ammonia tanker does not exceed any of the route constraints defined as per Table 1.

4. Chemical tanker ship carrying LOHC. As per Table 3, one tone of a typical LOHC (benzyltoluene) is assumed to carry 0.063 ton of hydrogen. Hence, in order to carry 235 ton of hydrogen the tanker needs to carry  $235 \text{ ton} * (1/0.063) \approx 3730 \text{ ton}$  of LOHC. Based on Clarksons Research (2024), a typical 3730 DWT chemical tanker does not exceed any of the route constraints defined as per Table 1.

**Table 3 Storage densities by volume and weight (Weichenhain, 2021).**

Energy carrier	Storage volume density [kg H <sub>2</sub> /m <sup>3</sup> of carrier]	Storage weight density [kg H <sub>2</sub> / ton of carrier]	Storage weight density [ton of carrier/ ton H <sub>2</sub> ]
CH <sub>4</sub>	23	1 000	1 000
LH <sub>2</sub>	71	1 000	1 000
NH <sub>3</sub>	121	178	5.62
LOHC	55	63	15.87

The above defined preliminary solutions were derived without considering stochastic factors (e.g. variations in port-turnaround times), or more importantly, the role of the intermediate port-based storage in Bremerhaven acting as a buffer against short term variations in the production rate. Based on engineering judgement, we assume that it is preferable to store hydrogen in the intermediate storage in the same format in which it is to be transported forward. Hence, the type of storage tanks to be installed in Bremerhaven depends on the choice of hydrogen carrier for the maritime transport. Among the considered hydrogen carriers, we assume that the storage of LH<sub>2</sub> is the most challenging. The capacity of the largest commercial LH<sub>2</sub> storage tank that we are aware of is 2 500 m<sup>3</sup> (Kawasaki, 2021). As a preliminary solution we consider a hydrogen storage with a net capacity corresponding to four such tanks, providing a total capacity of 10 000 m<sup>3</sup>, which assuming a LH<sub>2</sub> density of 70.9 kg/m<sup>3</sup>, corresponds to around 709 ton.

In order to be able to consider both stochastic factors, and the role of the intermediate port-based storage, we simulate the operations of the system using the technique of Discrete Event Simulation (DES) using an approach originally presented by Bergström et al. (2016). An overview of the applied DES model is presented in Figure 3. As per the figure the model consists of five main blocks representing different components of the system. A more detailed presentation of the blocks representing the Port of Bremerhaven, the sea voyages, and the port of Kiel is provided in Figure 4. The time step of the simulation is one hour.

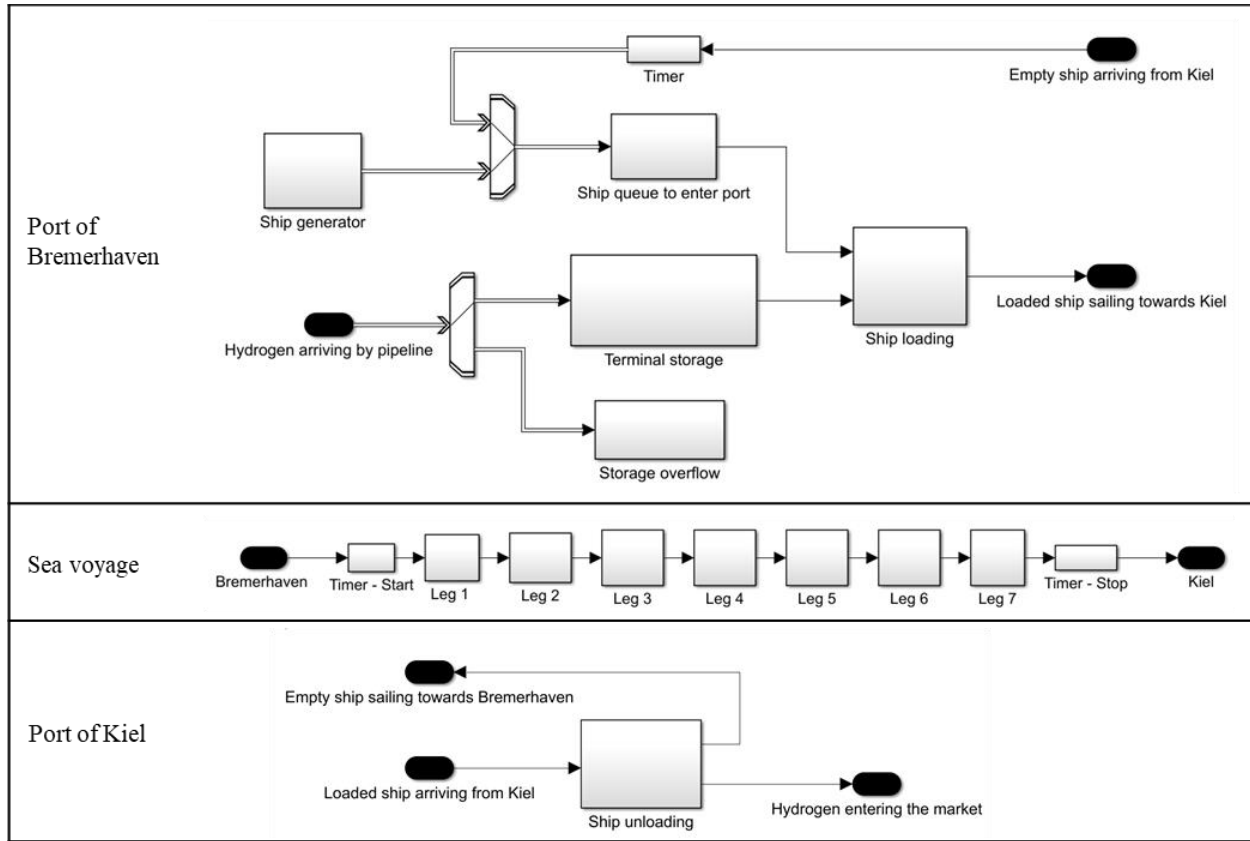

In the ‘hydrogen production’ - block, entities that each represent one ton of hydrogen, are produced at a rate corresponding to that simulated by Eden et al. (2024). All produced hydrogen entities proceed to the ‘Port of Bremerhaven’ block in which they are merged into a batch corresponding to that of the cargo capacity of the approaching or waiting ship. Once a cargo batch is completed, incoming cargo entities wait in a server with a capacity corresponding to the capacity of the port-based storage minus the capacity of the waiting cargo batch (ship load). If the port-based storage becomes full, entities are directed to a storage overflow block where they are terminated.

**Figure 3: Overview of the applied DES model.**

In the ‘ship loading’ block (in Port of Bremerhaven, see Figure 4), the completed cargo batch entity is merged with a waiting/incoming ship entity, resulting in a composite entity representing a fully loaded ship. Once a composite entity has been created, it will be held up for a time corresponding to the port-turnaround time, which is modelled as a normal distribution with a mean value of 12 hours and a standard deviation of 1 hour. Subsequently, the composite entity will proceed to the ‘Voyage: Bremerhaven-Kiel’ block, in which it will complete one leg at a time as shown in Figure 4. Once the composite entity has reached the ‘Port of Kiel’ block it will be split into its original components, i.e., an entity representing an empty ship plus a number of entities each of which represent one ton of hydrogen. Following a waiting time corresponding to the port turnaround time, which is modelled in the same way as the port-turnaround time in Kiel, the entity representing the empty ship will embark

on its return voyage towards Port of Bremerhaven and the entities representing hydrogen will enter the ‘hydrogen market’ block in which they are terminated.

**Figure 4: DES modelling of the Port of Bremerhaven, sea voyages, and Port of Kiel. The sea voyage Kiel-Bremerhaven is modelled in the same fashion as the distance Bremerhaven-Kiel.**

**Figure 5: (a) Monthly hydrogen production and (b) the corresponding amount of hydrogen waiting for onward transport in Bremerhaven using a ship with net cargo carrying capacity of 209 ton operating as per Table 2. A storage capacity of 709 ton is sufficient to ensure that no production is lost.**

With the help of the DES model, we iteratively find that a terminal storage capacity of 709 ton makes it possible to reduce the required net hydrogen cargo carrying capacity of the ship from the preliminary estimated 235 ton to 209 ton, assuming that the ship’s speed is as per Table 2. For this solution, Figure 5 presents the amount of hydrogen waiting in the intermediate storage

in Bremerhaven as a function of time together with the corresponding monthly production rates. As per the figure, the peak storage value appears at the start of year 4 as a result of a slightly higher than normal hydrogen production, indicating that the required storage capacity is sensitive to variations in the production rate. As shown in Figure 6, which shows in higher detail the development of the production rate together with corresponding development of the storage volume during the considered period, the increase in storage volume is a result of an increase in the frequency of days with high production.

**Figure 6: Detailed illustration of (a) the development of the daily production rate and (b) the resulting storage volume during the end of year 3 and start of year 4.**

**Figure 7: Amount of lost production for (a) 50 % reduced intermediate cargo storage (709 → 355 ton), (b) 10 % reduced ship cargo capacity (209 → 188 ton), and (c) reduced ship design speed (14 → 12 knots).**

As also shown in Figure 5, except for a few short periods of high production, during most of the simulated operating years only a fraction of the storage capacity is utilized. This indicates that the solution is not particularly resource efficient. Measures that could be taken to reduce such waste during an average year include a reduction of the capacity of the intermediate storage and or of the transport system. To assess the cost of such measures in terms of the resulting production loss, we simulated the production losses resulting from the following system modifications: (a) reduction of the capacity of the intermediate storage by 50 % from 709 to 355 ton, (b) reduction of the ship's cargo carrying capacity by 10 % from 209 ton to 188 ton, and (c) reduction of the ship's design speed by 2 knots from 14 to 12 knots. Figure 7 presents the resulting production losses separately for each modification. As per the figure, both modification A and modification B results in a cumulated production loss of around 1 250 ton, corresponding to an annual average of 114 ton, which represents 0.5 % of the average annual production. Modification C results in an insignificant cumulated production loss of around 100 ton, corresponding to an annual average of

around 10 ton. Based on engineering judgement we assess that both modification A and C would result in significant savings that would exceed the costs associated with the resulting production loss. Hence, we decide to adopt both modifications.

For the selected system design modifications, involving an intermediate storage capacity of 355 ton and a ship with a net hydrogen carrying capacity of 209 ton and a design speed of 12 knots, Figure 8 shows the simulated development of the storage volume, the cumulated production loss, and estimated monthly production losses.

**Figure 8: Development of the (a) storage volume, (b) cumulated production loss, and (c) monthly production losses for the selected system design involving an intermediate storage capacity of 355 ton and a ship with a net hydrogen carrying capacity of 209 ton and a design speed of 12 knots.**

As per Table 4, for each considered hydrogen carrier we specify a simplified parametric ship design meeting the above defined requirements in terms of net hydrogen cargo carrying capacity and design speed. The dimensions and deadweight (DWT) of the ships are specified based on reference ships provided by Clarksons Research (2024), whereas the power demand at different speed are estimated as per Eq. 1.

$$V_{estimated} = (V_{ref\_avg} - m_v) \cdot \left( \frac{\Sigma P_{me}}{0.75 \cdot MCR_{avg}} \right)^{\frac{1}{3}} \quad (1)$$

, where  $V_{ref\_avg}$  is a ship type- and size-specific statistical mean of distribution of ship speed defined as  $V_{ref\_avg} = A \times B^C$ , where A, B, and C are given by IMO (2021). Parameter  $m_v$  is the considered ship's performance margin, defined as 5 % of  $V_{ref\_avg}$ , or one knot, whichever is lower.  $MCR_{avg}$  is a ship type- and size-specific statistical mean of distribution of MCRs for main engines and is calculated as  $MCR_{avg} = D \times E^F$ , where D, E, and F are given by (IMO, 2021). Because diesel engines should not be operated below around 30 % of their MCR, the ships' power demand at low speed is calculated per Eq. 2.

$$P_{min} = 0.3 * \frac{P_{me(14 \text{ knots})}}{0.85} \quad (2)$$

**Table 4: Specification of transport ships based on reference ships (Clarksons Research, 2024).**

Hydrogen carrier	CH2	LH2	Ammonia	LOHC
Net H2 carrying capacity	209 ton	209 ton	209 ton	188 ton
Type of ship	Gas tanker	Container ship	LPG/Ammonia carrier	Chemical tanker
Required ship capacity (m <sup>3</sup> , TEU, or DWT)	9010 m <sup>3</sup> , 6800 DWT	140 TEU (70 FEU), 2010 DWT	209 ton x 5.62 ≈ 1175 ton	209 ton x 15.87 ≈ 3317 ton
Length	120 m	80 m	72 m	86 m
Beam	21 m	14 m	12 m	14 m
Draft	7 m	4 m	4 m	6 m
$P_{me}$ (12 knots)	1660 kW	880 kW	1060 kW	1600 kW
$P_{me}$ (6.5 knots)	590 kW	310 kW	375 kW	565 kW
$P_{me}$ (5 knots)	590 kW	310 kW	375 kW	565 kW
Average specific fuel consumption	190 g / kWh	190 g / kWh	190 g / kWh	190 g / kWh

Each of the considered hydrogen carriers is associated with energy penalties related to the what is often referred to as ‘packing’ and ‘unpacking, i.e., the processes of converting hydrogen to the desired transportation form, and subsequently to convert it back to hydrogen at the transport destination. For some of the energy carriers there is an additional loss in terms of boil-off. In the present study, such losses are assumed to be as per Table 5. As per the table, because many of the processes have not yet been applied on a large scale, there is a significant degree of uncertainty regarding their energy consumptions (IRENA, 2022). This appears to be especially true for LOHCs. There are many different types of LOHCs and there is a large variation between the energy consumption values reported in the literature for their "packing" and "unpacking". In part, this may be due to differences between theoretical values and the actual consumption of existing equipment. The values used in this study are intended to be indicative of ‘typical’ LOHCs.

**Table 5: Energy penalties and boil-off estimates for the considered energy carriers (IRENA, 2022) (Parks, Boyd, Cornish, & Remick, 2014) (Melcher, George, & Paetz, 2021).**

Energy carrier	Energy consumption, packing	Energy consumption, unpacking	Boil-off
CH <sub>2</sub>	2 – 4 kWh/kg-H <sub>2</sub>	negligible	negligible
LH <sub>2</sub>	10 – 12 kWh/kg-H <sub>2</sub>	negligible	Boil-off 0.05-0.25 % / day
Ammonia	0.5 – 0.8 kWh/kg-NH <sub>3</sub>	4 – 11 kWh/kg-H <sub>2</sub>	Boil-off 0.004 % / day
LOHC	9 - 10 kWh/kg-H <sub>2</sub>	6-12 kWh/kg-H <sub>2</sub>	negligible

Based on the above defined data and assumptions we calculate the energy consumption for an average round trip as per Figure 9. As per the figure, for each energy carrier we calculate both an optimistic value, based on the lower values defined in Table 5, and a pessimistic value, based on the higher values of the same table. As can be seen from the figure, we find that for both the pessimistic and optimistic assumptions, CH<sub>2</sub> appears to be the overall most energy-efficient option. Whether LH<sub>2</sub> or NH<sub>3</sub> is the second most cost-effective solution depends on assumptions concerning energy penalties related to hydrogen packing and unpacking.

**Figure 9: Comparison of the energy consumption of the different solutions for an average round trip.**

## CONCLUSIONS

In this study, a discrete-event simulation-based approach is applied to a case study to derive concepts for short sea shipping of green hydrogen produced at an offshore wind farm over a sea distance of around 130 NM. To meet the transport demand during a typical year, our simulation results indicate that a ship with a net hydrogen transport capacity of 209 ton and a design speed of 12 knots is needed. Among four considered hydrogen carriers, CH<sub>2</sub>, LH<sub>2</sub>, NH<sub>3</sub>, and a LOHC, we find that CH<sub>2</sub> provides the overall best energy-efficiency. The simulation results further reveal that it does not appear resource-efficient to invest in the transport and storage capacities needed to be able to handle the expected 11-year maximum production peak without production limitations, as this would result in significant overcapacity most of the time. Future research is recommended to address safety, regulatory, and cost-efficiency aspects, as well as to investigate the required port infrastructure in detail, and to investigate potential hydrogen carrier specific differences in terms of loading/unloading times. Future research is also recommended to address uncertainties regarding how much energy is lost in the packing/unpacking of different hydrogen carriers, or through boil-off.

# Technical and Economic Feasibility Study on Reducing CO<sub>2</sub> Emissions of Dutch Beam Trawlers

Arnoud de bruin<sup>1,2</sup>, Walter van Harberden<sup>2</sup>, Austin A. Kana<sup>3,\*</sup>

## ABSTRACT

*This paper examines the technical and economic influence of CO<sub>2</sub> reduction measures on the design and operation of Dutch beam trawlers. This is done by means of a parametric model used to assess the influence on the overall design of the vessel. Technical feasibility is determined by meeting operational effectiveness requirements, maximum added draught, maximum added length, and a reduction of CO<sub>2</sub> emission by at least 40%. Secondly the model evaluates the new energy carrier and fish storage layout as a result of additional required volume. Additional volume is gained within the net store, fish hold, or by hull extension. Additionally, various propeller configurations, waste heat recovery, and regenerative braking systems are explored to reduce energy consumption. The economic performance is assessed using yearly operational requirements, capital expenses of configuration, and total cost of ownership.*

## KEY WORDS

Beam trawlers; feasibility study; parametric modeling; zero-emission

## INTRODUCTION

The most recent estimates in the Fourth International Maritime Organization (IMO) Greenhouse Gas (GHG) Study 2020 show that GHG emissions of shipping have increased by 9.6% between 2012 and 2018 (IMO, 2020), while the IMO strives to reduce CO<sub>2</sub> emissions by at least 40% by 2030, pursuing efforts towards net zero by 2050, compared to 2008 (IMO, 2023). Although a Dutch beam trawler has a gross tonnage below or just above 400GT and the IMO regulations do not apply to it, there is nevertheless an aim to reduce GHGs of these vessels. The last decade the Dutch beam trawler fleet has been confronted with a lot of developments (MEPC, 2024) which has led to the reduction of profitability of the vessels. Two developments stand out in the last decade, namely: (1) BREXIT, which has resulted in a reduction of available fishing ground, and (2) the ban on pulse fishing, which is a method of fishing which reduced the operational expenses by around 30-40%. Due to the current state of the fishing fleet the Dutch government has introduced a plan called “Noordzee Visie (Northsea Vision)” (Rijksdienst voor Ondernemend, 2019) which aims to reduce the environmental impact of the Dutch fishing fleet. This plan consists of buying out weak companies and investing money in the form of a subsidy to make the remaining fishing vessels more sustainable.

To continue fishing a Dutch beam trawler has to comply with these regulations, thus requiring implementing the use of sustainable fuels together with energy saving technologies. Vessel owners want to implement these technologies without sacrificing operational effectiveness. Therefore, this study aims to assess the technical and economic feasibility of reducing the CO<sub>2</sub> emissions of Dutch beam trawlers to meet the 2030 IMO CO<sub>2</sub> emission regulations, while maintaining vessel operational effectiveness.

## LITERATURE

With the buyout and high fuel costs on the horizon studies have been done on the reduction of CO<sub>2</sub> emissions by means of alternative energy carriers on new build (beam) trawlers. These research topics concern: feasibility study fishing on natural gas ('t Hart, 2009), LNG potential energy source (Taal and Hoefnagel, 2012) and Design Green shrimp trawler (van Urk, 2012). These studies are limited to other fishing vessel types and only consider gas-like fuels. There are mainly three ways to reduce the emitted emission of a vessel: (1) reducing the energy consumption of the vessel, (2) after treatment of the rest product of energy converter or by (3) changing to an alternative fuel. All the mentioned and open source studies are done on new build beam trawlers, discuss one methods to reduce CO<sub>2</sub>, and do not combine all three options and aspects together. Additionally, and the economic perspective has been missing from previous literature. Looking at emissions and fishing regulations there is large future uncertainty driven by future availability fishing grounds and alternative fuel characteristics. It is thus necessary to get insight in the performance of multiple propulsion configurations on economic and technical performance. The review below covers: (1) determining the current state and operation of a Dutch beam trawler, (2) exploring methods to reduce the CO<sub>2</sub> emissions, and (3) establishing requirements for an assessment model.

### Vessel State

The latest study (Wageningen Marine & Research, 2023) showed the average age of the 284 active Dutch beam trawlers to be 32 years (build 1990), with 75% being older than 20 years. The vessels are powered by a conventional engine room set up. For these vessels this means the main engine is a MGO fueled 4-stroke medium speed internal combustion engine, and is indirectly coupled to the propeller by means of a gearbox. The installed Pb varies between 1000kW and 1450kW. The vessels average characteristics range from: L<sub>pp</sub>: 35-42m, B<sub>moulded</sub>: 6-9m, T<sub>mid</sub>: 3-4.5m, D<sub>prop</sub>: 2-3m and Prop-speed: 180–280rpm. The main energy consumers besides the engine propulsion the propeller onboard are the ice & cooling machines, safety & communication, and the winch. From which the cooling system is responsible for the preservation of caught fish and the winch for the setting and hauling of the nets.

The state of the art of beam trawlers limits itself to optimized propeller and diesel engine configurations but does not go any further. The operational profile of the vessel can be divided into the short and long cycle. The long cycle is the time from sailing out from port, the fishing and the return into port. The short cycle is the fishing cycle covering the repetition of setting, fishing and hauling the nets. Two types of long cycles exist in the Dutch fleet: a 100hr and a 160 hour per week, based on geographic and demographic preferences within the Netherlands. The short cycle has an average duration of 2.5 hours.

### Emission Reduction Exploration

The energy converters, energy carriers and emission reduction methods identified in Table 1 have the highest potential in achieving the stated goals.

**Table 1: Combination of systems, similar numbers indicate technical combinations**

Converter	Energy Carrier	Energy Reduction
Diesel ICE (1)	MGO (1) HVO (1) FAME (1)	Propeller (1,2,3,4) - 3.4m 4 blade - 3.4m 5 blade - 4.0m 4 blade - 4.0m 5 blade
DF ICE (2)	Methanol (2)	Orcan, WHR (1,2,3)
LT PEMFC (3)	Hydrogen (3)	SRC, WHR (1,2,3)
NMC-Li battery (4)		Winch (1,2,3,4) - Regenerative braking - Operational optimization

The four energy converters identified demonstrate promising potential for implementation on a beam trawler. These converters were selected based on their capacity to reduce CO<sub>2</sub> emissions while ensuring technical reliability.

- **MGO ICE:** This engine was considered for its cost-effectiveness and its proven track record in efficiently converting chemical energy into mechanical or electrical energy (DNV, 2020; Streng et al, 2022).
- **DF ICE:** The DF (Dual Fuel) technology was chosen as it has already been validated by several engine manufacturers. Furthermore, its utilization of methanol fuel offers the potential to significantly decrease CO<sub>2</sub> emissions (Dierickx et al, 2021; Pendle Government, 2018).

- **LT PEMFC:** The Low-Temperature Proton Exchange Membrane Fuel Cell (LT PEMFC) was selected due to its reliability, high energy density, rapid response to load variations, and a simplified system compared to high-temperature fuel cells (Leon, 2008; Welaya et al, 2011).
- **Nickel Manganese Cobalt-Lithium (NMC-Li) Batteries:** These batteries were preferred over other options because of their high energy density, extended cycle life, and relatively fast charging capability (Freudenberg E-power systems, 2022).

Additionally, five energy carriers are employed, carefully selected based on their ability to exhibit low Tank-To-Wake (TTW) emissions and ensure minimal safety risks for both the crew and the environment.

- **MGO:** MGO is being considered to assess its feasibility in meeting IMO targets without transitioning to alternative fuels.
- **HVO and FAME:** Hydrotreated Vegetable Oil (HVO) and Fatty Acid Methyl Ester (FAME) are highly regarded by IMO for their exceptionally low TTW emissions due to their bio-based production (IMO, 2023). Their similarity to Marine Diesel Oil (MDO) makes their application relatively straightforward (DNV, 2019).
- **Methanol:** Methanol is partially classified as a drop-in fuel, and its lower carbon content provides the potential to reduce TTW emissions.
- **Hydrogen:** Hydrogen, chosen for its zero TTW emissions, is a favored fuel option. Hydrogen in liquid form is preferred due to its higher storage efficiency compared to compressed hydrogen, attributed to the significant reduction in volume resulting from its low temperature (DNV, 2022).

At last three types of energy reducing methods are explored. (1) Propeller: due to its high rotational speeds and high blade loading it is found that there is potential for efficiency improvement by increasing the diameter of the propeller, which would reduce blade loading and rotational speed, leading to an overall increase in efficiency (Laurens et al, 2013). (2) Winch: with the application of regenerative braking on the winch a small amount of electrical energy can be recovered during the setting of the nets. Secondly by optimizing the winch operation the required propulsion power during setting and hauling can be reduced. (3) Waste heat recovery (WHR): depending on the propulsion setup, energy can be recovered from exhaust gas or cooling water (Mat Nawi et al, 2019; Benvenuto, et al, 2016; Ouyang et al, 2020).

## Combination of Systems

The proposed configurations consist of various combinations of energy converters, energy carriers, and energy consumption reduction strategies. However, certain combinations are not feasible due to system working principles. With the exception of the original propulsion configuration, all other combinations are designed to be either diesel-electric or fully electric, aligning with the Dutch subsidy regulations outlined in the Noordzee Visie. The calculations are designed to store the maximum amount of the main energy carrier on board, considering a 40% reduction in  $CO_2$  emissions. The remaining required energy is stored as the secondary energy carrier. These hybrid combinations of energy carriers are chosen based on the assumption that they are the most economically feasible. The combination of Hydrogen and NMC-Li for example will result in significant capital investments, and complex combination of systems. HVO and FAME already achieve 40%  $CO_2$  and are therefore not used in the hybrid configurations.

In addition to the mono-fueled configurations, four hybrid configurations are explored. The selection of these hybrid combinations is based on the goal of achieving the lowest initial investment while still achieving a 40% reduction in  $CO_2$  emissions. Consequently, combinations involving HVO, FAME, Hydrogen, and batteries are not chosen, as they already comply with the TTW fraction requirements. The following four combinations remain:

1. MGO-Hydrogen (liquid) (MGO-H<sub>2</sub>(l))
2. MGO-Nickel Manganese Cobalt-Lithium (MGO-NMC-Li)
3. DF-Hydrogen (liquid) (DF-H<sub>2</sub>(l))
4. DF-Nickel Manganese Cobalt-Lithium (DF-NMC-Li)

The fraction of delivered energy in each combination is determined by using the maximum amount of MGO or DF, with the remaining energy supplied by the second energy carrier.

## METHOD

To evaluate the potential of various combinations of systems, an assessment model was developed (Figure 1), consisting of three main components: literature, technical, and economical. The literature section gathered inputs from specific system characteristics found in a literature study. The technical segment involved calculations to determine the required energy and

new vessel dimensions for different storage options, ensuring compliance with all necessary requirements. In the economic part, proposed configurations that met the requirements were evaluated using three performance indicators: capital expenses, operational expenses, and total cost of ownership.

The primary focus of this research was to assess the technical and economic feasibility of reducing CO<sub>2</sub> emissions in a beam trawler. For this purpose, a parametric assessment model was employed. This method assigned points to various criteria and evaluated their fulfillment to assess the viability of the proposed solution. The model considered crucial factors such as emission reduction potential, cost-effectiveness, and alignment with existing infrastructure and regulations. By aggregating scores assigned to each criterion, a comprehensive and objective evaluation of CO<sub>2</sub> reduction measures was achieved. This parametric approach offered a systematic and transparent decision-making process, facilitating the selection of the most suitable emission reduction strategies for beam trawlers while considering both technical and economic aspects.

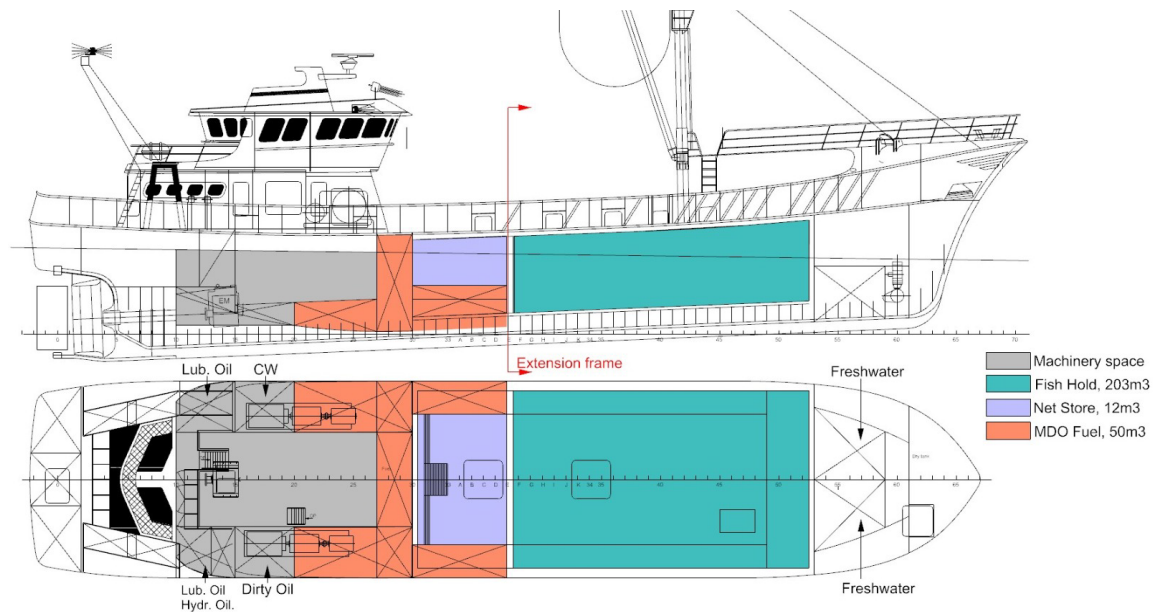

Figure 1. Flowchart of the assessment model.

### Technical Feasibility Assessment

In this phase of the assessment, calculations are performed to transform the operational profile and propulsion configuration into new vessel parameters. By considering the system characteristics, vessel data, and operational requirements, the necessary energy per long cycle, volume of energy carrier, weight of energy carrier, and weight of propulsion configuration are determined. To accommodate the calculated volume of energy carrier, including the tank storage arrangement (See Figure 2), various storage methods are suggested. These methods involve combining the original storage tanks with additional volumes such as the net store, fish hold, or creating new storage space if the hull is extended.

**Figure 2: Original tank plan (Padmos, 1987)**

Examining the energy density and storage arrangements of drop-in fuels such as MGO, HVO, and FAME requires relatively straightforward investigation. However, when dealing with energy carriers like methanol and liquid hydrogen, specific tank storage arrangements become necessary. In order to estimate the optimal position and quantity of tanks, this research took into account the average Dutch beam trawler, its energy carrier consumption, and hull dimensions. Additionally, the requirements for cofferdams and cryogenic tanks were considered, ultimately determining the average energy density, including the storage tank, used in this study.

Different organizations employ diverse formulas, often incorporating non-empirical values and correction factors, to calculate emission reduction. However, approaches like EEXI, EEDI, and CII, which work with emission ratios per ton of cargo per mile, are unsuitable for fishing vessels due to their limited transportation of goods, primarily consisting of a few tons of fish. Moreover, these ratios often use generalized correction factors that may not be applicable to specific sectors or may lack relevant data, leading to an insufficient understanding of the actual impact of various configurations.

To address these concerns, the assessment of CO<sub>2</sub> emission reduction for fishing vessels will be presented as a percentage relative to the original emission during the long cycle. The focus will be on considering TTW emissions, as Dutch, EU, and IMO regulations calculate, penalize, and evaluate emissions based on this criterion. It is important to note that fuel producers bear the responsibility for well-to-tank (WTT) emissions, and well-to-tank (WTT) emissions, being a separate study, are beyond the scope of this study.

Once the new estimated hull parameters are established, the configuration is examined for its technical feasibility. To be deemed feasible, the configurations must meet various types of requirements.

- (1) Operational effectiveness requirements
  - Towing capacity
  - Endurance
  - Fish hold capacity
  - Cooling
  - Winch
  - Storage area
- (2) Maximum 0.3m added average draught
- (3) Maximum 3m hull extension
- (4) Minimum 40% CO<sub>2</sub>emission reduction

The maximum added draught and length of a vessel are unique to each vessel and determined by factors like minimum required freeboard, maximum GT, seaworthiness, and stability. If a configuration fails to meet these specific requirements, it is considered technically infeasible. Conversely, if it fulfills these criteria, it is deemed technically feasible, and the assessment model proceeds to evaluate its economic feasibility.

## Economic feasibility assessment

This part assesses the economic performance of the configurations based on three indicators: (1) Operational expenses, (2) Capital expenses, and (3) Total cost of ownership.

### Operational expenses

The operational expenses is the summation of the yearly costs of energy carrier consumption, the paid tax on CO<sub>2</sub> emission to the Dutch government, and the maintenance (Equation 1).

$$OpEx = Energy\ Carrier + CO_2\ emission\ taxes + maintenance \quad [1]$$

Using:

- Energy Carrier, required amount of energy carrier per year multiplied by price
- CO<sub>2</sub> emission taxes, CO<sub>2</sub> emission per year multiplied by tax price
- Maintenance, the yearly costs required to keep propulsion configuration and ship in good and reliable condition.

### Maintenance costs

To obtain the most accurate estimate of the expected costs per propulsion configuration, the annual maintenance costs need to be determined. These costs will always be an approximation as they depend on various variables such as operational hours, whether the work is performed in-house or by a subcontractor, etc. Additionally, predicting breakdowns is challenging. However, through the expertise of Padmos and insights from case studies, an attempt has been made to determine an annual cost estimate for ship maintenance.

### Capital expenses

With the propulsion configurations that meet the requirements, an estimation can be made on the system prices and vessel retrofitting prices. The propulsion configuration system prices can be estimated using average e/kW fractions. The retrofitting prices of the vessel are difficult to estimate, since they are vessel specific. Steel prices and labour prices are fixed but the required amount of hours and steel are difficult to estimate. The capital costs of retrofitting are significant and therefore must be included in the economic feasibility. The company's history in vessel retrofitting is used to estimate working hours for the different retrofitting options. With the cross section drawings and the weight of steel the added weight of the extension section is calculated. With an average price on steel welding, cutting and pre-forming costs this results in the overall costs to make the section. The CapEx is built up as the sum of propulsion configurations costs, propeller, winch modifications, WHR and vessel extension costs (see Equation 2).

$$CapEx = Propulsion\ configuration + Energy\ saving\ devices + Hull\ extension \quad [2]$$

### Total cost of ownership (TCO)

TCO is one widely used approaches in the analysis of economic performance (see Equation 3). TCO takes into account not only the upfront investment costs but also the operational and maintenance expenses over the system's lifetime. A new propulsion configuration may require significant investment upfront, but its long-term cost implications are equally crucial. TCO analysis helps in identifying potential cost savings over the operational lifespan of the system. For instance, a propulsion configuration with higher fuel efficiency and lower maintenance requirements may result in substantial cost reductions over time, offsetting the initial investment. TCO analysis allows for a fair comparison of different propulsion configurations (Terun et al, 2022). By calculating and comparing the total costs associated with each option, decision-makers can identify the most economically viable solution.

$$TCO_{yearly} = CapEx + OpEx \quad [3]$$

- $TCO_{yearly}$ , the yearly total cost of ownership[e/year]
- $Capex$ , the capital expenditures[e]
- $Opex$ , the operational expenditures[e/year]

In the context of the new propulsion configuration, the vessel's expected lifetime is considered to be 15 operational years. Consequently, the residual value of the investment, or the remaining value of the system after its useful life, is expected to be negligible or zero. This expectation arises from factors such as technological obsolescence, wear and tear, and the introduction of newer, more efficient propulsion technologies over time. Given the vessel's expected lifetime of 15 operational years, the TCO analysis typically focuses on this relatively short time horizon. Since the remaining value of the investment is negligible or zero by the end of this period, including it in the TCO analysis would not significantly impact the overall economic

assessment. Only at a later stage when a new build vessel is included into the configurations, a remaining value will be included since this vessels lifetime is more than 15 years. The remaining value is determined according to Equation 4.

$$TCO_{yearly,remaining} = CapEx + OpEx - remaining\ value \quad [4]$$

## CASE STUDY

To obtain a realistic picture of the technically and economically feasibility of the configurations, a case study is conducted on an existing beam trawler. The vessel has the following characteristics (Table 2), and as can be seen from the literature it matches the average Dutch beam trawler parameters.

**Table 2. Case vessel particulars**

Lpp	33.75m
Beam	7.5m
Draught	3m
Displacement	500 tons
Block Coefficient	0.6
Main engine	1200kW Stork Werkspoor
Propeller diameter	2.5
Winch	100kW

Given the significant impact of operational expenses on the economic feasibility of the configuration, it is necessary to conduct scenarios with varying energy carrier prices and CO<sub>2</sub> emission tax prices. This analysis aims to determine whether the most promising configurations also perform well under different circumstances. By exploring different scenarios, insights can be gained into the robustness and versatility of the potential configurations beyond their primary conditions. Within this study three scenarios are explored: (1) high energy carrier price, and (2) high emission tax price, and (3) forecasted energy carrier and emission tax prices. The last scenario will be used to actually find the answer to the problem of this research.

### Energy Carrier Prices

Although best estimates are used on forecasted carrier prices, the last decade showed large deviations from forecasted prices due to pandemics or wars (Olusanya et al. 2021; Pavlenko et al, 2020). By considering a case in which with high energy carrier prices, it allows for an analysis of the economic viability of different propulsion configurations under various cost conditions. The projection for 2050 is increased and decreased by 30% to find the influence of the price of the energy carrier on the economic feasibility of the beam trawler vessel. A 30% uncertainty is chosen after considering the enormous volatility that energy prices have shown.

### Emission Tax Prices

The Dutch Government imposes taxes or levies on carbon emissions to incentivize emission reductions. This regulation has been set until 2030; however, this research aims to further explore the economic performance of the configuration. Therefore, there will be a need to make assumptions about the price trajectory post-2030 (Enerdata, 2023), introducing uncertainty into the model. To assess the model's sensitivity to these uncertainties, a scenario is applied assuming a high emission price. By evaluating this scenario with different emission tax prices, it helps in understanding the cost implications of environmental regulations and their influence on the economic viability of the proposed propulsion configurations. The scenario proposed will work with a upper limit of 50% above predicted prices. A 50% uncertainty is chosen after considering the enormous volatility that future regulations have shown. After finding the sensitivity of the model with Scenario 1 and scenario 2, the last scenario (3) uses the prices for both energy carrier prices and emission tax as forecasted in Table 3 and 4.

**Table 3. Energy carrier price current and future, [ e/GJ ]**

	Fuel Costs 2022	Fuels Costs 2050	Source
MGO	17	17	(LR, 2023)
HVO	31	31	(DNV, 2019)
FAME	28	28	(DNV GL, 2019)
Methanol	39	27	(Pothaar, 2022)
Hydrogen	70	33	(IEA, 2022, 2023)
Electricity	27	10	(GRO, 2020)

**Table 4. Statutory price trajectory of carbon levy in 2021 (OECD, 2021)**

	2021	2022	2023	2024	2025	2026	2027	2028	2029	2030
Levy rate (€ / tonne CO <sub>2</sub> )	30	40.56	51.12	61.68	68.12	76.42	83.21	89.72	94.20	103.92

## RESULTS

The results of the assessment model are presented for different configurations applied to the case beam trawler, sailing with both the 100hr and the continuous long cycle. In the economic evaluation, it is assumed that the retrofitted case vessel will have an operational lifespan of 15 years. The model generates various outputs, from which the required amount of energy per configuration per long cycle is the first value calculated. This is then converted into the necessary volume and weight. In this section, the required volume, including the storage tank, is presented to provide an overview of the quantities involved and to understand the impact of specific energy reduction methods. The outcome is presented in Table 5 and 6. The required volumes mentioned here are including storage tank.

**Table 5. Required storage volume [m<sup>3</sup>] for mono fuels configurations. Red indicates more volume than available.**

Converter	Fuel	Config.	100 hr long cycle					Continuous long cycle

Methanol	NMC-Li	D-E	114	75	54	75	54	186	120	88	120	88

### Both long cycles

None of the mono battery configurations are deemed feasible as they exceed the maximum added draught and extension length limitations. However, fuels like HVO and FAME show technical feasibility due to their similarity to MDO, provided the IMO continues to consider them as zero-emission fuels. Regarding the hybrid propulsion configurations, both MGO-H<sub>2</sub>(l) and DF-H<sub>2</sub>(l) are technically feasible for all propeller types, including the original propeller. This is mainly attributed to the relatively high energy density of methanol and MGO when compared to liquid H<sub>2</sub>.

It is worth noting that in all situations, the presence or absence of waste heat recovery (WHR) or regenerative braking, or a combination of these systems, does not directly determine whether the 40% CO<sub>2</sub> emission reduction target is met or not (see Table 7). However, this does not imply that installing these systems would not be beneficial. While they may contribute to additional complexity, volume, and weight in the overall machinery configuration, they may still provide other advantages and improvements.

**Table 7: CO<sub>2</sub> emission reduction, green: configurations technical feasible**

Converter	Fuel	Conf.	Propeller				
			Original	1	2	3	4
ICE	MGO	D-D	0%	19%	31%	19%	31%
ICE	MGO	D-E	-4%	16%	28%	16%	28%
ICE	HVO	D-E	90%	92%	93%	92%	93%
ICE	FAME	D-E	93%	94%	95%	94%	95%
ICE	DF	D-E	16%	32%	42%	32%	42%
PEMFC	Hydrogen	E	100%	100%	100%	100%	100%
Battery	NMC-Lithium	E	100%	100%	100%	100%	100%

## 100hr long cycle

The dual fuel configuration can achieve a 40% reduction in CO<sub>2</sub> emissions only when combined with the application of propeller type 2(4.0D). This is because carbon is still present in methanol and the pilot fuel, necessitating a larger diameter propeller to reduce energy consumption during the cycle. For a mono-fuel hydrogen configuration, upgrading the propeller to type 1 and type 2 is required to prevent exceeding the maximum extension limits. On the other hand, the hybrid configuration MGO-NMC-Li is feasible for all propellers, primarily due to MGO's high energy density, which requires only a small amount of energy from batteries. However, the hybrid configuration DF-NMC-Li is feasible only with propeller type 2, owing to the lower energy density of the batteries and methanol in comparison to MGO.

## Continuous long cycle

The DF configuration can be feasible if combined with a type 2 propeller, even though it requires hull extension or storage in the fish hold. However, using H<sub>2</sub>(l) as a mono fuel is not technically feasible for any propeller type, as it exceeds the extension length or results in too much lost volume in the fish hold. The technically feasible hybrid configurations are generally similar to the 100hr long cycle, with the exception of DF-NMC-Li. This configuration requires additional volume of methanol compared to MGO, leading to the need for additional energy from batteries. Consequently, DF-NMC-Li is only feasible with the type 2 propeller.

Since the mono fuels use the same emission factor for both 100hr and continuous long cycles, their CO<sub>2</sub> emission reductions are equal. As previously mentioned, the hybrid fueled configurations are designed to achieve a 40% CO<sub>2</sub> reduction, and thus, their emission reductions are not visualized, as they all achieve the same reduction target of 40%. For the WHR systems, the battery is not taken into account since it does not have enough heat flow in the exhaust.

If it is found that the proposed configuration meets the requirements, it is considered technically feasible. Subsequently, further analysis will be conducted to assess the economic performance of the different configurations. The unfeasible configurations will be excluded from the scenarios which follow in the upcoming sections. Table 8 summarizes the technical feasible propulsion configurations. Based on these developments it is assumed that using a larger diameter propeller is highly cost-effective regardless of the chosen energy carrier and thus it was decided to further analyze the configuration with the type 2 and type 4 propeller applied. Figure 3 demonstrates the economic performance of the 100-hour and continuous long cycle, combined with either a type 2 or type 4 propeller, for all technical feasible propulsion configurations. Figure 4 represents the total cost of owner ship, minus the remaining value of the ship including its propulsion configuration, (Equation 4).

**Table 8. Technically feasible configurations**

	Fuel	Config.	100 hr long cycle	Continuous long cycle
			Propeller type	Propeller type
Mono	HVO	D-E	Original, 1,2,3,4	Original, 1,2,3,4
	FAME	D-E	Original, 1,2,3,4	Original, 1,2,3,4
	DF	D-E	2,4	2,4
	Hydrogen	E	1,2,3,4	-
Hybrid	MGO-H <sub>2</sub>	D-E	All	All
	MGO-NMC-Li	D-E	2,4	2,4
	DF-H <sub>2</sub>	D-E	All	All
	DF-NMC-Li	D-E	1,2,3,4	2,4

A number of trends can clearly be spotted for the long term 15 year projection in Figure 3. First, the new build vessel surpasses all retrofit configurations in performance, primarily due to two factors. Firstly, the maintenance costs of the hull, including auxiliary systems, are significantly lower compared to retrofit configurations due to the age of the hull and systems. Secondly, fuel costs are low because MGO is relatively inexpensive, and the energy consumption is minimized due to the hull being optimized for a 4.0 meter diameter propeller. In contrast, the DF hybrid configurations yield poorer results compared to the MDO hybrid configurations. This is directly attributed to methanol being a more expensive fuel than MGO, and the carbon emission tax not compensating for the equal amount of emissions generated by both fuels. Although the HVO and FAME show promising numbers, they still exhibit a significant operational increase compared to the original configuration. However, over the long term, this difference diminishes as the emission tax rises. The TCO analysis for the 100-hour long cycle indicates that while the new build vessel has low operational costs, its performance is somewhat hindered by a high TCO resulting from substantial capital expenses in 2023. Despite higher operational expenses, the HVO and FAME demonstrate promising TCO lines due to being drop-in fuels, which require lower capital expenses. The MDO-Hydrogen, despite having higher capital expenses compared to fuels like MGO, HVO, FAME, or DF, shows good results owing to the low forecasted electricity prices.

**Figure 3: Opex and TCO, for type 2 propeller, 100hr and continuous long cycles, including new build vessel. The MGO DD is the reference to original costs**

**Figure 4: TCO – remaining value, for type 2 propeller including new build vessel. The MGO DD is the reference to original costs**

Based on Figure 4 a short description is provided on what can be concluded when including the remaining value of ship and propulsion configuration into the TCO. In contraction to Figure 3 the high capital expenses in year 2023 are roughly included for in these figures. The hybrid MDO-NMC Li option shows promising performance despite its high capital expenses in 2023, this is again assumed to be caused by the low forecasted electricity. It is important to note that the average battery life is 15 years for the two long cycles, depending on the number and types of charges and charges. Therefore if, for any reason, there is a desire to proceed with the vessel, it would require a significant capital investment for the battery configurations. This is not the case for the other options. The options for mono hydrogen can be concluded to be technically or economically not feasible using the forecasted parameters from Table 3. The drop in fuels HVO and FAME actually show to be a very good option, but as mentioned their TTW factor is very sensitive to interpretation of IMO regulations, and thus could result in not being technically feasibly in 2030 when regulations change. To eliminate this uncertainty, an alternative option could be chosen, such as methanol. The main drawback of this option is the currently predicted higher energy carrier prices, which consequently increase the TCO.

## CONCLUSIONS

This study employed an assessment model to evaluate various technical configurations of energy carriers, energy converters, and energy reduction methods on Dutch beam trawlers. The findings include analyses performed on different emission reduction techniques for a case vessel operating under either a continuous or 100-hour operational profile.

### Technical Feasibility

#### *Both long cycles:*

None of the mono battery configurations are feasible due to exceeding the maximum added draught and extension length. However, fuels such as HVO and FAME are technically feasible as long as they are considered zero emission fuels by the IMO. The hybrid propulsion configurations MGO-H2(l) and DF-H2(l) are technically feasible for all propeller types, including the original propeller, due to the relatively higher energy density of Methanol and MGO compared to liquid H2. It can also be concluded that the implementation of WHR or regenerative braking systems, or a combination of both, does not determine whether the 40% CO<sub>2</sub> emission reduction target is met or not. However, installing these systems will contribute to additional complexity, volume, and weight of the overall machinery configuration.

#### *100hr long cycle:*

Dual fuel configuration only achieves the 40% CO<sub>2</sub> emission reduction target when combined with propeller type 2(4.0D) to reduce energy consumption. The mono-fuel hydrogen configuration requires propeller upgrades to prevent exceeding the maximum extension. The hybrid configuration MGO-NMC-Li is feasible for all propellers due to the high energy density of MGO, requiring only a small amount of energy from batteries. The hybrid configuration DF-NMC-Li is only feasible with propeller type 2 due to the low energy density of the batteries and methanol.

#### *Continuous long cycle:*

The DF configuration, when combined with a type 2 propeller, results in a feasible configuration, although hull extension or storage in the fish hold may be required. The mono fuel H2(l) is not technically feasible for any propeller type due to exceeding the extension length or losing volume in the fish hold. The technically feasible hybrid configurations are similar to the 100hr long cycle, except for DF-NMC-Li, which requires additional volume due to methanol requirements. The energy scale of batteries is such that this hybrid configuration is only feasible with a type 2 propeller.

### Economic feasibility

Depending on the amount of available financial resources, available subsidy, and to what extent one is willing to take risks, the following conclusions can be made for different categories of initial capital expenses:

#### *€0-€2.5M*

The cheapest option to meet the 2030 regulations is the switch to bio-diesels HVO and FAME. Because these options are fully drop-in, there is no need for significant investments in system and vessel conversion, which applies to both types of long cycles. However, a major drawback of this strategy is the sensitivity to future regulations. This is partly due to the fact that the low CO<sub>2</sub> emissions for these fuels are entirely determined by regulations and the limited availability of raw materials. As a result, it is possible that within a short period, this option will no longer ensure IMO compliance.

A second option that can be recommended for any type of fuel and long cycles is to increase the propeller nozzle diameter. Although the Orcan WHR is estimated to have a payback period of 8-9 years (100-hour cycle) and 5 years (continuous cycle),

the investment of approximately €250k is still significant and does not determine compliance with the IMO regulations. Although in the long run the Orcan will result in a reduction of TCO compared to not applying it.

For both long cycles an option which requires more initial investments although less sensitive to regulations and can be cheaper in the long run is the conversion to methanol dual fuel configuration or to hybrid MDO-battery option, this applies to these configurations with 4.0m diameter propeller. The methanol option requires a lower investment, but the MDO-battery option outperforms it despite the high initial investment, thanks to the low predicted operational costs mainly caused by low forecasted electricity prices.

### **€2.5M+**

In addition to the retrofit options, this option also includes the possibility of building a new ship. Once again, it is recommended to use a larger propeller for all configurations. Looking at Figure 3 and 4, it can be observed that in the long term, both types of long cycles show that the hybrid MDO-battery and the new build options deliver the best results in terms of TCO. For both options, it is again noted that they will be less sensitive to future prices of alternative fuels or the impact of (inter)national regulations on tax emissions.

In the assessment between the retrofit option to MDO-battery and the newbuild, it should be considered that after the assumed 15-year lifetime, the retrofit option will have virtually no remaining value, and the hull of the ship will be technically written off due to its age. This is not the case for the newbuild option, which still holds significant remaining value and is technically capable of many more years of service, provided it is well-maintained. As calculated with this model, no attempt has been made to calculate the labor hours required for installing the new propulsion configuration. However, the mentioned newbuild price does include the total cost of materials and labor. As a result, the lines for retrofit and new build may give a distorted picture. Therefore, despite the ease of saying it and the possibility of achieving it financially, committing the company to a large debt for many years, a newbuild ship is considered a better option when considering costs and lifespan.

### ***Energy carrier storage***

Due to practical considerations, it is not advised to use both the net store and fish hold to store the energy carrier. The costs to extend the vessel are very small compared to the costs for new propulsion configurations. This trend means that if one decides to extend the vessel, the extension length is not that important when looking at costs. This also reinforces why you wouldn't want to use a net store if you extend, since the costs to prevent giving up such a practical volume are very low.

The practical influence of using the fish hold is the reduction of storage volume for fish boxes. The practical influence of hull extension is a potential increase in operational costs due to increased hull resistance. The increase in operational costs, in reference to the original configuration, is very small. Only in the absence of financial resources would the choice be made to store the energy carrier in the fish hold. However, if an owner is convinced to have an excessively spacious fish hold and only a small additional volume is needed for energy carrier storage, then the fish hold can also be used.

# Ammonia Bunker Vessel: Ship Design for Energy Transition

Friederike Dahlke-Wallat<sup>1</sup>, Katja Hoyer<sup>1</sup>, Ljubisav Isidorović<sup>1</sup>, Sophie Martens<sup>1</sup>, Nathalie Reinach<sup>1</sup>, Benjamin Friedhoff<sup>1</sup>, and Igor Bačkalov<sup>1,\*</sup>

## ABSTRACT

*This paper presents the basic design of a coastal ammonia carrier, intended to facilitate the energy transition by providing small-scale bunkering services to ferries in the South Baltic Sea. Due to the size and the purpose of the ship, a classic design process which builds on the experience and benefits from the prototype ships cannot be implemented in a straightforward manner. It follows that the energy transition may have a substantial impact on the design of otherwise conventional ship types, and that a hybrid approach to ship design comprising traditional design methodologies, advanced CAD tools, and experimentation is needed.*

## KEY WORDS

Ammonia; Energy transition; Bunker vessel; Coastal ship; CAMPFIRE.

## INTRODUCTION

Alternative fuels play a major role in the energy transition of shipping, whereby one of the considered solutions is ammonia. While most of the ship design studies focus on the development of ships powered by novel fuels, this paper addresses the development of the infrastructure necessary for the reliable supply of such fuels, which also includes new bunker ships. Namely, the technologies for both the waterborne transport of liquid ammonia and the (ship-to-ship and truck-to-ship) refueling of ships with ammonia are being developed. This paper presents the design of a coastal ammonia bunker vessel, which is intended to provide small-scale bunkering services to future ammonia-powered ferries operating in the South Baltic Sea.

Liquefied gas carriers have been in use since the 1930s. The current fleet stands at approximately 1600 units (see SIGTTO, 2021), whereby some 200 ships can carry ammonia as cargo (see DNV, 2020). Thus, it may be concluded that substantial experience in design of ammonia carriers already exists. Such experience, however, may be of limited assistance in the present study, as the coastal ammonia bunker vessel has several unique features setting it apart from the conventional gas carriers. To compensate for the absence of an appropriate prototype ship, the design process described in the paper utilizes a “hybrid” approach, where the traditional ship design methodology (characteristic for the “design spiral”) is blended with the advanced CAD tools, and the decision-making is supported by the statistical data on similar vessels, collected for the purpose of the study. Additional insights gained from the model tests are used primarily for the design appraisal but may also serve to assess the reliability of some of the classical methods for evaluation of powering requirements often used in early stages of design. Therefore, the purpose of the paper is two-fold. On the one hand, it explores the impact of energy transition on the design of bunker ships. On the other hand, it investigates the applicability of the classical methods in a design process which is handicapped by the lack of reliable data and by virtual nonexistence of the specific design guidelines.

## OWNER'S REQUIREMENTS AND DESIGN OBJECTIVES

The “owner’s requirements” follow from a scenario considered within the project. In future, the ammonia which can be supplied as fuel may be available from the tank storage in Peez situated in the vicinity of the port of Rostock. Alternatively, green ammonia may be collected from the offshore wind parks in the Baltic Sea. The ferries operating in the Baltic Sea have been identified as potential clients. Using Rostock as the homeport, the ship would supply with ammonia the long-range ferry sailing on the route Travemünde–Trelleborg and the short-range ferry sailing on the route Gedser–Rostock, see **Figure 1**. This determines the South Baltic Sea as the operational area of the ship. The principal “owner’s requirement” – cargo capacity of the ship – is decided based on the estimated requirements for ammonia as fuel of the two ferries: 650 m<sup>3</sup> and 300 m<sup>3</sup> of ammonia would be necessary for the long- and the short-range ferries respectively to complete their round trips. It follows that the ship’s cargo capacity should be around 1000 m<sup>3</sup>.

**Figure 1. Routes of (future) ammonia-powered ferries (base map: <https://d-maps.com/>).**

The targeted ship speed is 11 kn. The ship is to be conventionally powered to overcome the initial “supply-demand” obstacle of the green transition, that is, the limited implementation of greening technologies due to the lack of infrastructure providing sustainable alternative fuels which is, in turn, justified by the limited number of potential customers. An ammonia bunker vessel powered by diesel and/or drop-in fuels would be, therefore, an initial step towards the acceleration of the shipping energy transition.

Design objectives follow from the owner’s requirements. As with any cargo ship, the primary goal is to provide efficient transport and supply of the required cargo volume to the customers. The costs of the cargo tanks’ production should be low and cargo space should be easy to maintain. Thus, the geometry and arrangement of cargo tanks – which have to comply with the safety regulations – have a decisive influence on the design as a whole. The design should facilitate the bunkering operations and safe handling of ammonia, which also affects the design of the cargo tanks as well as the deck arrangement and positioning of the related equipment. Considering that the cargo capacity is relatively small, the ship will be small as well, which is not favorable from the seakeeping point of view. The seakeeping performance of the vessel may be improved to an extent with a favorable hull form (or its operation may be limited with respect to the relevant seakeeping criteria).

## SELECTION OF MAIN PARTICULARS

The ship design process usually benefits from a prototype vessel; if an adequate prototype is available, main dimensions may be selected with more confidence, weight estimation may be carried out with more precision, a range of technical solutions implemented on the prototype may be adopted, while the layout of the systems and the general arrangement of the prototype could be used as blueprints for the new design, and so on. It will be shown, however, that a suitable prototype is nonexistent in this case.

The initial selection of the main particulars (mass of displacement, length, beam, draught, depth, and hull form coefficients) was performed using the empiric regression formulae available from the literature (see Barras, 2006; Papanikolaou, 2014; Schneekluth and Bertram, 1998; Takahashi et al., 2006; Watson, 1998). However, it may be questioned how adequate such

formulae are considering that most of the authors used other ship types (such as e.g., general cargo ships and bulk carriers) in generating the underlying databases, with only occasional references to ship types which are only marginally relevant for this study, such as oil tankers. Additionally, it should be taken into account that some formulae were based on nowadays outdated hull forms and ship types, as pointed out by Papanikolaou (2014). Therefore, to verify the fitness of thus obtained values, a database containing the information on 41 relevant ships (liquefied gas carriers, chemical tankers, product carriers, bunker vessels, etc.) was created for the purpose of this study using a range of sources (hereinafter “DST database”). The features of the database are reported in the Appendix to this paper.

Assuming that the mass of deadweight is approximately:

$$m_{DWT} \approx 1.1 \cdot m_{cargo} \quad [1]$$

the first estimation of the mass of ship displacement may be done using the deadweight coefficient, expressed as the deadweight-over-displacement ratio:

$$\eta_{DWT} = \frac{m_{DWT}}{\Delta} \quad [2]$$

The deadweight coefficient may significantly vary depending on the ship type, so its value should be carefully selected. In the examined case, however, this is not a trivial task, because the references to adequate ship types (e.g., liquefied gas carriers) are seldom. In addition, a difference in density of liquefied ammonia ( $\rho_{NH_3} = 0.68 \text{ t/m}^3$ ) when compared to LPG ( $\rho_{LPG} = 0.525\text{--}0.58 \text{ t/m}^3$ ) and LNG ( $\rho_{LNG} = 0.43\text{--}0.48 \text{ t/m}^3$ ) exemplifies the uncertainty related to a proper selection of the deadweight coefficient. Barras (2004) reports  $\eta_{DWT} = 0.62$  for “LNG or LPG ships”. Takahashi et al. (2006), on the other hand, report  $\eta_{DWT} = 0.72$  for LNG ships. In addition to the difference in cargo density, this value is found not to be relevant for the present study, as it was obtained by analyzing mostly very large ships: gross tonnage of more than 90% of the analyzed LNG ships was greater than 30000 GT, while small ships made less than 2% of the database used by Takahashi et al. (2006). On the other hand, the LPG carriers analyzed by Takahashi et al. (2006) feature two distinct groups of vessels: ships up to 50000 GT and ships around 100000 GT. Considering that only the smaller ships are of interest for the present study, a displacement-gross tonnage relation applicable to ships up to 50000 GT was established. Based on this  $\Delta$ –GT relation and the available  $m_{DWT}$ –GT relation, it follows that the deadweight coefficient of LPG carriers (of up to 50000 GT) would be  $\eta_{DWT} = 0.625$ . Finally, the DST database of relevant ships shows that there is a strong correlation between the displacement of the ships and their cargo capacity (coefficient of determination of the regression line is  $R^2 = 0.955$ ), see **Figure 2**, which can be expressed as:

$$\Delta = 1.6374 \cdot V_{cargo} - 219.73 . \quad [3]$$

**Figure 2. Correlation of ship displacement and volume of the cargo tanks of the relevant ships in the DST database.**

The preliminary estimation of displacement is thus adopted as the average of the three values which are computed based on Barras (2004), Takahashi et al. (2006) for ships of up to 50000 GT, and equation [3]. This allows for assessment of the ship

length  $L$  which is computed as the average of five values ranging from 55.7 m to 60.8 m, obtained by regression formulae given in Papanikolaou (2014), Takahashi et al. (2006), and Watson (1998). The ship beam  $B$  is estimated based on considerations of Takahashi et al. (2006), and Watson (1998). The block coefficient  $C_B$  is decided based on the range of recommendations (mostly related to the Froude number of the ship) given in Schneekluth and Bertram (1998) and Watson (1998). The longitudinal center of buoyancy  $LCB$  is estimated based on the recommendations given in Schneekluth and Bertram (1998) and Papanikolaou (2014). Once the values of  $\Delta$ ,  $L$ ,  $B$ , and  $C_B$  are known, calculating design draught  $d$  is straightforward. Nevertheless, each of the parameters could be subject to further refinement. In addition, even though the values of some of the parameters, such as the block coefficient, may be indicative of the existing designs if obtained by empiric formulae, they may as well be a matter of decision which deviates to an extent from the calculated values, depending on the targeted performance. A similar argument applies to the waterplane area coefficient  $C_{WL}$  which may be calculated using the empiric formulae as well (such as the ones provided by Papanikolaou, 2014) but may be also reconsidered in light of a specific design aspect. For instance, the  $C_{WL}$  value may be tuned aiming at improved seakeeping performance: to improve seaworthiness and diminish the resonance of heave and pitch in head seas, the non-dimensional natural heave and pitch periods should be as short as possible which may be achieved by the increase of the waterplane area coefficient (with unchanged values of the main dimensions, displacement, and speed). The midship area coefficient  $C_M$  is calculated as the average of three values obtained using formulae given in Schneekluth and Bertram (1998). The depth of ship  $D$ , as a minimum, should comply with the requirements of the International Convention on Load Lines (ICLL, 2003) for Type A ships. The first estimate of the main particulars is reported in **Table 1**.

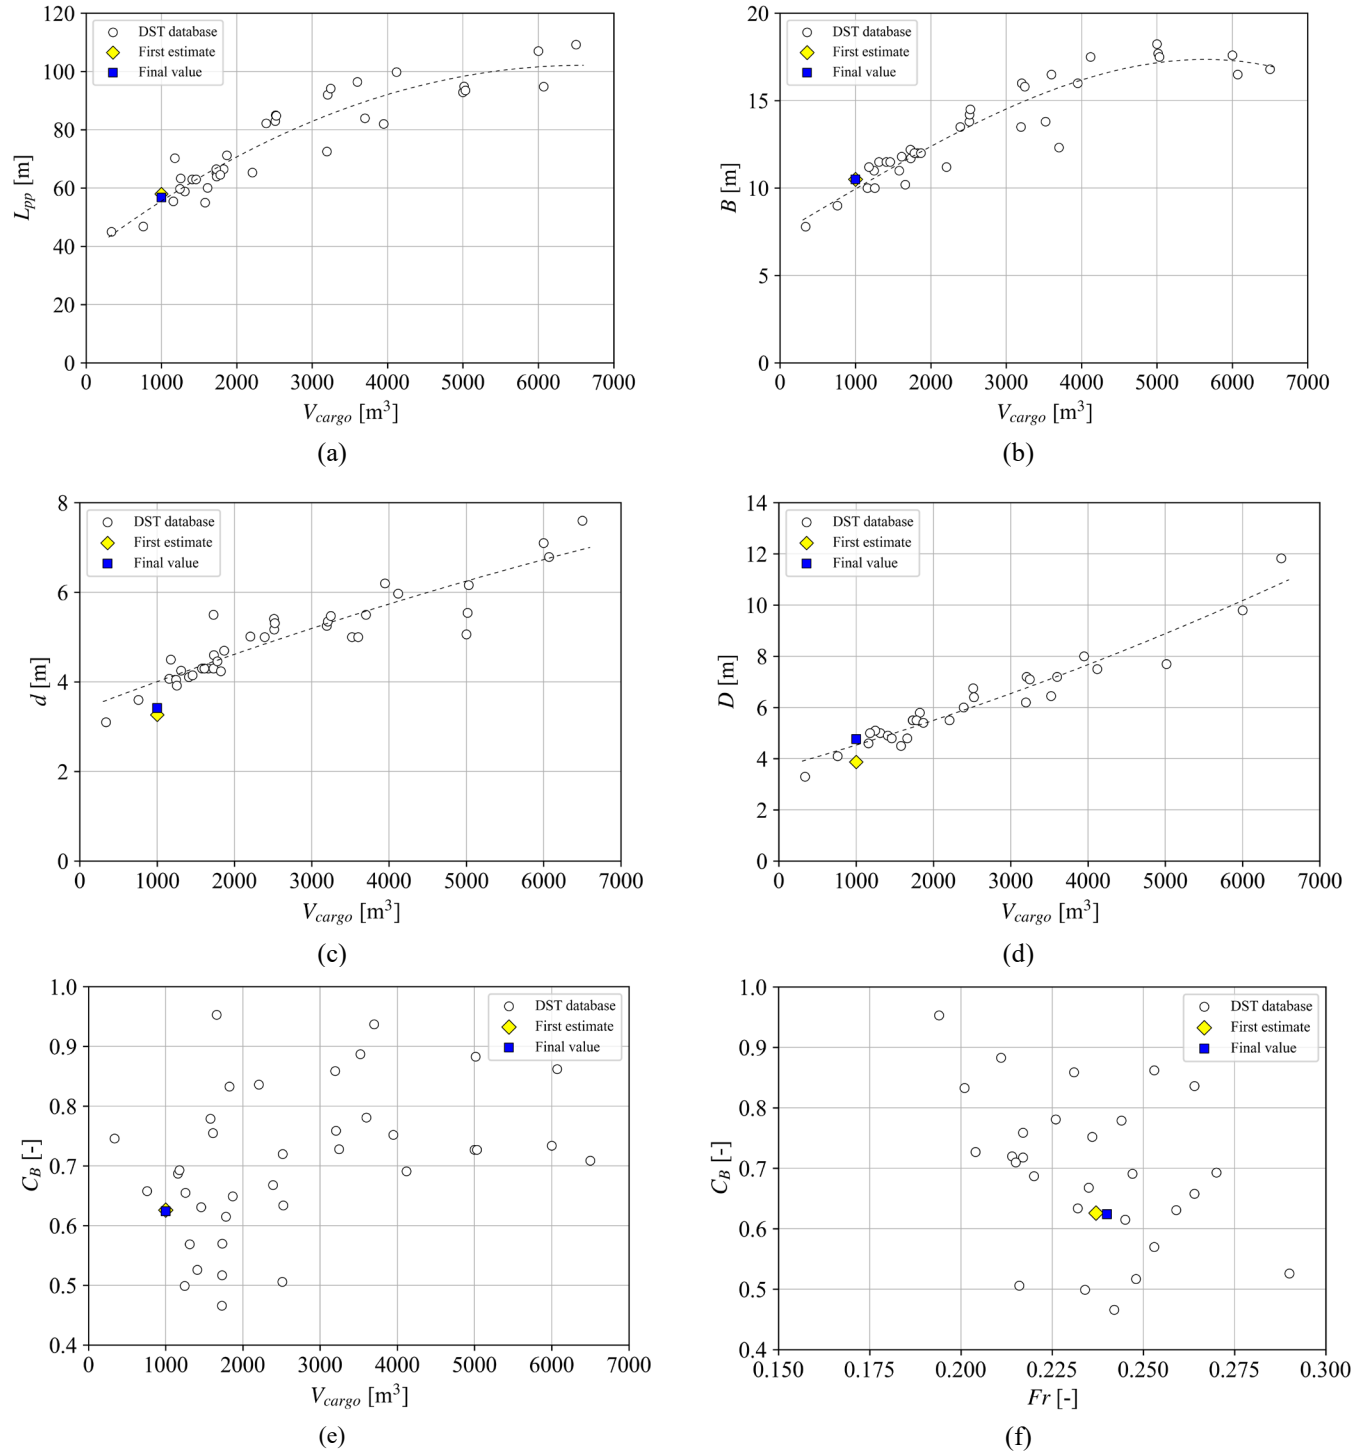

**Table 1: First estimate of the main ship particulars**

Cargo capacity	$V_{cargo}$	1000 m <sup>3</sup>
Mass of deadweight	$m_{DWT}$	750 t
Displacement	$\Delta$	1275 t
Length	$L$	58 m
Beam	$B$	10.5 m
Draught	$d$	3.26 m
Depth	$D$	3.87 m
Freeboard	$f$	0.61 m
Block coefficient	$C_B$	0.626
Waterplane area coefficient	$C_{WL}$	0.790
Midship area coefficient	$C_M$	0.969
Longitudinal center of buoyancy	$LCB^*$	-2 % $L$

\* In reference to midships

The estimated main particulars were subsequently compared to the trends observed in the DST database of relevant ships (note that the trendlines shown in **Figure 3** are indicative only and were not used in the calculation of the main particulars). **Figure 3a** and **Figure 3b** show that the first estimates of length and beam fit well into the trends detected for the existing ships. This may not be stated for the estimated design draught, which appears to be lower than what could be expected for the ship of the given cargo capacity, see **Figure 3c**. As previously pointed out, the draught depends on the block coefficient, provided that  $L$ ,  $B$ , and  $\Delta$  are fixed. However, there is no clear trend in the  $C_B$  values of the existing ships, as may be seen in **Figure 3e**. The scatter of  $C_B$  values is particularly large for ships of smaller cargo capacity, up to 2500 m<sup>3</sup>. An increase of the draught would imply a further decrease of the (already relatively low) block coefficient, which could result in a loss of volume available for the cargo space, and, consequently, complex geometry and high production costs of cargo tanks. On the other hand, increase of the block coefficient would lead to a further decrease of the draught, which is generally favorable from the cargo stowage point of view but may lead to a higher frequency of slamming. Block coefficient is equally poorly correlated to the Froude number, see **Figure 3f**. The absence of correlation of  $C_B$  to both  $V_{cargo}$  and  $Fr$ , confirms that the block coefficient is often a matter of a deliberate choice rather than an outcome of a statistical analysis. Ship depth is also well correlated to cargo volume of the existing ships, see **Figure 3d**. A weaker correlation is found between the freeboard  $f$  and ship length, see **Figure 4**. A higher freeboard implies improved safety (greater righting lever, larger reserve buoyancy, and lower frequency of shipping of green water) but comes at a cost (e.g., increase of operational costs related to higher gross tonnage). The deviation of the freeboard of the existing ships from the minimum freeboard as prescribed by the International Convention on Load Lines (ICLL, see IMO, 2003) may be substantial and may vary considerably for the ships of approximately the same length. It follows that the selection of  $f$  and  $D$  is not straightforward and that it is probably guided by the suitability of space for cargo stowage. As a first estimate, the selected freeboard is close to the minimum value required by IMO (2003) since the trends observed for the existing ships of similar lengths comply well with the ICLL provisions.

Finally, it should be noted there are only two ships with  $V_{cargo} \leq 1000 \text{ m}^3$  in the DST database (i.e., less than 5% of the total number of ships in the database): a chemical tanker and a product tanker. This highlights the difficulty of finding an adequate prototype ship.

**Figure 3. Comparison of estimated and adopted ship particulars to the trends observed in the DST database of relevant ships. Yellow diamonds correspond to the first estimate of the ship particulars (reported in Table 1). Blue squares correspond to the final values of the ship particulars (reported in Table 2).**

Once the main particulars are selected, the preliminary stability assessment and resistance prediction may be performed, and the so-called “weight groups” may be estimated by means of approximate formulae, see e.g., Watson (1998) and Kalajdžić (2010). This allows for reassessment of the mass of displacement which can be calculated as the sum of the weight groups masses. At this stage, the weight groups are not detailed, primarily because the cargo tanks and the related systems and equipment are still undefined. For the sake of brevity these intermediate steps are not shown.

**Figure 4.** Comparison of estimated and adopted freeboard to the trend observed in the DST database of relevant ships (dashed line) and to the minimum values required by the International Convention on Load Lines (solid line). Yellow diamond corresponds to the first estimate of the ship freeboard (reported in Table 1). Blue square corresponds to the final value of the ship freeboard (reported in Table 2).

## HULL FORM AND CARGO TANKS

In absence of the prototype vessel, the initial hull form (see **Figure 5**) was based on typical geometries of coastal cargo ships, as found in e.g., Journee and Versluis (1999). The hull form is subject to modifications which may be needed to accommodate sufficient space for cargo tanks and associated cargo-handling equipment and attain the targeted hull properties (hull form coefficients and the longitudinal center of buoyancy as given in **Table 1**). At this stage, the CAD tools (NAPA Designer and SolidWorks) are extensively used to check the effect of the hull modifications on the sizing and arrangement of the vessel’s main “blocks”: cargo space, machinery rooms, accommodation and working spaces, ballast and fuel tanks, etc.

The shape of cargo tanks intended for liquefied ammonia depends on whether the liquefaction is achieved by pressurizing the gaseous ammonia (resulting in fully pressurized ammonia), by pressurizing in combination with refrigeration (resulting in semi-refrigerated ammonia) or by refrigerating the ammonia to temperatures below  $-33^{\circ}\text{C}$  at ambient pressure (resulting in fully refrigerated ammonia). All the above liquefaction methods are used on seagoing ships, whereby refrigeration is usually used for larger quantities while pressurizing is more often used for the transport of smaller ones. Thus, the decision on the cargo tank geometry and arrangement (which also affects the hull form) depends on the selection of the liquefaction approach. Pressurized and semi-refrigerated ammonia are carried in cylindrical pressure vessels (the so-called Type C tanks). Type C tanks may bring some benefits in view of the simpler (structural) design. On the other hand, the utilization of the hull volume available for cargo space is relatively low with the Type C tanks. Fully refrigerated ammonia is carried in prismatic Type A tanks where overpressure is managed by a boil-off management system, i.e. the re-liquefaction unit. The Type A tanks are self-supporting tanks, typically made of flat surfaces and shaped so as to maximize the space available for cargo. The prismatic tanks may allow up to 40% more cargo containment space (DNV GL, 2019). (For the main features of different types of cargo tanks used on liquefied gas carriers and typical design solutions see e.g. SIGTTO, 2021.) Characteristics of materials suitable for cargo systems of liquefied gas carriers (cargo tanks, process pressure vessels, and cargo piping) are detailed in the International Code for the Construction and Equipment of Ships Carrying Liquefied Gases in Bulk (IGC Code, see IMO, 2014). In view of the small cargo capacity, it was initially assumed that the ammonia would be pressurized and carried in Type C tanks. However, it will be shown that the final decision on the liquefaction method and, consequently, the design of the cargo tanks, depends on several design and operation aspects.

To attain sufficient volume of the cargo space and provide adequate room for the propeller, while maintaining the desired values of the block coefficient and the longitudinal center of buoyancy, it was necessary to increase the depth of the ship, from  $D = 3.87$  m to  $D = 4.77$  m. It was previously indicated that while the increase of freeboard is to the benefit of safety, it

also adds to the production costs (and some operational costs). Nevertheless, as it was pointed out by Schneekluth and Bertram (1998), the depth is the “cheapest” ship dimension since its increase results in a relatively small increase of steel weight. (Interestingly, the new depth value results in  $B/D = 2.2$ , which seems to be the most common ratio for the small gas carriers, see **Figure A1** in the Appendix to the paper.) Additionally, the raising of the deck caused the distortion of the hull lines which led to a decrease of the wetted surface at the stern, which is beneficial from the ship resistance point of view. The evolution of the hull lines of the vessel – from the initial hull form (shown in gray lines) to the final hull form with the raised main deck (shown in blue lines) – is reported in **Figure 5**. The cross sections from “0” to “54” are equally spaced at 1 m distance; the section “-1” is at -1.55 m. In both cases, the sections are shown up to the main deck (i.e., the geometry of the poop and the forecabin is not shown). In addition to attaining the targeted values of  $C_B$  and  $LCB$ , a positive “side effect” of the hull modification is the increase of the waterplane area coefficient in comparison to the first estimate given in **Table 1**, which is beneficial from the seakeeping point of view.

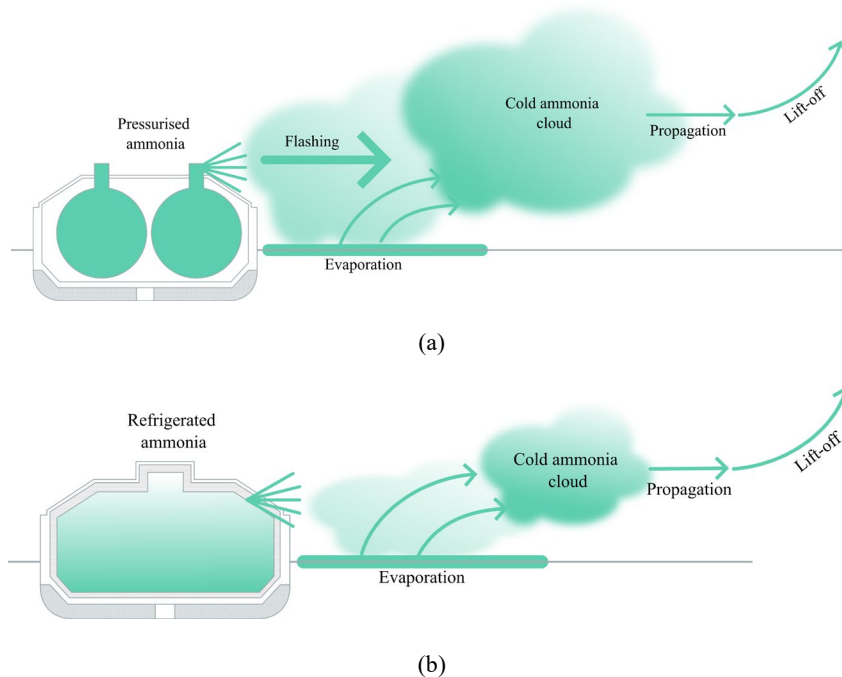

**Figure 5. Body plan of the vessel. The initial hull form is shown in gray lines; final hull form is shown in blue lines.**

The completion of the hull form was followed by the fitting of the cargo tanks. Despite the increase of the ship depth, the Type C tanks intended for pressurized ammonia could not be fitted without further considerable modification of the hull form. In order to comply with the ship survival capability and location of cargo tanks provisions of the 2014 IGC Code, that is, to attain the minimum distances between the cargo tanks and the hull, the diameters of the cylindrical tanks have to be limited. To attain the required cargo volume with the constrained tank diameters, the length of the cylinders has to be increased; this, however, results in the substantial loss of space available for forward and aft engine rooms. A compromise may be partly achieved by positioning the tanks higher relative to the baseline. In such a case, however, intact stability criteria cannot be satisfied. This led to reconsideration of the adopted liquefaction method.

Considering the toxicity of ammonia, a major factor to be accounted for when it comes to the selection of the liquefaction method is safety. As observed by the Society of International Gas Tanker & Terminal Operators, despite a good safety record of gas carriers, the risks related to accidents are greater in ports than at sea (see SIGTTO, 2021). The bunker vessel which is the subject of this study is supposed to serve passenger ferries; the vessel should, thus, operate in the vicinity of the passenger terminals in Travemünde and Rostock where an average of 10 and 20 passenger ships port calls respectively are recorded daily. Therefore, the consequences of potential accidents involving leakage of ammonia may be grave in view of the possibly large number of casualties. The spreading of ammonia in the event of leakage, however, differs depending on the liquefaction method. In the event of refrigerated ammonia leakage, the ammonia gas cloud forms due to evaporation of the cold pool of spilled ammonia (**Figure 6b**). The gas cloud formed as a consequence of pressurized ammonia leakage is significantly larger as it is fed by both a high flow velocity jet from the damaged tank and the evaporation of the pool of spilled ammonia (see **Figure 6a**). Once evaporated ammonia reaches ambient temperature, it will rise – this process will, however, take more time (i.e., the exposure to ammonia will be prolonged) if the ammonia was pressurized.

Some operational aspects may also affect the choice of the liquefaction method. Considering that the vessel should operate in ports and in a coastal area with dense traffic, less obstruction of the view from the wheelhouse could be advantageous. This becomes particularly important in view of complex systems and numerous equipment for handling ammonia and bunkering operations arranged on the main deck. Cylindrical tanks, required for carrying the pressurized ammonia, would have to be positioned higher with respect to the baseline, which could have a negative impact on the visibility from the bridge. Furthermore, in direct relation to the vessel’s purpose – bunkering – it is to be noted that at high pressures required for compression liquefaction the dry disconnect couplings of bunkering hoses cannot be manually operated by the crew.

Therefore, based on the considerations given above (space utilization, safety, and operational aspects) it was decided to change the liquefaction method used on the bunker vessel. Instead of carrying pressurized ammonia in the cylindrical Type C tanks (**Figure 7a**), the vessel would carry refrigerated ammonia in the prismatic Type A tanks (**Figure 7b**) which would be a common solution on large liquefied gas carriers, rather than on small ones (see SIGTTO, 2021). The space utilization with Type A tanks would be indeed much better: the total length of the Type A tanks is 26.5 m, while the length of the Type C tanks would be (at least) 33.4 m. The visibility from the bridge would also improve: the highest point on the tank covers relative to the baseline would be 6.68 m for Type A tanks, as compared to (at least) 8.1 m for Type C tanks. The stability and survivability requirements can be satisfied in all relevant loading conditions if Type A tanks are utilized.

**Figure 6. Spreading of ammonia in case of leakage of (a) pressurized ammonia and (b) refrigerated ammonia.**

**Figure 7. Comparison of the space requirements for (a) pressurized ammonia carried in the Type C tanks and (b) refrigerated ammonia carried in the Type A tanks.**

This allows for a more precise estimation of weight groups' masses and centroids. The mass of the cargo tanks, which form a sizable part of the lightship mass and thus can significantly affect a range of design aspects, can be assessed based on the detailed CAD model of the tanks built in SolidWorks. The specific equipment and systems used for handling of ammonia could be itemized. Other weight groups may be determined with more reliability as well. The mass of machinery may be based on the actual main engine; the corresponding fuel consumption allows us to determine the required fuel supplies more precisely. The actual dimensions of the accommodations, poop and forecastle may be used in steel weight estimation, etc. The knowledge of the weight groups' masses and centroids makes it possible to determine the floating position of the ship in a range of relevant loading conditions and to calculate the ship stability parameters and compare them to the applicable regulatory requirements.

The main ship particulars, as adopted, are given in **Table 2**. The final value of the mass of displacement is less than 5% greater than the initially estimated value reported in **Table 1** (despite the increase of the depth), which is generally regarded to be within the acceptable boundaries. Greater differences would indicate that the main dimensions were not properly selected, which would require the process to be restarted, instead of advancing to the next stage of design. Considering the large initial uncertainty related to the type and size of cargo tanks and the related equipment, the questionable adequacy of formulae used in early stages, as well as the lack of an adequate prototype vessel which would be normally used in the estimation of the weight groups, the relatively low deviation of the mass of displacement from the preliminary assessment is most certainly a positive, yet (admittedly) somewhat unexpected outcome.

**Table 2. Main ship particulars**

Cargo capacity	$V_{cargo}$	1000 m <sup>3</sup>
Mass of deadweight	$m_{DWT}$	746.4 t
Displacement	$\Delta$	1337.8 t
Length over all	$LOA$	58 m
Length between perpendiculars	$L_{pp}$	56.869 m
Beam	$B$	10.5 m
Draught	$d$	3.415 m
Depth	$D$	4.77 m
Freeboard	$f$	1.355 m
Block coefficient	$C_B$	0.624
Waterplane area coefficient	$C_{WL}$	0.833
Midship area coefficient	$C_M$	0.992
Longitudinal center of buoyancy	$LCB^*$	-2.1 %L

\* In reference to midships

## DECK ARRANGEMENT

One of the design objectives is safe and efficient handling of ammonia in the course of loading and bunkering operations. This requires the vessel to be outfitted with specific systems and equipment, which ought to be adequately arranged on the main deck. To facilitate a fitting positioning of the installations for handling of the ammonia, the 3D model of the ship built in SolidWorks was utilized, see **Figure 8**. The systems include manifolds (position 1 in **Figure 8**) to connect the bunker line (represented in green), the purge line (represented in light blue) and the vapor return line (represented in yellow) suitably positioned along the parallel midship. A vapor return line is necessary as during bunkering no gaseous ammonia in the customer's bunker tank may be vented to the open air; to avoid the pressure build-up, the gaseous ammonia shall be taken over by the bunker vessel. Via the purge line all lines can be purged with nitrogen. Via the condensate return line the reliquefied boil-off gas can be given back from the re-liquefaction unit in the forecastle to the cargo tanks. In case of an emergency such as tank over-pressure, both tanks are equipped with redundant pressure relief valves. The emerging ammonia is then led to the vent mast (position 2 in **Figure 8**). The IGC Code states that cargo tank venting openings "shall be arranged at distance at least equal to  $B$  or 25 m, whichever is less, from the nearest air intake, outlet or opening to accommodation spaces, service spaces and control stations, other non-hazardous areas, exhaust outlet from machinery or from furnace installations onboard" (IMO, 2014). Since the area around the manifold is regarded as a work area, the vent mast is placed furthest away.

In addition to the manifold, the vessel is equipped with a bunker arm (position 3 in **Figure 8**) to serve customers with a high freeboard. A set of all bunker lines is directly attached to the arm. Bunker hoses can be stored on deck. To keep a safe distance from customers, the bunker vessel has four Yokohama fenders (position 4 in **Figure 8**). The safe distance also ensures that the bunker hose is not pinched or kinked during the bunker process.

All the auxiliary equipment, such as the re-liquefaction unit and the nitrogen plant, is stored in the forecabin, away from the bunker area. Often, on board larger ships, there is a dedicated deck house in the midship area. For this design it is assumed that the vessel is mainly operated very close to the shore/the terminal and does not need the amount of inert gas that a large gas carrier would need. Also, the re-liquefaction unit is rather small, and the ammonia is only transported over a relatively short distance to the next customer.

**Figure 8.** Simplified view of the main deck: arrangement of systems and equipment for handling of the ammonia

## POWER PREDICTION AND MODEL TESTS

Ship resistance and power demand were estimated in each of the described design phases. The resistance estimations were carried out using the well-known empiric methods, such as the “Holtrop & Mennen” (see Holtrop, 1984) and the “Admiralty coefficient” approach (see Telfer, 1963) which is based on the data of comparable ships. Additionally, the resistance and propulsion model tests with a 1:14.5 scale model were performed in the large shallow water basin of DST, at two different water depths corresponding to  $h_w = 12.5$  m and  $h_w = 5$  m in full scale. Effective power calculated based on the resistance estimations made by the empiric methods and the model tests are reported in **Figure 9**.

**Figure 9.** Comparison of effective power calculated using resistance estimations obtained with empiric methods and by means of model tests performed in the towing tank of DST.

The ship has a conventional drivetrain consisting of a diesel engine (691 kW@1406 rpm). The model was equipped with a four-bladed DST stock propeller (the propeller diameter being  $D_p = 1.84$  m in full scale, and pitch ratio being  $P/D_p = 0.955$ ). Since the main engine was selected based on the estimations done with empiric methods in the course of the basic design, the model tests were primarily used to verify if the predicted power would satisfy the owner's requirements. In addition, the model tests allow us to assess the reliability of the aforementioned empiric methods which are often used in the basic design. For instance, it may be observed that the Holtrop & Mennen method underestimates the resistance obtained in the model tests by some 20%. On the other hand, the best prediction was achieved using the Admiralty coefficient approach based on "ship 3" (red circles in **Figure 9**), which is indeed the most comparable one to the designed vessel (see **Table 3**).

**Table 3. Features of the ships used in the ship resistance estimation based on the Admiralty coefficient approach.**

		"ship 1"	"ship 2"	"ship 3"	design
$L_{pp}$	[m]	63.4	48	66	56.869
$L / \sqrt[3]{\nabla}$	[-]	5.62	4.71	4.95	5.21
$B/d$	[-]	3.58	3.53	3.41	3.07

Finally, the comparison of the total resistance recorded in model tests performed in two selected depths is reported in **Figure 10**. The chosen water depths are representative of the operational conditions in the designated area. As expected, a significant increase in resistance and, consequently, a reduction of speed in  $h_w = 5$  m can be observed, which needs to be considered in the prediction of the operational profiles.

**Figure 10. Comparison of total resistance obtained in model tests performed in the towing tank of DST in both tested water depths.**

## CONCLUSIONS

Energy transition of shipping goes beyond the modification of the ship propulsion and fuel systems and requires the development of the supporting infrastructure, including the vessels which could provide the bunkering service to ships utilizing novel fuels. The paper presented the basic design of a small ammonia bunker vessel, intended to provide ship-to-ship refueling services to future ammonia-powered ferries in the South Baltic Sea. Because of the size of the vessel (dictated by the cargo capacity at the lower boundary of capacities of the present ships) and its specific purpose (bunkering of passenger ships with toxic ammonia), the existing gas carriers could not be successfully used as prototypes. However, the formulae typically used in early stages of design (which may be found in the literature) proved to be robust enough to predict the vessel's mass of displacement and the main particulars with sufficient accuracy, despite not being developed with this specific ship type in mind. The inability to utilize the ship design spiral in a straightforward manner due to the absence of the prototype vessels was compensated for with an extensive use of CAD tools (NAPA Designer and SolidWorks) which facilitated architectural design of the vessel (i.e., arrangement of spaces and equipment) and minimized the uncertainties related to weight estimations.

The design is heavily influenced by the liquefaction method of ammonia, which in turn, depends on the ship operational profile and safety requirements. Even though liquefaction by pressurizing is typically used in maritime transport of smaller quantities of ammonia, in this case, the adopted liquefaction method was full refrigeration. Such a decision was driven by several design and operational aspects including much better cargo space utilization than it would be achieved by the pressurizing of ammonia, compliance with the survivability requirements of the IGC Code and intact stability requirements of the IS Code, more favorable dynamics of spreading of the toxic ammonia cloud in case of a spillage, and better visibility from the bridge (see Yang et al., 2022; SIGTTO, 2021; DNV, 2020; DNV GL, 2019). Again, the CAD tools enabled the sizing and positioning of the cargo tanks and arrangement of the associated systems and equipment, and fast verification of compliance with the design objectives and applicable regulations.

It is to be acknowledged that, considering the scarcity of adequate data which could be used in support of the decision-making, as well as the nonexistence of the design guidelines specifically intended for this kind of bunker ships, many decisions had to be made by the “designer” with the support of the CAD tools. This indicates that the design process could be further improved by implementing an automated multi-objective optimization (a “holistic ship design” as described in e.g., Papanikolaou, 2010; Marzi et al., 2018) provided that adequate software tools and computing resources are available. Such an approach allows for a fast analysis of dependencies between influential factors and exploration of a large number of (feasible) designs in search of an optimal solution. Nevertheless, regardless of accessibility of the tools and the implemented procedure, it is the designer who formulates the optimization criteria by considering the relevant regulatory, societal, and commercial aspects. In case of ammonia bunker vessel analyzed in this study, the formulation of criteria requires the knowledge of intricacies of energy transition, the understanding of operational risks associated with bunkering of ammonia, the specific environmental conditions in the operational area, etc.

The outcome of the study – presented in **Figure 11** – is a design which may be regarded as unconventional, primarily due to a fine hull form atypical for bunker ships and the adopted type of cargo tanks which is not common for small liquefied gas carriers. The success of the design was partly assessed with the model tests described in this paper, which addressed powering requirements in calm water. The design will be, however, the subject of the extended model tests which shall include the seakeeping performance and stability in waves of the vessel with partially filled cargo tanks. Only then, the success of the proposed design may be fully appreciated. Nevertheless, the outcome of the study indicates that the energy transition may require the development of new designs rather than reiteration of “off-the-shelf” ship design solutions.

# Retrofit modeling for green ships

Julien J. M. Hermans<sup>1</sup> and Austin A. Kana<sup>2,\*</sup>

## ABSTRACT

*This paper proposes a data-driven approach to reduce emissions in international shipping, aligning with the IMO's goal of achieving net-zero greenhouse gas emissions by around 2050. Digital twins (DTs) offer promise for maritime decarbonization due to their simulation and big data handling capabilities. However, fully realizing DTs for new-build is by definition challenging as it requires a real-time data connection. Thus, the research begins with retrofitting existing ships using operational data collected through Bunker Delivery Notes (BDNs), a mandatory method for larger ships since January 2019. The proposed framework constructs digital models to support the retrofit DT, that are tested on a 300m bulk carrier. A fuel consumption model is built using a gray box approach, while various wind-assisted ship propulsion systems are modeled using a white box approach. The study evaluates the design implications and emissions reduction potential of implementing these systems.*

## KEY WORDS

## INTRODUCTION

During the United Nations Climate Change Conference near Paris in 2015, the Paris Agreement was adopted by the 196 parties present which stated that global warming must be limited to below 2°C (EC, 2015). Unfortunately, international shipping together with international aviation were not taken into account in this agreement. As a reaction, the International Maritime Organization (IMO) adopted in 2018 an initial strategy in order to reduce greenhouse gas (GHG) emissions by international shipping (IMO, 2018).

The goal of this initial strategy is set on a reduction of GHG emissions by 50% in 2050 compared to emission levels of 2008. During their annual meeting in July 2023, the strategy was revised to net-zero GHG goal close to 2050, addressing the IMO's environmental ambitions (IMO, 2023). The maritime industry generates vast amounts of data concerning vessel operations, route details, port activities, and more. Yet, much of this data remains underutilized due to factors such as manual processing and limited application beyond specific purposes like incident assessment or environmental impact measurement (Swider et al., 2018). This is due to the involvement of multiple stakeholders and the complexity of modern vessel design and operation. To address this challenge, researchers recommend focusing on research and innovation in digitalization and data usage within the shipping industry, exploring technologies such as artificial intelligence, augmented reality, virtual reality, high-performance computing, and big data analytics (Mouzakitis et al., 2023; Swider et al., 2018). These technologies hold potential for various maritime applications, including vessel traffic management, energy system design and operation, autonomous shipping, fleet intelligence, and route optimization. Despite ongoing digitalization efforts in other industries, such as aerospace and manufacturing, the maritime industry lags behind in embracing these advancements due to its complex and heavily regulated nature (Mouzakitis et al., 2023). However, leveraging shipping data has the potential to drive beneficial developments in marine engineering and propel the industry toward more digitally driven processes.

As a result of the Paris Agreement, the European Commission delivered in 2021 their European Green Deal in which they adopted a series of project proposals in order to achieve their own goal of reducing European GHG emissions by at least 55% by the year 2030, relative to 1990, and zero-net GHG emissions by 2050. By achieving this goal, the EC wants to become the first climate-neutral continent in the world, hence zero emission for international shipping (EC, 2021a,b). One of these projects is the Digital Twin for Green Shipping (DT4GS) project, funded by the European Union's Horizon research program. The goal of DT4GS is to eventually accomplish zero emissions by 2050 for the ship types of the collaborating companies within the DT4GS project; represented by an oil tanker, a container ship, a bulk carrier, and a ROPAX vessel. The collaborating vessels function as so-called 'Living Labs' (LLs), where operational data is collected to be used for improving green ship design based on digital twin (DT) methods. This research supported the DT4GS project by investigating the feasibility of a data-driven design method to reduce ship's CO<sub>2</sub> emissions.

## WIND-ASSISTED SHIP PROPULSION

One obvious strategy regarding green shipping is the use of renewable energy, especially wind power. Due to its history with shipping and its availability at sea, the focus within renewable energy is shifting towards wind power (de Kat and Mouawad, 2019). Wind-assisted ship propulsion (WASP) systems have proven to achieve significant power reductions under favorable wind conditions: Thies and Ringsberg (2023) achieved a reduction between 10% and 14% by applying a Flettner rotor during the retrofitting of a ROPAX vessel, providing new-build design parameters for future ships with this WASP system. Bentin et al. (2018) investigated the energy-saving potential of using a towing kite, DynaRig sail, and Flettner rotor for a multi-purpose carrier, bulk carrier, and tanker. A saving potential of up to 35% was found when incorporating route optimization regarding favorable wind conditions. The investigated ship types were selected because they identified them to be suitable for WASP installation without changing the ship's capacity and the cargo loading and unloading function of the ship (Bentin et al., 2018). This is also addressed by Reche-Vilanova et al. (2021), where tankers and bulk carriers are identified to be especially suitable for WASP system installation due to their available deck space.

## DEFINITION DIGITAL TWIN

In order to provide a clear explanation of the conducted research, a definition of a DT is chosen that is strictly followed during this study. Mauro and Kana (2023) identified that the term ‘digital twin’ is often falsely used throughout scientific research. In order to not contribute to this error in nomenclature, the model distinction adopted by Kritzinger et al. (2018) will be used throughout this research:

- A *digital model* (DM) which is a virtual representation of the physical product, but without any form of exchange of automated data between both. Data exchange could occur but only be performed manually. The DM is mostly used for simulation and planning-based operations which does not require automatic data integration.
- A *digital shadow* (DS) which is an extended version of a DM including only an automated data flow from the physical product towards the virtual product by which it is actively updated.
- And lastly a *digital twin* (DT) is, composed of a physical and virtual product including an automated data flow between both entities.

## DT-SUPPORTED RETROFIT DESIGN

In order to investigate the state-of-the-art DT applications for maritime design, Mauro and Kana (2023) conducted a systematic literature review regarding maritime DT applications. Additionally, Hermans (2024) conducted a literature survey up to October 2023 for DT ship design. In these investigations, no publications are found on concrete DT applications for both new-build vessels and retrofits considering a whole vessel. Only theoretical frameworks and concepts are presented. In this research, a DT for retrofit design is investigated. First, the objective of the DT needs to be determined before starting with the actual modeling process for a DT-supported design. The objective covers the DT composition by indicating the required virtual models, and this composition consequently depends on the available data used by the final DT for performing simulations. The available operational data thus drives the modeling process of the DT (Giering and Dyck, 2021). The virtual models that are feasible to construct are identified by investigating this data. Finding the overlap between the required models (derived from the DT objective) and the feasible models (derived from the available data) provides the model selection for the final DT (see Figure 1).

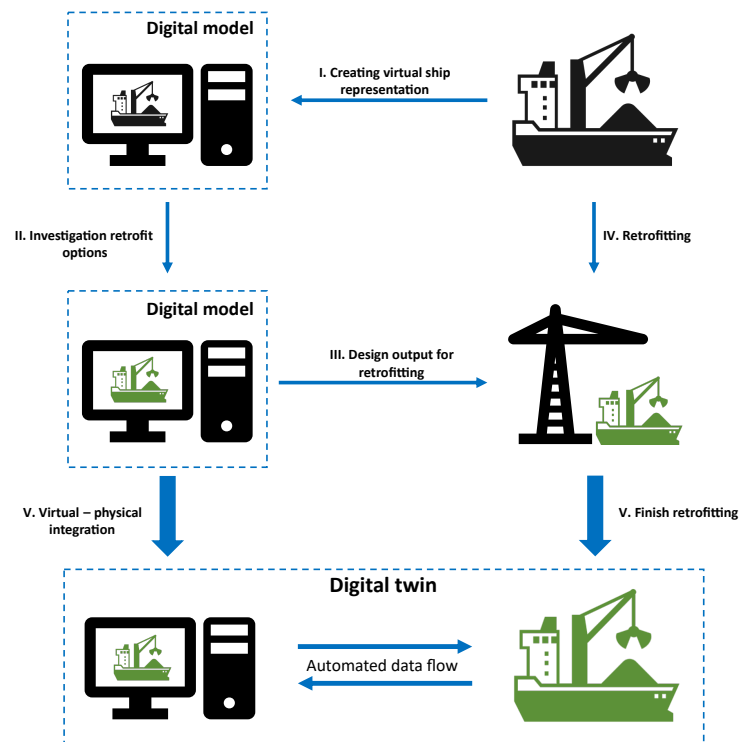

**Figure 1:** Selection process for DT models (Hermans, 2024)

After establishing the DT’s objective and the model selection process, the modeling phase involves the following general steps, where the details can be found in Hermans (2024) and Papanikolaou et al. (2024):

1. Set-up the data acquisition
2. Choose modeling approaches for virtual models
3. Perform model training in case of statistical-based models
4. Integrate the virtual part with the physical part

Figure 2 shows a schematic representation of the transition towards a DT for retrofitting, where a detailed description can be found in Hermans (2024) and Papanikolaou et al. (2024).

**Figure 2:** The development of the digital twin for retrofitting, based on the adopted DT definition (Hermans, 2024)

CONDUCTED RESEARCH

A DT with a retrofit design purpose starts as a digital model which becomes a DT after the retrofitting is completed. This research focuses on the modeling of the virtual part within the DT environment which will lay the basis for a green ship DT using this operational ship’s data. Thus, using the definition by Kritzinger et al. (2018), this research will work on a green ship DM, supporting the process of constructing the DT (Figure 3).

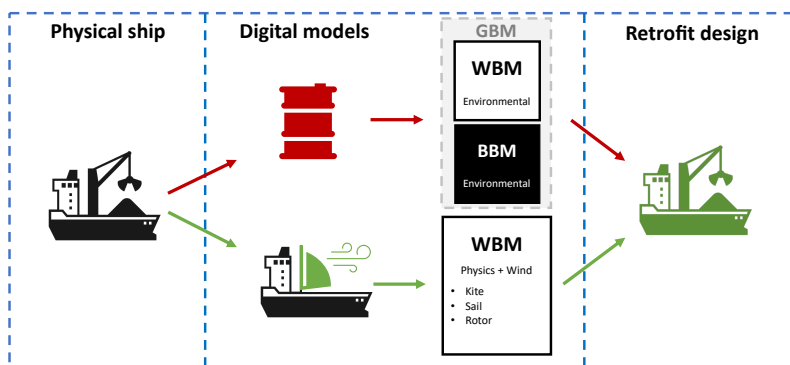

**Figure 3:** Focus of this research: representation of the green ship digital model (gray) within final digital twin

For the modeling construction, a model that represents the ship and a model that represents the green ship technologies are developed, which ultimately are integrated into one green ship DM. Within the DT4GS project, bunker delivery notes (BDNs) of a 300m bulk carrier are available as the data source. The main DT objective is set to reduce CO<sub>2</sub> emission through ship design, for which the Energy Efficiency Existing Ship Index (EEXI) and the Carbon Intensity Indicator (CII) are used

to evaluate this objective. The EEXI and CII are both IMO's environmental measurement tools which have been mandatory for most transport vessels since January 2018. Using these principles, the model selection (Figure 1) resulted in a fuel consumption model (FCM) which represents the ship, and three WASP models (towing kite, DynaRig sail, Flettner rotor), which represent the green ship technologies. The FCM will be composed of a resistance model and an artificial neural network (ANN). The resistance model will be modeled as a white box model (WBM), and the ANN as a black box model (BBM). Both are connected in a serial coupled fashion which results in an FCM constructed as a gray box model (GBM). The WASP models are all three modeled as WBMs. By combining these models into one green ship DM a potential retrofit design can be examined (Figure 4).

**Figure 4:** Overview of chosen method for constructing green ship DM. Combination of part representing the ship (red oil barrel) and part representing green ship technologies (green wind sail) resulting in one green ship DM for retrofit design (green bulk carrier)

A 300-meter bulk carrier is used as the case-study to investigate the proposed data-driven design approach. Besides evaluating the environmental impact of the EEXI and CII, a financial and feasibility assessment will be performed to investigate if the proposed retrofit of the respective vessel can be achieved. The payback period functions as the financial assessment. During the selection of WASP system configurations, the spatial feasibility per configuration is evaluated.

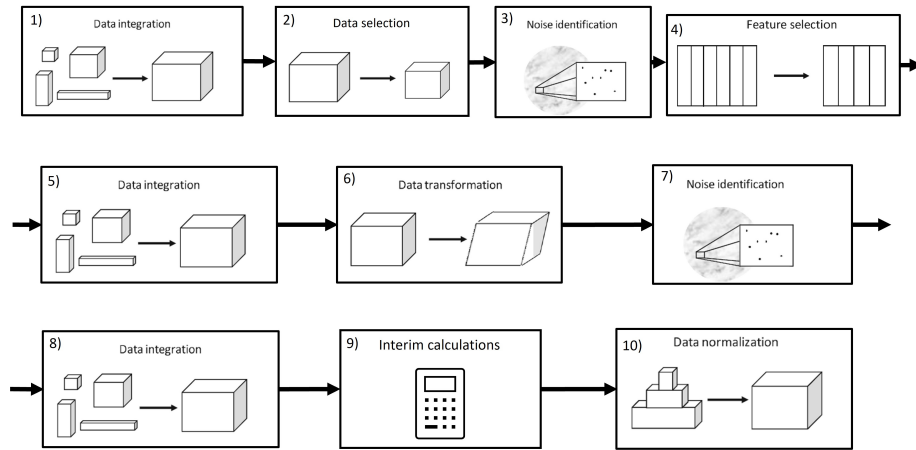

## DATA PREPROCESSING

The available BDNs of the bulk carrier contain over 129,000 data points, with a time interval of 5 minutes during the following periods:

- Q2 2022: 02/06/'22 - 30/06/'22
- Q3 2022: 01/07/'22 - 30/09/'22
- Q4 2022: 01/10/'22 - 31/12/'22
- Q1 2023: 01/01/'23 - 24/02/'23
- Q2 2023: 01/04/'23 - 30/06/'23
- Q3 2023: 01/07/'23 - 30/09/'23

The abundance of operational data from the BDNs does not necessarily imply that all these data are of good quality and in the right format to be utilized. In order to be of use for the case-study, the data is first preprocessed. Figure 5 shows the steps performed within the adopted data preprocessing framework of this research. These preprocessing steps are based on the techniques described by García et al. (2016).

For the case study, only data points corresponding to sailing conditions of the ship are considered, with a minimum ship speed of 6 knots through water selected to filter out non-sailing data points during the data selection process (step 2). During the noise identification (step 3), outliers within the dataset are identified, as they can negatively impact the accuracy of the models if left untreated. To address this issue, outliers are either replaced through interpolation around the respective

**Figure 5:** Adopted preprocessing data framework, based on techniques by García et al. (2016) (Hermans, 2024)

data points or entirely disregarded. In this research, identified outliers are simply disregarded. The following criteria are used during the noise identification process:

- Brake power is negative or zero
- The instant specific fuel consumption of the main engine is negative or zero (a result of a calculation)
- Sampling time is not 5 minutes
- Speed through water difference between 2 data points (= 5 min) is more than 3 knots, the second point is then disregarded

The other preprocessing steps within the adopted framework are discussed more thoroughly in Hermans (2024). The resulting amount of data points reduced per preprocessing step is provided in table 1. After performing the adopted data preprocessing steps, 5,687 data points remained. However, inspecting the resulting data points per period, significant anomalies were observed in Q2 2022, resulting in only 9 useful sailing hours. These 9 hours are just a tiny fraction of the resulting 5,687 hours (0.2%) and are therefore disregarded. This results in 5,678 data points, representing ‘pure’ sailing conditions, to be used for model construction.

**Table 1:** Data preprocessing results of BDNs data

	Data integration	Data selection	Noise identification				Data transformation
Period	Raw	$V_s \geq 6$ kts	$sf_{CME} \leq 0$	$P_B \leq 0$	$T_s \neq 5$ min	$\Delta V_s \geq 3$ kts	Hour conversion
Q2 2022	8,267	3,165 (-5,102)	2,769 (-396)	148 (-2,621)	148 (0)	147 (-1)	9 (-39)
Q3 2022	26,488	15,582 (-10,906)	15,579 (-3)	15,572 (-7)	15,572 (0)	15,570 (-2)	1,284 (-162)
Q4 2022	26,493	18,281 (-8,212)	18,280 (-1)	18,280 (0)	18,279 (-1)	18,276 (-3)	1,514 (-108)
Q1 2023	15,697	9,756 (-5,941)	9,756 (0)	9,756 (0)	9,756 (0)	9,755 (-1)	802 (-131)
Q2 2023	26,207	12,586 (-13,621)	12,586 (0)	12,586 (0)	12,586 (0)	12,586 (0)	1,047 (-22)
Q3 2023	26,022	13,404 (-12,618)	13,353 (-51)	12,647 (-706)	12,645 (-2)	12,641 (-4)	1,031 (-269)
$\Sigma$	129,174	72,774 (-43.7%)				68,975 (-5.2%)	5,687 (-1.1%)

## MODEL CONSTRUCTION

### Fuel consumption model - GBM

#### Resistance model - WBM

The resistance model calculates the sum of the ship's calm water resistance ( $R_{cw}$ ), according to the Holtrop and Mennen (1982), and the wind resistance ( $R_{AA}$ ) using the method of Andersen (2013). The available sea trial report provides 6 runs with which the output of the resistance model can be verified. The  $R_{cw}$  and  $R_{AA}$  for each of these runs is calculated and compared with the measured value during the run. The mean errors from this comparison are listed in Table 2. The ship had a course direction of  $60^\circ$  during runs 1 to 3, and a course direction of  $240^\circ$  during runs 4 to 6.

**Table 2:** Mean percentage error resistance. Run 1 to 3 with course direction  $\Psi = 60^\circ$ , run 4 to 5 with course direction  $\Psi = 240^\circ$

Resistance	Run 1	Run 2	Run 3	Run 4	Run 5	Run 6
$\Sigma(R_{cw} + R_{AA})$	+10.0%	+12.1%	+20.5%	-7.2%	-0.0%	+7.5%
$R_{cw}$	+12.9%	+14.4%	+24.2%	-7.1%	-0.0%	+7.6%
$R_{AA}$	-0.4%	-0.0%	-0.4%	-1.8%	-0.4%	+0.7%

As it can be noticed, the resistance prediction with a course direction of  $240^\circ$  is more accurate than the  $60^\circ$ . Moreover, the prediction of the additional wind resistance has a maximum error of 1.8%. The prediction of the calm water resistance fluctuates the most but within a 15% error when indicating run 3 as an outlier. There is no explanation found for the resistance difference between the two course directions and the relatively high error of run 3. The overall mean absolute percentage error is 9.6% which is deemed acceptable.

#### Artificial neural network - BBM

The ANN is constructed with Keras, which is an open-source neural network API written in Python (v3.11.5) that runs on top of the TensorFlow library (Keras, 2023). Before determining the architecture of the ANN, model inputs are chosen from the available data in the BDNs. The BDNs contain over 100 different data types. To ensure the accuracy and representativeness of fuel consumption predictions for future scenarios, an initial selection is made of potential model input parameters. This selection is based on the following assumptions:

- The goal is to predict fuel consumption with an operating WASP system, which will influence engine characteristics in a way that is currently unknown. Thus, parameters strongly related to the operating engine are left out of consideration
- Environmental parameters can be predicted for future situations by means of weather models, and are therefore taken into account
- Voyage characteristics such as ship speed and rudder position are route-dependent and can be chosen for future voyages

Following this filtering process, 12 potential model input parameters are identified. To refine the selection further, a Spearman correlation analysis is conducted for these parameters, specifically focusing on their correlation with the fuel consumption of the main engine. The analysis results, presented in Table 3, guide the final input selection process. Notably, in terms of engine output, engine torque is disregarded in favor of selecting brake power, as both parameters exhibit similar correlation factors, and power is deemed more suitable for WASP implementation.

**Table 3:** Spearman correlation for determination ANN inputs

Data types	Correlation with fuel consumption main engine	Selection
Brake power output	0.787	✓
Engine torque output	0.789	✗
Ship's heading	-0.082	✗
Rudder angle	-0.241	✓
Rudder rate of turn	0.002	✗
Relative wind direction	0.131	✓
Relative wind speed	0.226	✓
Speed over ground	-0.068	✗
Speed through water	0.142	✓
Speed difference	-0.170	✓
Total power diesel generators	0.041	✗
Sea water temperature	-0.174	✓
Fuel consumption main engine	1.000	—

From the Spearman correlation analysis, 7 parameters from the BDNs are chosen as model inputs. Additionally, the output of the resistance model,  $\Sigma(R_{cw} + R_{AA})$ , is incorporated as an additional input, which results in a total 8 model inputs for the ANN. This inclusion of the resistance as ANN input gives the model its gray box characteristic, and in this case, serially coupled. The 8 model inputs are:

- Brake power output
- Rudder angle
- Relative wind direction
- Relative wind speed
- Speed through water (ship speed)
- Speed difference
- Sea water temperature
- Sum of calm water and air resistance (result WBM)

The resulting 5,678 data points from the preprocessing are used for constructing the ANN. Initially, 500 data points are randomly selected for later cross-validation (referred to as the test set), leaving 5,178 points for training and intermediate validation to determine the optimal ANN architecture. These remaining data points are divided into a training set and a validation set at a ratio of 90% - 10%. The division is made using a specified random state ( $rs$ ) parameter. During training, the weights of neurons are adjusted using the training set, while the validation set is used to monitor the ANN's loss.

The majority of research on ANNs for fuel consumption prediction suggests using a single hidden layer to balance complexity and accuracy (Hu et al., 2019; Bal Beşikçi et al., 2016). However, some studies propose the use of multiple hidden layers for improved prediction accuracy (Parkes et al., 2018; Fam et al., 2022). The accuracy of the ANN is closely tied to the number of hidden layers and neurons, with more units allowing for the modeling of complex relationships (Parkes et al., 2018). Nevertheless, networks with too few layers and neurons may struggle to capture all necessary relationships effectively. To address this, both one and two hidden layer configurations are explored, using the Fletcher-Gloss method described in da Silva et al. (2017) to determine the number of neurons. This resulted in 209 potential configurations of which the resulting configuration was chosen (Figure 6). The final ANN characteristics and training parameters are listed in Table 4. The choice and background of the training parameters are discussed more thoroughly in Hermans (2024).

The resultant ANN configuration with the highest accuracy is a network with 1 hidden layer containing 16 neurons. Three additional networks with the same configuration (1 hidden layer of 16 neurons) are constructed for cross-validation, each using a different  $rs$  value during training to yield networks with different weights per neuron. These networks are cross-validated using a test set of 500 data points that were set aside, ensuring that the achieved accuracy is independent of the specific data split used for training. The mean absolute percentage error (MAPE) for each network is listed in Table 5, along with the overall MAPE and corresponding standard deviation.

**Figure 6:** Investigated ANN configurations with 1 input layer (yellow), 1 or 2 hidden layers (green), and 1 output layer (red) (Hermans, 2024)

**Table 4:** ANN characteristics and training parameters

Characteristic - parameter	Value
Training algorithm	Adam
Activation function	ReLU
Number of inputs	8
Number of outputs	1
Number of hidden layers	1
Neurons in hidden layer	16
Dropout	0.2
Test set	500 data points
Training - validation set	90% - 10%
Batch size	16 data points
Max number of epochs	500
Learning rate	0.001
Patience	35 epochs
Monitor loss function	MSE

**Table 5:** Cross-validation using test data set between 4 models with equal configuration

Random state	MAPE
49	1.8%
59	2.1%
61	1.9%
80	1.9%
Overall	1.9%
Standard deviation	+/- 0.1%

The confidence interval is a common practice in statistics to indicate if the adopted method is within a desired accuracy (Carney et al., 1999). The minimum desired confidence interval for machine learning, and especially ANNs, is generally 90% (Carney et al., 1999). The constructed ANN is well within this interval, with an overall MAPE of 1.9% indicating the high accuracy of the network.

## WASP models

In this research three distinctive WASP system models are constructed: a towing kite, a DynaRig sail, and a Flettner rotor. The selection for the towing kite and DynaRig sail is based on available literature (Bentin et al., 2018; Reche-Vilanova et al., 2021) on these models that use wind data that corresponds with the available data in the BDNs. Within the DT4GS project, a digital model of a Flettner rotor is constructed by Witzgall (2023) which is used in this research.

### Wind conversion

The wind sensor which measures the wind speed and direction found in the BDNs is mounted on the mast on the bridge deck. As the wind profile is not constant over the height, the wind speed needs to be converted to the corresponding effective height of the respective WASP system. This conversion is calculated with Equation 1, which represents the power-law of the wind profile (Hsu et al., 1994).

$$V_{z_{WASP}} = V_{z_{measured}} \cdot \left( \frac{z_{WASP}}{z_{measured}} \right)^P \quad (1)$$

The power-law exponent ( $P$ ) is a spatial parameter depending on the surroundings of the specific situation (e.g., at sea, open or undulating terrain). Hsu et al. (1994) concluded from their experiments that an exponent of  $P = 0.11$  is an accurate approximation for the wind profile over the sea. This is also in line with the recommended procedures and guidelines provided by the ITTC (2021) concerning this wind speed conversion.

### Towing kite - WBM

The constructed model is based on the research of Bentin et al. (2018). The resultant propulsion force by the towing kite is approximated with Equation 2.

$$F_{kite} = 0.5 \epsilon \rho_a V_a^2 S_{wi} F_{norm,kite} \quad (2)$$

The relative wind speed ( $V_a$ ) acts on the effective wind surface of the kite ( $S_{wi}$ ). Here  $F_{norm,kite}$  is the normalized propulsion force of the towing kite as a function of only the relative wind direction and elevation angle ( $\delta$ ), and can be calculated with Equation 3.

$$F_{norm,kite} = \left( \cos \left( \frac{180^\circ - \varphi_{a,rel}}{2} \right) \right)^2 \cdot (\cos(\delta))^2 \quad (3)$$

Four kite configurations were investigated during the case-study, referred to as: *Kite300*, *Kite800*, *Kite1280* and *Kite2500*. These configurations vary in kite sail area, which are respectively: 300 m<sup>2</sup>, 800 m<sup>2</sup>, 1,280 m<sup>2</sup> and 2,500 m<sup>2</sup>. The characteristics per kite configuration are listed in Table 6. It is assumed that the kite system is a fully autonomous system, including kite deployment and retrieving. An electric motor, included in the kite system, controls the flight and logistics. Such a fully autonomous system is also considered in the book chapter by Fritz (2013). The power usage of the electric motor is estimated at 2 kW with an electric efficiency of 0.95.

**Table 6:** Towing kite configurations

Kite characteristic	Kite300	Kite800	Kite1280	Kite2500
Kite sail area [m <sup>2</sup> ]	300	800	1,280	2,500
Height [m]	77.6	150	250	400
Elevation angle [°]	15	30	30	30

### DynaRig sail - WBM

As with the kite model, the DynaRig sail model is also based on the modeling methods described by Bentin et al. (2018), together with the research conducted by Reche-Vilanova et al. (2021). The resultant propulsion force by the sail is calculated

with Equation 4. Here, the sail surface is represented by  $A_S$ . The normalized propulsion force  $F_{norm,sail}$  is derived from the relative wind angle  $\varphi_{a,rel}$  and the lift and drag coefficients ( $C_L$  and  $C_D$ ). These coefficients characterize a specific sail.  $F_{norm,sail}$  is calculated with Equation 5.

$$F_{sail} = 0.5 A_S \rho_a V_a^2 F_{norm,sail} \quad (4)$$

$$F_{norm,sail} = C_L \sin(\varphi_{a,rel}) - C_D \cos(\varphi_{a,rel}) \quad (5)$$

Bordogna (2020) conducted wind tunnel tests for 3 different DynaRig sail configurations and only investigated the lift and drag coefficients of the respective sail without interaction effects. For this reason, the derived force coefficients by Bordogna (2020) are used for this DynaRig model. The sails were virtually trimmed during Bordogna's experiments to optimize for the maximum thrust per apparent wind angle. During the experiments 3 different sail configurations are investigated: 1 sail, 2 sails with a gap distance ratio (GDR) of 2.5, and 2 sails with a GDR of 4. The GDR is defined as the ratio of the distance between two sails and the chord length of a sail. These configurations will be referred to as *DynaRig single*, *DynaRig double 2.5*, and *DynaRig double 4*. The resultant configurations are listed in Table 7, where the dimensions are determined based on the characteristics of the conducted experiments and the available spatial feasibility of the bulk carrier.

**Table 7:** DynaRig sail configurations

Sail characteristic	Single	Double 2.5	Double 4
Gap distance ratio [-]	-	2.5	4
Chord length [m]	20	20	12.5
Height sail [m]	37.1	37.1	23.2
Camber [%]	10	10	10

#### **Flettner rotor - WBM**

Unlike with the kite and DynaRig model, an already constructed model of a Flettner rotor adopted by Witzgall (2023) will be used. In collaboration with the DT4GS project, Witzgall (2023) used a non-linear regression method to develop a surrogate rotor model based on 7 distinctive studies conducted in the field of Flettner rotor lift and drag coefficients. Two rotor configurations are investigated: the installation of 1 rotor and 4 rotors. The configuration of 4 rotors consists of four times the same rotor as used for the configuration of 1 rotor. The goal of this research is to reduce the CO<sub>2</sub> emissions (i.e., fuel consumption), thus the largest feasible rotor available in the industry is selected to be investigated: a 35m high rotor with a diameter of 5m and an endplate with a diameter of 10m. Both configurations are referred to as *1x Rotor H35D5* and *4x Rotor H35D5*.

## **MODEL INTEGRATION**

The goal of the green ship DM is to calculate the fuel consumption in case of an operating WASP. Comparing this with the fuel consumption without a WASP results in potential fuel reduction which provides an insight into the WASP's environmental and financial benefits. The output of the WASP's WBMs is propulsion force and possible power demand. One of the inputs of the ANN in the FCM is the ship's brake power. Thus, the ship's brake power including WASP force needs to be determined while maintaining the same ship speed and sailing time. The WASP's propulsion force is implemented with the propeller thrust demand in the ship's force balance to overcome the experienced resistance. This force balance is represented by Equation 6. Using this force balance a new working point of the propeller is derived, which is also known as the propeller-matching procedure. Vigna and Figari (2023) have performed this matching procedure including an operating Flettner rotor in order to derive the ship's brake power. The adopted integration framework is based on this procedure. The

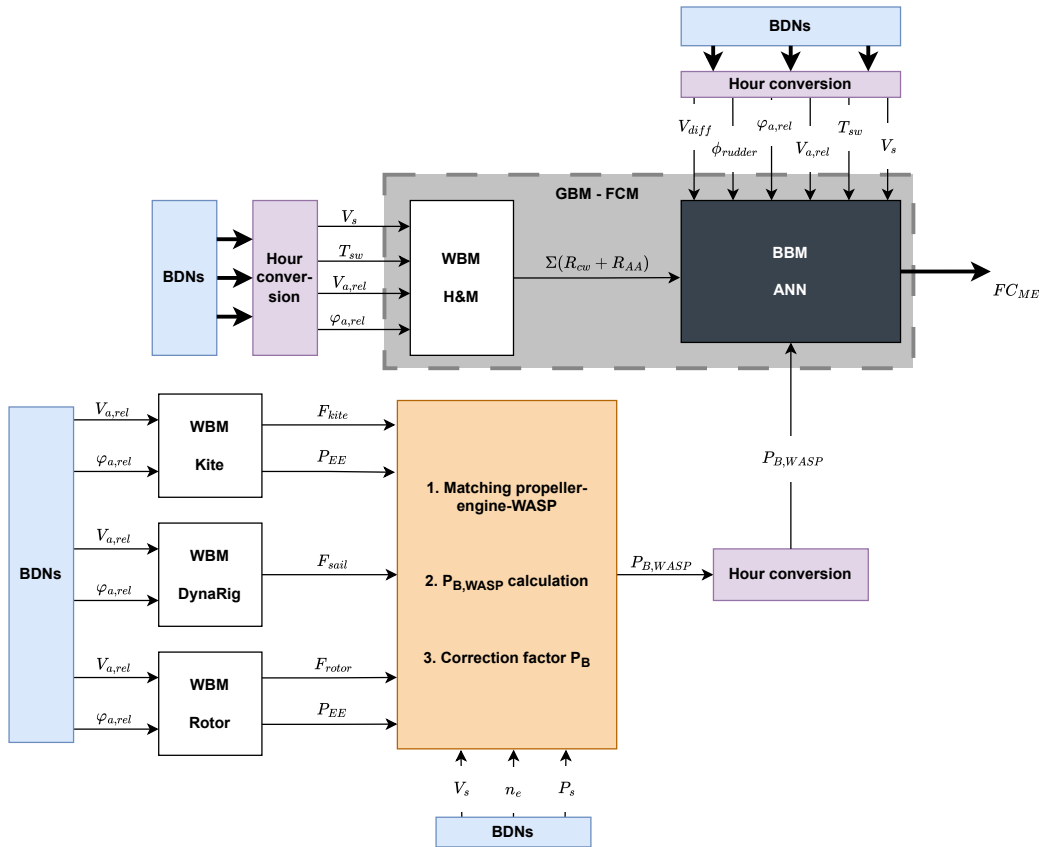

ship speed and sailing time are kept the same as only the influence on the ship's brake power by the installed WASP system is being considered.

$$\underbrace{R_T = (1 - t) \cdot T}_{\text{Without operating WASP}} \Rightarrow \underbrace{R_T = (1 - t) \cdot T + F_{WASP}}_{\text{Including operating WASP}} \quad (6)$$

Equation 6 is rewritten to the forward equilibrium equation including the terms of the propeller characteristics and hull demand resulting from the required ship speed, to derive the new working point of the propeller (Vigna and Figari, 2023), resulting in Equation 7.

$$\underbrace{\frac{K_T}{J^2} - \frac{R_T}{\rho_{sw} \cdot (1 - t)(1 - w)^2 \cdot V_s^2 \cdot D_p^2}}_{\text{Without operating WASP}} = 0 \Rightarrow \underbrace{\frac{K_T}{J^2} - \frac{R_T - F_{WASP}}{\rho_{sw} \cdot (1 - t)(1 - w)^2 \cdot V_s^2 \cdot D_p^2}}_{\text{Including operating WASP}} = 0 \quad (7)$$

The established model integration framework for this research is depicted in Figure 7. The output of the WASP WBMs is firstly transformed into brake power, and next integrated into the FCM to predict the corresponding fuel consumption. The required steps for this integration are depicted in orange and are discussed in Hermans (2024). This presented framework is based on evaluating the known data from the BDNs. Necessary calculation adjustments in this framework for future data sets are also presented in Hermans (2024).

**Figure 7:** Schematic overview digital models including, the adopted model integration framework in orange (Hermans, 2024)

Step 3 in the integration framework (Figure 7) consists of a correction factor ( $cf$ ) calculation of the ship's brake power. Because the current brake power is recorded in the BDNs, this  $cf$  can be calculated per data point to improve accuracy in the power computation. This  $cf$  can be seen as a variable value for all the efficiencies used in the brake power calculation (i.e.,  $\eta_S, \eta_{GB}, \eta_R$ ). The ship's forward equilibrium equation without operating WASP (in Equation 7), together with the derivation for the brake power (Equation 8) using the BDNs is used to calculate the ship's brake power. Because the bulk carrier does not have a gearbox, the propeller rotation ( $n_p$ ) is assumed to be equal to the measured main engine rpm ( $n_e$ ) available in the BDNs. This calculated value is compared with the measured brake power (BDNs) to derive the  $cf$  per data point (Equation 9). The correction factor is then multiplied by the ship's brake power with operating WASP.

$$P_B = \frac{2\pi\rho_{sw}D_p^5n_p^3K_Q}{\eta_S\eta_{GB}\eta_R} \quad (8)$$

$$cf = \frac{P_B \text{ (BDNs)}}{P_B \text{ (calculated)}} \quad (9)$$

## RESULTS

### Overall savings Q3 2022 - Q3 2023

For each configuration of the WASP systems, the money, fuel, and CO<sub>2</sub> savings are calculated over the 5,678 sailing hours ( $\approx 237$  sailing days) using a fuel price of \$618.50/mt-fuel. These results are presented in Table 8. Percentage reductions apply to all listed savings, as they are all directly linked to fuel consumption. The savings are computed as the difference between the predicted fuel consumption by the green ship DM with and without the WASP system. The MAPE between the actual fuel consumption (BDNs) and the predicted consumption (green ship DM), both without installed WASP, is 0.3%, indicating high model accuracy and reliability. This supports the validity of using the model. Calculating the difference between both predicted values by the green ship DM ensures consistency in accuracy.

**Table 8:** Total WASP savings during 5,678 sailing hours

WASP configuration	Fuel savings [mt]	\$-savings [K\$]	CO <sub>2</sub> savings [mt]	Percentage savings [%]
Kite300	1,031	637	3,240	-12.5
Kite800	1,048	648	3,293	-12.7
Kite1280	1,070	662	3,364	-13.0
Kite2500	1,129	698	3,549	-13.7
DynaRig single	1,145	708	3,599	-13.9
DynaRig double 2.5	1,148	710	3,610	-14.0
DynaRig double 4	1,068	660	3,357	-13.0
1x Rotor H35D5	1,197	740	3,762	-14.6
4x Rotor H35D5	1,598	989	5,025	-19.4

The overall results indicate a CO<sub>2</sub> reduction potential ranging from 12% to 19% across the investigated WASP configurations. This finding aligns with a literature study conducted by Bouman et al. (2017) on CO<sub>2</sub> reduction through green ship technologies, who found savings potentials between 7% and 22% of similar WASP technologies. When comparing individual configurations of each WASP system (1 kite, 1 sail, 1 rotor), it is observed that the rotor configuration offers the most significant savings potential. Additionally, kite configurations demonstrate progressively increasing savings potential with larger kite sail areas. Variations in the savings potential between the two double DynaRig configurations are attributed to differences in sail sizes as discussed in the WASP model construction.

## Environmental assessment

### EEXI

The power reduction due to an operating WASP is calculated according to the procedure presented in IMO (2021). Examining the sailing route of the bulk carrier during the period Q3 2022 - Q3 2023 showed that the vessel had sailed approximately 90% on the same shipping routes on which the IMO's wind probability matrix is based. This indicates that this wind prediction method, used in the EEXI calculation, has sufficient accuracy regarding this ship's operational area. The ship's current, required, and resulting EEXI values per investigated WASP configuration are provided in Table 9.

**Table 9:** New EEXI value per installed WASP configuration

WASP configuration	EEXI [g/(mt-nm)]	Reduction [%]
Required value (max)	2.370	-
No WASP (current)	2.120	-
Kite300	2.112	-0.4
Kite800	2.101	-0.9
Kite1280	2.085	-1.6
Kite2500	2.044	-3.6
DynaRig single	2.054	-3.1
DynaRig double 2.5	2.052	-3.2
DynaRig double 4	2.095	-1.2
1x Rotor H35D5	2.029	-4.3
4x Rotor H35D5	1.754	-17.2

All the investigated WASP configurations decrease the ship's EEXI value as suspected and consequently comply with the required EEXI value. Moreover, as noticed with the aforementioned overall savings, installing a rotor results in the highest CO<sub>2</sub> reduction. The *4x Rotor H35D5* configuration is simply a factor 4 environmental beneficial in terms of design potential, as the result of the calculation by the IMO.

### CII

The evaluation of the ship's operational aspect involves calculating the CII. However, there are data gaps and errors in the data for March 2023 and in the period Q3 2023, rendering the CII calculation for those periods unreliable. As the CII calculation requires a complete calendar year, it cannot provide the official CII value. Nevertheless, the calculation is performed with the data of 11 consecutive months (Q3 2022 - Q2 2023) which still offers a useful indication of the vessel's operational impact. The required CII values for the years 2023, 2024, and 2025 for the specific bulk carrier used are illustrated in Figure 8.

For the calculations of the attained CII per installed WASP configuration, a fuel oil density of 0.8352 g/cm<sup>3</sup> is used. The fuel consumption is predicted with the constructed green ship DM. The results are provided in Table 10, including color labeling per CII corresponding to its rating for the year 2023.

The bulk carrier is currently above the required CII, in the C-rating. All the WASP configurations bring the bulk carrier in the B-rating regarding the year 2023, whereas both rotor configurations also comply with the B-rating regarding the year 2024 and *4x Rotor H35D5* extend B-compliance for the year 2025.

**Figure 8:** Attained CII values of the investigated bulk carrier; required CII values for 2023, 2024, and 2025 are respectively 2.212, 2.166, 2.119

**Table 10:** CII approximation of 11 months during Q3 2022 - Q2 2023

WASP configuration	Attained CII [g/(mt-nm)]
Required (2023)	2.212
No WASP	2.248
Kite300	2.059 (-8.4%)
Kite800	2.056 (-8.6%)
Kite1280	2.051 (-8.8%)
Kite2500	2.039 (-9.3%)
DynaRig single	2.035 (-9.5%)
DynaRig double 2.5	2.035 (-9.5%)
DynaRig double 4	2.052 (-8.8%)
1x Rotor H35D5	2.020 (-10.2%)
4x Rotor H35D5	1.931 (-14.1%)

## Financial assessment - payback period

Even though the main objective is directly related to the environmental assessment, the financial assessment is done to give an idea of the feasibility in terms of time and money. The calculation of the payback period calculation per WASP configuration is performed with Equation 10, which is based on the financial assessments by Kiran (2022); van der Kolk et al. (2019).

$$P = \frac{B + C}{A - D} \quad (10)$$

Where the financial parameters represent:

- A: \$-savings per sailing hour using WASP
- B: Purchase & installation system
- C: Out of service costs & dry docking
- D: Hourly operational & maintenance costs WASP

The \$-savings per hour is the driving parameter (A) of the payback period. This parameter for each of the investigated WASP configurations (A) is derived by dividing its respective money savings in Table 8 by the total sailing hours (5,678 hrs). For the purchase and installation costs (B), the estimations provided by GloMEEP (2019) are used. GloMEEP is an international collaborating project established within the IMO aiming to support and provide insights into implementing energy-efficient measures for global shipping. Costs ‘C’ are not considered as there is no evident information available on these costs. This is mainly due to the fact shipping companies and maintenance docks only provide such information through a direct offer. The costs associated with the operations and maintenance of WASP systems are typically provided by the manufacturer. In this research, these costs are estimated to be annually equivalent to 2% of the WASP installation costs. This estimation aligns with a study conducted by van der Kolk et al. (2019), which performed a technological and economical assessment of WASP systems for transport vessels.

The payback period (P) for each WASP configuration can be calculated based on operational data, excluding costs ‘C’. The results are presented in Table 11, considering the vessel in operational condition (minimum ship speed of 6 knots). To determine the total payback period accounting for all configurations, one must include the term  $\frac{C}{A}$  to the provided payback period results, where ‘C’ represents the known value for costs and ‘A’ represents the annual savings.

**Table 11:** Payback period (P) of WASP configurations expressed in operating time, without costs ‘C’

WASP configuration	P [hrs]	P [days]	P [years]
Kite300	4,091	170	0.5
Kite800	10,121	422	1.2
Kite1280	15,596	650	1.8
Kite2500	22,128	922	2.5
DynaRig single	1,368 ~ 2,419	57 ~ 101	0.2 ~ 0.3
DynaRig double 2.5	2,735 ~ 4,850	114 ~ 202	0.3 ~ 0.6
DynaRig double 4	2,943 ~ 5,220	123 ~ 218	0.3 ~ 0.6
1x Rotor H35D5	5,437 ~ 7,411	227 ~ 309	0.6 ~ 0.8
4x Rotor H35D5	16,696 ~ 21,702	696 ~ 904	1.9 ~ 2.5

Analyzing the payback periods of the selected configurations indicates that the *Kite2500* and *4x Rotor H35D5* configurations require the longest time to become financially profitable. On the other hand, DynaRig configurations are generally the most favorable option in terms of payback period, averaging better results compared to other configurations.

## CONCLUSION

Incorporating operational data into ship design through a DT-supported method allows for the evaluation of environmentally friendly ship designs, particularly focusing on reducing CO<sub>2</sub> emissions with WASP systems. The DT’s capacity to handle vast amounts of data and conduct virtual simulations mitigates risks associated with such designs. Operational data from the IMO’s mandatory BDNs serves as a valuable source for modeling construction, facilitating the development of a green ship DM. This DM incorporates ship characteristics, route-dependent factors, and environmental data to predict fuel consumption with and without a WASP system installed, thus estimating potential CO<sub>2</sub> emission reductions (environmental) and payback periods (financial). Environmental assessments conducted through IMO’s EEXI and CII tools highlight the *4x Rotor H35D5* configuration as yielding the highest CO<sub>2</sub> reduction, while also with the longest payback time. Conversely, DynaRig configurations result as the most financially attractive on average, although dry-docking and out-of-service costs are not taken into account. Ultimately, ship owners’ decisions will be guided by specific requirements and considerations, informed by the presented results.

## DISCUSSION

The research focuses on integrating operational data into retrofit design, using high-level WASP models. However, these models are simplified, such as approximating aerodynamics in the towing kite model with a single value, the wind energy transfer efficiency ( $\epsilon$ ). To enhance the accuracy of propulsion force predictions, more refined WASP models are recommended. One key assumption is regarding fuel consumption prediction by the green ship DM with an operating WASP system. The FCM is validated with high accuracy for known sailing conditions, with one input being the ship's brake power. During the case-study, only the brake power value is altered to investigate the effect of an installed WASP system, assuming the resulting fuel consumption corresponds to that situation. To verify this assumption accurately, model or full-scale tests including WASP system installation are necessary. These tests would close the verification loop of the proposed method. The BDNs serve as a feasible data source for the modeling construction chosen in this research, providing ample data points related to route-dependent and environmental information for fuel prediction. However, there is a lack of information regarding the method and quality of the sensors used for data collection, raising uncertainty about potential errors within these values due to sensor sensitivity or recording methods. Additionally, despite the variety of recorded data types, important parameters such as waves, trim, and draft are absent. Incorporating these data types into the constructed resistance model could improve the estimation of the ship's resistance and total resistance. Although water depth data, which can influence speed loss due to shallow water effects, are present in the BDNs, they are incomplete and contain significant anomalies, leading to their exclusion from the research. Moreover, no interaction effects are considered regarding the WASP systems and the vessel during this research. While the IMO's calculations overlook these effects, deeming them significant only during unsafe operations that need to be prevented, they must be considered when investigating WASP retrofitting. The change in the center of gravity due to installing WASP systems can lead to differences in the power reduction prediction (Thies and Ringsberg, 2023). Moreover, induced trimming moments and heel angles as a result of operation WASP systems negatively influence the aero and hydrodynamic performance of the vessel's propulsion system (Smith et al., 2013; Stark et al., 2022).

# Overall scheme design of green typical demonstration ship types under the background of Double Carbon Policy

ZhengChen Lian<sup>1,\*</sup> and LiZheng Wang<sup>2</sup>

## ABSTRACT

*In order to explore the overall design and research issues of green typical demonstration ship types, this article takes Hunan Province's green typical demonstration ship types as an example. Using a combination of policy interpretation, research analysis, theoretical analysis, and overall design, with the Double Carbon Policy as the background, the overall positioning analysis of the ship type is conducted first. Then, the key technical features and application solutions of the ship type will be introduced to ultimately achieve the goal of matching the design ship type with the waterway conditions.*

## KEY WORDS

Green ship type scheme, ship type positioning, power mode selection, ship adaptability

## INTRODUCTION

Inland waterway shipping has important strategic significance for the development of the national economy. With the completion of cascade development and a series of shipping construction projects, the conditions of China's inland waterways have greatly improved. However, it is also noted (Lian Zhengchen, Wang lizheng 2023) that the seasonal changes in the navigation conditions of China's inland waterways after channelization are significant, resulting in low load capacity, poor navigation performance, insufficient navigation safety, and potential safety hazards for ships navigating in such key sections. The comparative advantages of large transportation capacity, low cost, low energy consumption, and light pollution in inland waterway shipping have not been fully utilized. At the same time, in combination with the current implementation of the national strategy of "carbon peak and carbon neutrality" and the need for green and high-quality development of inland ships, there is an urgent need to promote the emission reduction and green upgrading of green standard ship types in the new era. This puts forward higher requirements for the overall plan research of ship types and is also an important prerequisite for the economic and efficient operation of ships. Therefore, it is crucial to explore the overall design and research issues of green typical demonstration ship types.

This article takes the green typical demonstration freight ship types in Hunan Province as the research object, with "carbon peak and carbon neutrality" as the policy background. At the same time, it strengthens the research on the "one river, one lake, and four water" ship types, especially the "four water" ship types, clean and environmentally friendly ship types, and new energy ship types in Hunan Province, and matches them with the Three Gorges ship type to achieve the urgent goal of connecting the river and the sea. Therefore, this article proposes an overall plan for Hunan Province's green typical standard demonstration ship type from the perspectives of market demand and navigation environment characteristics, overall positioning analysis, key technical characteristics analysis, and overall design scheme application. Through the above research, it points out the direction for the application and engineering demonstration of emission reduction technology for standard ship types in inland rivers in Hunan Province, and provides strong support for promoting the transformation and upgrading of the shipbuilding industry and green and high-quality development.

# ANALYSIS OF THE OVERALL FRAMEWORK POSITIONING OF THE GREEN FREIGHT STANDARD DEMONSTRATION SHIP TYPE

## Ship type positioning analysis

In terms of policy orientation, in order to achieve the strategic goals of "dual carbon", becoming a strong transportation country, and developing inland waterway shipping, and promoting high-quality development of inland waterway shipping, the selection of green standard demonstration ship types for waterway freight transportation in Hunan should meet the following three policy requirements (*Implementation Opinions of the Ministry of Industry and Information Technology and Five Other Ministries on Accelerating the Green and Intelligent Development of Inland River Ships*, 2022).

- i. Guided by the goals of carbon peak and carbon neutrality, guided by promoting the green and standardized development of inland river ships in Hunan, and focusing on the development of new energy and clean energy powered ships, the typical scenarios of Hunan waterway freight transportation are selected to carry out demonstration applications according to local conditions, so as to accelerate the transformation and high-quality development of green energy applications of inland river ships in Hunan, implement the "14th Five-Year Plan" water operation and operation development plan in Hunan, and promote the green upgrading of inland river standard ship types in Hunan Province in the new era.
- ii. Adhere to policy guidance, strengthen the coordination and linkage of departments, localities and enterprises, develop green and energy-efficient ships and green shipping, and improve the level of safe and green development. Promote scientific and technological innovation, adhere to demonstration and promotion, support representative enterprises in the inland river basin of Hunan to take the lead in the trial, summarize typical experience and practices, and steadily promote the basic principles.
- iii. Comprehensively consider the perspectives of economy, energy efficiency and design optimization to create a standardized green energy ship type that meets the needs of typical scenarios of Hunan waterway freight, realize the demonstration application of Hunan inland river operation routes, form an experience that can be implemented, replicated and promoted, and form a green model of Hunan freight ships.

It was noted ("*Analysis Report on the Capacity Structure of Waterway Freight Ships in the Province*", 2022) that, from the perspective of water transportation demand in Hunan Province in 2021, the province completed a freight volume of 212.72 million tons, an increase of 7.20% compared to the previous year, and a freight turnover of 45 billion ton-kilometer, an increase of 13.75% compared to the previous year. Among them, inland waterway transportation completed a freight volume of 211.31 million tons and a cargo turnover of 36.1 billion ton-kilometer; Ocean transportation has completed a freight volume of 1.41 million tons and a cargo turnover of 8.9 billion ton-kilometer. Although the water freight volume in the province has declined to a certain extent since 2014 due to the ban on sand and gravel mining in Dongting Lake and the significant decrease in water transportation volume, the development of container "water shuttle buses" has been actively guided to optimize and adjust the water freight structure, serving foreign trade transportation, and continuously optimizing the water freight transportation structure in recent years. The water transportation volume and proportion of bulk goods such as metal ores, coal, grains, and oil products in the province have significantly increased. In the long run, with the development of the economy and correct guidance, the structure of waterway freight transportation in Hunan will gradually transform and develop towards energy, steel, grain, equipment manufacturing, and more, serving the industrial development of Hunan Province. At the same time, considering further adjustment and optimization of the comprehensive transportation structure, with the adjustment of freight transportation from public transportation to water and from public transportation to rail, the medium and long-term water transportation volume will still show a gradual growth trend.

Subsequently, the Hunan Provincial Department of Transportation proposed key tasks for green transportation in the 2022 plan. Among them, in the key task of "optimizing transportation structure and innovating organizational methods," it was pointed out to deepen the promotion of the transportation of bulk goods and medium and long-distance goods from rail to rail and from water ("*Analysis Report on the Capacity Structure of Waterway Freight Ships in the Province*", 2022). Focus on developing direct transportation between the Xiang River trunk line and the Dongting Lake area, consolidating the routes from Chenglingji Port to Yichang Port, Jingzhou Port in Hubei Province, and various ports in the upper reaches of the Yangtze River; In the key task of promoting resource conservation and intensive utilization, it is pointed out to promote the use of new and clean energy in highway service areas, ordinary national and provincial trunk highway service areas or overload control stations, CNG refueling stations and port shore power facilities, LNG refueling stations, and promote the use of new and clean energy in vehicles, ships, and other transportation equipment.

From an overall development perspective, from 2016 to 2020, the number of container arrivals and departures in Hunan Province has shown a continuous upward trend. In the first half of 2020, due to the impact of the epidemic, container transportation suffered a significant impact and demand declined. In the second half of 2020, with the gradual recovery of global trade, the demand for container waterway transportation increased, and the scale of transportation capacity quickly recovered. From 2016 to 2020, container waterway transportation ports in Hunan Province were mainly distributed in Changsha, Yueyang, Hengyang, and Changde cities. More than 60% of the export containers are shipped from Changsha New Port. Due to the limitations of the Xiangjiang River waterway, export containers from Hengyang Port, Changde Port, and Changsha Port need to transfer to Yueyang Chenglingji Port. In 2020, the total volume of container arrivals and departures in Hunan Province was 653693 TEUs, of which 327745 TEUs were inbound and 325948 TEUs were outbound (*"Analysis Report on the Capacity Structure of Waterway Freight Ships in the Province"*, 2022). Therefore, there is little possibility of a significant increase in the capacity of inland dry ship bulk cargo in Hunan Province in the future, and the development prospects of container transportation are promising. Therefore, this study chooses container waterway transportation as the demonstration object.

From the perspective of navigation environment, there are mainly two types of container transportation modes in Hunan Province: container "waterbus" transportation mode and river sea direct transportation mode. In the long run, with the development of the economy and correct guidance, the structure of waterway freight transportation in Hunan will gradually transform and develop towards multi-industry transportation such as energy, steel, grain, and equipment manufacturing, serving more industrial development, and the proportion of sand and gravel transportation will decrease. At the same time, considering further adjustment and optimization of the comprehensive transportation structure, with the adjustment of freight transportation from public transportation to water and from public transportation to rail, the water transportation volume in Hunan Province will continue to gradually increase in the medium and long term. Therefore, for the water container transportation mode in Hunan Province, this study chooses the inland river of Hunan as the research water area.

## Determination of demonstration ship types

According to the current situation, development plan, and policy direction of water transportation in Hunan Province, the demand for typical demonstration ship types in Hunan Province has the following characteristics: firstly, the focus is on container cargo transportation; secondly, the development direction is based on the two transportation modes of inland river container "waterbus" (container liner shipping) and river sea direct transportation; thirdly, the development direction is driven by new energy and clean energy. Through market demand analysis, this article focuses on the transportation mode of container "waterbus" (container liner shipping) in Hunan's inland rivers, combined with transportation demand and typical scenarios of green energy application. From the perspective of adaptability, environmental protection, technological maturity, and economy of green technology application, short-term routes will be oriented towards electrification. At the same time, drawing on the development path of gasification and electrification of the Yangtze River, the demonstration ship selection is guided by building a green, low/zero carbon container benchmark ship for the Xiangjiang trunk line.

Based on the above analysis, in line with the national "dual carbon" strategy, meeting the urgent market demand, considering the navigable environment, the representativeness of transportation vessels, and scientifically positioning demonstration ship types. After market research, based on factors such as logistics environment, navigation environment, market environment, technology environment, and policy environment, a demonstration ship type suitable for the "waterbus" container transportation mode in inland rivers of Hunan has been determined as follows: considering adapting to the market's demand for multi cargo transportation, it is planned to use Lingji Port in Yueyang City as the hub port, and ports in Hunan Province such as Changsha Xianing Port, Changde Yanguan Port, Hengyang Songmu Port, etc Jinshi Port is a multi-purpose green container ship type fed to the port. The initial consideration of the deadweight of this ship type is 200 TEU container level, which is driven by electric motors.

For the determination of ship size, there has been a certain increase in the past two years for bulk carriers with a length exceeding 88m and a width exceeding 15.5m, as well as container ships with a length exceeding 85m and a width exceeding 15m. At the same time, a "shuttle bus" mode for containerized water transportation from various container ports in Hunan Province to Yueyang Chenglingji Port has been opened, and a 200TEU container level inland river container ship has been selected as the research object. This article is based on the limitation of ship size by the channel conditions of the Changsha Yueyang section, and calculated under the provided unified ship type demonstration platform to obtain the accuracy index results of each feasible ship type scheme. The trend chart of accuracy index changes with the main scale of the ship type is drawn, and the impact of variable changes in ship type schemes on the technical and economic performance of ship operation is analyzed. At the same time, the operation of the Changsha Yueyang route needs to pass through the Changsha hub, so the ship size needs to meet the requirements of the container ship series for the Yangtze River branch line lock transportation ships in the national mandatory standard GB38030.1. The preferred ship type size is CZ-J6 (with a length of 88m and a width of 15m), which is relatively close to the scale series. At the same time, considering that appropriately increasing the ship

width is beneficial for container stability, and combining the analysis of the changes in the above indicators with the ship size, it is advisable to choose the ship type with a length of 88m and a width of 15.00m. As mentioned above, the specific ship type parameters are obtained as shown in Table 1.

**Table 1: Optimal ship type scheme for container ship**

Project	Numerical Value
Length (m)	~88.00
Width (m)	~15.00
Draft (m)	~2.80
Container load capacity (TEU)	~200 container level

## RESEARCH AND DEVELOPMENT OF DEMONSTRATION SHIP TYPES FOR ELECTRIC CONTAINERS IN HUNAN INLAND RIVERS

Based on factors such as logistics environment, navigation environment, market environment, technology environment, and policy environment, and considering adapting to the needs of multi cargo field transportation in the market, this demonstration ship type is planned to use Yueyang Chenglingji Port as the hub port, and Changsha Xianing Port, Changde Yanguan Port, Hengyang Songmu Port, and Jinshi Port as feeding ports to achieve a container "shuttle bus" water transportation mode, realizing Changsha Port, Hengyang Port, and Changde Port All containers entering and exiting Tianjin Port are transshipped at Yueyang Port. Develop a new generation of inland green container multi-purpose transport vessel that can sail on the ports and routes of Yueyang in Hunan Province, integrating safety, green, and economy. By optimizing the overall layout and line design, as well as applying advanced integrated power systems, we aim to reduce the carbon emissions of ships, improve the safety level of ship navigation, and create a "Hunan sample" of electric freight ships.

According to the previous analysis, the overall positioning of the demonstration ship type for inland electric containers in Hunan Province consists of the following parts. Firstly, from the perspective of transportation cargo types, the main focus is on loading containers and dry bulk cargo. Secondly, from the perspective of transportation routes, the transportation route of this demonstration ship type is from Changsha to Yueyang. Specifically, the container "shuttle bus" water transportation model is adopted, with Yueyang Chenglingji Port as the hub port and Changsha Xianing Port, Changde Yanguan Port, Hengyang Songmu Port, and Jinshi Port as the feeding ports. All containers entering and exiting Changsha Port, Hengyang Port, Changde Port, and Jinshi Port are transshipped at Yueyang Port. Finally, in terms of fuel power selection, in order to implement the national "dual carbon" strategy, starting from promoting green and low/zero carbonization of water transportation in Hunan, combined with the cargo demand and navigation environment conditions of Changsha Yueyang, considering various green energy energy density ratios, dynamic responsiveness of ships, container scheduling arrangements (*Green ship regulations*, 2020), distance and other factors, this ship adopts electric propulsion mode.

Next, this article introduces the overall overview of developing ship types. Firstly, for the main scale elements, the basic parameters of the ship are determined according to the applicable specifications based on its purpose and route (*Technical rules for statutory inspection of inland vessels*, 2019), as shown in Table 2.

**Table 2: Basic parameters for developing ship types**

Project	Numerical Value
Total length	88.00m
Length between perpendicular lines	85.36m
Molded breadth	15.00m
Molded depth	5.30m
Full load draft	3.52m
Load capacity	~3000t
Container capacity	208 TEU
Block coefficient	0.85
Maximum speed	18km/h
Rated power of propulsion motor	500kW×2

According to the Freund's number range and according to the speed requirements and characteristics of electric boats, this boat is a low-speed boat. It is also noted (Sheng Zhenbang et al, 2010) that educing shape resistance and improving propulsion efficiency are the main means to improve the speed of ships. In order to improve the flow of the tail propeller, improve the propeller propulsion efficiency, and adapt to the navigation environment of the inland river, the stern of the ship

1015

Series extended range hybrid mode refers to the configuration of a certain amount of chemical energy storage batteries and diesel or other internal combustion engine generator sets on board the ship. When the batteries are charged, pure electric propulsion is used, and when the batteries are depleted, the generator sets are used to generate electricity and charge the batteries to increase endurance. It is also noted (Tang Tianhao, Han Chaozhen 2015) that its biggest feature is that the batteries and generator sets can be placed in a fixed position inside the cabin, or can be placed in a container form and can be moved or suspended externally.

The container ships for inland water transportation in Hunan Province have a large tonnage and a long voyage. The biggest advantage of this method is that it solves the problem of navigation endurance and does not conflict with battery swapping and charging. In other words, in terminals with replaceable battery conditions, the battery can be directly swapped, and in terminals with charging piles, it can also be charged. If sailing in navigation areas where battery swapping and charging are not possible for a long time, the mode of generator range extension is adopted for continuous navigation. The use of series extended range in the transportation of bulk cargo can better solve the problem of endurance, improve the charging process and operational efficiency. In different situations, pure electric navigation, charging navigation, and charging or battery swapping can be flexibly selected. Its application can also meet the current policy implementation for new energy subsidies and development. Therefore, for the distance between Changsha and Yueyang, considering that the shore support is not yet sound and the route is not a short distance fixed point-to-point route, it can be seen from a technical perspective that the series extended range hybrid mode is more suitable for this demonstration ship.

**Figure 3: Series extended range hybrid mode**

The selection of ship battery capacity should consider the following three factors: firstly, the main propulsion energy consumption of the ship mainly depends on the operating power and operating time of the ship; The second is the electricity consumption for crew members, which mainly depends on the power distribution and usage time of the ship's daily life; The third is the attenuation of the battery, taking 85% of the maximum capacity of the battery pack. Among them, the selection of energy consumption and the calculation of battery capacity adaptability are shown in Table 3.

Table 3: Battery Capacity Adaptability Analysis Table		
Electricity consumption type	Project	Numerical Value
Main propulsion energy consumption	Route range	Approximately 150km
	Design Speed	18km/h
	Operational speed	12km/h
	Rated propulsion power	1000kW
	Operating propulsion power (12km/h)	Converted to approximately 297kW
	Single voyage time	12.5h
	Energy consumption for single voyage main propulsion	3713kWh
hotel load	Power of household distribution system	Approximately 30kW
	Waiting time for loading and unloading	1.5d
	hotel load and energy consumption	45kWh

According to Table 3, the ship is equipped with two box type power supplies. Due to the design specifications requiring that the capacity of each box type power supply should not exceed 2000kWh (*Battery Power Specification for Ship Applications*, 2023), two box type power supplies from 712 Institute were selected, each with a battery capacity of 1998kWh. The total battery capacity of this ship is 3996kWh. Calculated based on 85% effective capacity, it is 3397kWh, which cannot meet the energy demand of a single voyage of the ship, so diesel fuel range extension is still required.

### Economic and Environmental Analysis

From the perspective of technological adaptability, container ships for trunk and branch transportation in Hunan Province have a smaller tonnage and shorter voyage. Diesel powered ships, extended range electric ships, pure battery powered ships, and LNG powered ships all have no endurance issues and are technically feasible. Among them, pure battery powered ships require more electricity per journey than the maximum carrying capacity of the ship itself, requiring one battery exchange midway.

By selecting the existing operating ship types in Hunan as the object, the comparison of cost, carbon emission and payback period under different power schemes was calculated according to the parameters given by the shipowner. The specific calculation results are shown in Figure 4. From the perspective of environmental benefit analysis, compared with pure diesel ships, the carbon emissions of extended-range electric ships are reduced by about 40% to 70%, while pure battery-powered ships can achieve zero emissions, and the carbon emissions of LNG-powered ships are reduced by about 10-15%.

Similarly, through the technical and economic calculation and analysis of different power schemes of sample ships, the relationship between ship cost subsidy and payback period in Hunan inland river transportation and trunk branch transportation container scenarios is obtained. Compared with pure diesel ships, the necessary freight rates for pure battery-powered ships have increased by about 15%, and the necessary freight rates for LNG-powered ships have decreased by about 10%. The economic analysis mainly focuses on the cost comparison of electric propulsion vessels with conventional diesel-powered vessels. When the ship cost subsidy is 10% to 20%, the payback period of extended-range electric ships can reach the level of pure diesel ships, while the payback period of pure battery-powered ships is difficult to reach the level of pure diesel ships through subsidies.

**Figure 4: Calculation of cost, carbon emission and payback period of different power schemes in Hunan inland river transportation and trunk branch transportation container scenarios**

**Table 4: Comparison of prices between pure diesel and electric ship power systems**

Serial Number	Cargo capacity (ton)	Pure diesel power (Ten thousand yuan)	Pure battery power (Ten thousand yuan)	Extended range electric boat (10000 yuan)			
				Pure electric range 120km	Pure electric range 100km	Pure electric range 80km	Pure electric range 80km
1	1000	~80	~530	~420	~382	~344	
2	2000	~99	~730	~553	~494	~435	
3	3000	~119	~984	~717	~642	~566	
4	4000	~148	~1500	~910	~821	~732	
5	5000	~179	~1976	~1068	~966	~865	
6	6000	~203	~2452	~1232	~1120	~1008	
7	7000	~238	~2938	~1394	~1272	~1151	
8	8000	~260	~3014	~1535	~1405	~1275	

According to Table 4, the main source of cost increase for electric powered ships is energy storage batteries. It can be seen that due to the increase in initial investment, the economic performance of electric powered ships is worse than that of traditional diesel powered ships without government subsidies. However, the environmental advantages of electric propulsion for ships are significant. Starting from achieving the "dual talk" goal of water transportation in Hunan, we should vigorously promote the electrification of medium and short distance freight ships. Before the design and construction of this vessel, the shipowner and relevant parties have conducted in-depth investigations and economic calculations, and even without any policy subsidies, the profitability of its operation is predictable.

In addition, the ultimate goal of the design, construction, and operation of this ship is to achieve complete pure electricity and zero emissions. Not only does it have zero emissions in terms of power, but it also includes zero emissions of dirty oil, sewage, and domestic sewage. The ship is equipped with oil and sewage collection tanks and domestic sewage collection tanks, which are used to collect and store all oil and sewage generated on board. Except for receiving at the shore or anchorage, the entire life cycle of the ship will not discharge any oily or domestic sewage outward.

Based on the analysis of the adaptability and economy of battery powered ship technology, and considering the adaptability, environmental friendliness, technological maturity, and economy of battery powered technology application, it is recommended to use diesel extended range hybrid power scheme at this stage. At present, the use of series extended range hybrid mode can better adapt to the current conditions of the Changsha Yueyang route where the shore based support for electricity supply is not yet sound and is not a short distance fixed point-to-point route. Therefore, it is feasible for this demonstration ship to adopt series extended range hybrid mode.

## Overall Plan Description of 208TEU Inland River Electric Container Demonstration Ship Type

Based on the research and development concept mentioned earlier, and through the analysis of ship type positioning and ship power mode of the demonstration ship, modern design methods are adopted to meet the requirements of the latest applicable standards, conventions, and rules. Drawing on the research and development achievements of domestic and foreign inland river green ship types, the overall scheme design of the Changsha Yueyang 208TEU inland river pure electric distribution dual-use demonstration ship type is carried out. And introduce the plan from four aspects: cost estimation and construction progress of the hull, engine, electrical, and demonstration ship type.

### Hull design

This ship is a dual engine, dual propeller, lithium battery + diesel generator hybrid electric propulsion, all steel structure, open hatch type container and distribution dual-purpose cargo ship. It mainly carries containers or containers containing some dangerous goods, and can also load dry and miscellaneous cargo such as sand, cement, stones, coal, grains, metal ores, etc. It mainly navigates within the A and B level navigation areas of inland rivers. A container capable of loading dangerous goods in packaging such as 1.3G, 1.4G, 1.4S, 2.2, 8, 9, 3, 4.1, 4.2, 5.1, 6.1, etc. (*Code for construction of steel inland vessels*, 2016)

For the selection of ship type, this ship is a multi-purpose cargo ship with a straight aft leaning slightly curved bow, square stern, twin engine, twin propeller, and stern electric drive. The entire ship is of steel fully welded structural type. The overall layout is as follows: below the main deck, from the front to the tail, there are bow peak tanks (ballast tanks), bow ballast tanks, cargo tanks, engine rooms, stern shaft tanks, stern ballast tanks, and rudder rooms. The head position on the main deck consists of three decks: crew deck, pilot deck, and compass deck. Set up battery swapping containers on both sides of the stern deck, with battery swapping generator containers placed in the center. Machine repair rooms, CO<sub>2</sub> rooms, and lower engine stairwells are set up along the walkways on both sides of the stern deck. The front end of the upper structure at the bow is a raised deck, with wing bridges on both sides of the cab, and a full window in front. Since the ship is in the stage of actual ship construction and application, this paper models and displays an overview of the 208TEU inland river pure power distribution demonstration ship based on the software modeling and simulation platform based on the above overall layout, as shown in Figure 5.

For the performance analysis related to the demonstration ship type, this ship has two engines and two propellers, with a full load speed of 18km/h. Set up two streamlined balance helmets and equip them with a 160kN·m hydraulic servo. To effectively control vibration and noise, important compartments should be arranged away from noise sources; Optimize the shaft alignment and propeller design. Try to increase the gap between the propeller blade tip and the hull plate as much as possible, and design the propeller specifically to adapt to the uneven wake at the tail, delay the occurrence of cavitation or reduce the cavitation area, and reduce vibration; Properly strengthen the ship structure and ensure the reasonable strengthening and continuity of the entire ship structure. Strengthen the structure above the propeller and below the base. There is a good transition between bone materials and plates or between bone materials and bone materials.

Figure 5: Overview of 208TEU Inland River Pure Electric Distribution Demonstration Ship

# Marine Engineering

This ship adopts a dual motor propulsion and dual fixed pitch propeller linear transmission method. The power device consists of a propulsion motor, high elasticity coupling, reduction gearbox, propeller and propeller shaft, control and monitoring system, etc. Two TYC500-6 propulsion motors from Xiangdian Corporation are selected as the main engine, with fixed pitch propellers. Each motor, shaft system, and its corresponding power system form an independent system, and the two propulsion motors can operate independently. The propulsion motor and gearbox are remotely controlled in the cab, monitored in the monitoring room, and controlled locally at the machine side. The main propulsion device consists of a propulsion motor, a high elastic coupling, a marine directional reduction gearbox (with clutch), a control and monitoring system, a shaft system and its accessories, and a fixed pitch propeller. The basic parameters of the selected propulsion motor and gearbox are shown in Table 5.

**Table 5: Main propulsion device parameters**

Propulsion device type	Project	Numerical Value
propulsion motor	Model	Xiangdian Corporation TYC500-6
	Rated power	500kW
	Speed	1450r/min
	Number of units	2
Gearbox	Model	HCD800
	Reduction ratio	5.889:1

## Ship Electrical Design

It is recommended to use a range extender (diesel generator set) to meet the range extender requirements in the selection process of power mode for electric propulsion on this ship. This is mainly due to considerations of the operating scenario conditions being applied. At present, diesel power generation with extended range can be replaced with methanol power generation with extended range, hydrogen fuel cell with extended range, or other forms of power generation with extended range, which can increase the adaptability of new energy development to different new energy applications. In the design of this ship, sufficient design margin, interfaces, and equipment have been reserved to ensure charging, battery swapping, range extension, etc. Various modes can be freely switched, especially the range extension method. The system does not require any changes and can be directly connected for use.

In terms of power supply configuration, this ship is equipped with two containerized mobile power supplies and one generator set container on the main deck at the stern. Each containerized power supply is equipped with approximately 2000kWh of lithium iron phosphate battery packs and their supporting system equipment. Each generator set container is equipped with one 400kW marine diesel generator set and its supporting system equipment. The electrical protection level of the box type power supply shall not be lower than IP56, meeting the requirements for layout in outdoor deck spaces. There are emergency shutdown devices for each battery system on the driver's console and outside the box power supply, which can emit both visual and auditory signals during operation.

In addition, the box type power supply continuously provides power to the ship by replacing the fully charged box type power supply at the dock power station. The entire box type power supply includes a battery system, fire extinguishing system, plugging and unplugging system, fire protection design, air conditioning system, and seismic protection system. The battery system mainly consists of battery packs, high-voltage boxes, main control boxes, etc. The plug-in system mainly consists of plugs, sockets, and in place sensors. The fire protection system mainly consists of detectors, HFC-ea fire extinguishing, water sprinkler fire extinguishing, and monitoring. The fire protection design mainly consists of A60 compartments and A60 fire doors on both sides. The air conditioning system is mainly composed of air conditioning and air ducts, and the vibration isolation system uses steel wire isolators. The box type power supply is equipped with a BMS battery management system. The system has remote data monitoring function, which can be monitored and displayed in the cab.

This ship is a hybrid electric propulsion system consisting of lithium batteries, diesel generators, and dual engine propulsion. The propulsion motor is controlled by frequency conversion and commutation through a frequency converter to control the harmonic components of the ship's power grid. And there is an integrated transformer and distribution device in the engine room, which is the center of the ship's power system. The integrated transformer and distribution device distributes and converts the direct current output from lithium batteries and diesel generators into variable frequency and voltage alternating current required for propulsion motors and constant frequency and voltage alternating current required for daily electrical equipment, directly supplying power to the entire ship's propulsion motors and daily electrical equipment. The specific selection of the main propulsion motor is provided by Xiangdian Group with relevant technical information. The

specific parameters are shown in Table 5. The propulsion control system includes: 1 set of main propulsion driver control panel, 2 sets of machine side control boxes, 1 set of dual path propulsion motor tachometer, and 1 set of dual machine control handle. The main propulsion control box is located in the engine compartment. There is a remote control handle on the driver's console. In speed control mode, the speed signal can be sent to the distribution cabinet through the remote control handle, and the speed of the propulsion motor can be adjusted to achieve speed regulation.

This ship adopts a hybrid power scheme, and the propulsion control adopts an integrated design, collectively referred to as the integrated control system. It integrates the generation, use, and scheduling of energy in control functions and strategies, and is integrated into the integrated transformer and distribution device. This is mainly to reserve space for subsequent device upgrades. In addition, it is equipped with an intelligent ship system, which has functions such as remote transmission of information and data, real-time online detection of ship energy consumption parameters, and backend analysis and optimization. Many related interfaces are reserved for future upgrades and renovations of the intelligent system.

### Cost estimation and construction application situation

The estimated cost of the Changsha Yueyang 208TEU inland pure electric distribution demonstration ship is about 13 million yuan, as shown in Table 6.

**Table 6: Main propulsion device parameters**

Serial Number	Project	Amount (Ten thousand yuan)
1	Hull materials	~350
2	Main equipment of the hull	~50
3	Marine equipment and materials	~120
4	Electrical equipment and materials	~540
5	labor cost	~200
6	Value added tax and surcharges	~110
7	Other Expenses	~30
8	Total cost of ship engineering	~1400

In terms of practical construction applications, the 208TEU inland pure electric distribution dual-purpose demonstration ship officially held a groundbreaking ceremony on June 12, 2023, and construction began in July at Xinyu Shipyard in Xiangtan County. The ship is expected to be completed and put into operation by the end of December. After the delivery of the vessel, it will become the largest 88m standard lock pure electric dual-purpose ship with container loading capacity in China, and also the first new energy pure electric dual-purpose ship in Hunan, serving the 160km container shuttle bus route from Lingji Port Area of Yueyang Port City to Xianing Port Area of Changsha Port in Hunan Ocean Shipping. The construction of a 208TEU inland pure electric distribution demonstration ship is shown in Figure 6.

**Figure 6: Construction status of a 208TEU inland pure electric distribution demonstration ship**

With the construction and operation of the 208TEU inland pure electric dual-purpose demonstration ship, it is of milestone significance for promoting the green and low-carbon development of inland waterway navigation in Hunan Province's "one lake, four waters". In addition to the battery swapping function, in the future, ships will integrate digital and intelligent technology applications. After the formation of a large-scale network of ship charging and swapping stations, it is expected to achieve more than 10% of comprehensive energy-saving benefits.

## CONCLUSIONS

This article aligns with national development strategies such as "dual carbon" to promote green, low-carbon, and high-quality development of shipping in Hunan. Adhering to the development concept of safe, applicable, green, efficient, economical, and low-carbon standard ship types, guided by the goal of "green, low-carbon/zero carbon", following relevant policies, regulations, standards, and technical requirements, adapting to the navigation environment of Hunan waterway freight ships, adapting to the "waterbus" transportation mode of Hunan inland river containers, and considering adapting to the market demand for multi cargo transportation. At the same time, combining green energy, power system technology and other applications, we will develop demonstration ship types for green, high-energy and direct river and sea transportation in Hunan Province, leading the development of green and standardized ships. Develop an overall plan for the demonstration ship type of pure electric distribution in the Changsha Yueyang inland river. This ship type has a load capacity of approximately 200TEU container level and is propelled by an electric motor. Its container capacity is 208TEU, with a total length of about 88.00m and a total width of about 15.00m. The designed draft is about 2.8m.

# Hybrid and Alternative Fuel Power Management Systems in Ships - Multi-Criteria Decision-Making Assessment

Amin Nazemian<sup>1,\*</sup>, Evangelos Boulougouris<sup>2</sup>, and Sarath Krishnan Melemadom<sup>3</sup>

## ABSTRACT

*This paper addresses the maritime industry's imperative to cut greenhouse gas emissions by exploring hybrid propulsion systems for bulk carrier vessels, specifically focusing on battery systems and hybridized conventional four-stroke generator engines. Utilizing the Analytic Hierarchy Process (AHP) and MARCOS decision-making method, the study evaluates diverse factors, including capital and operational expenditures, risk, emissions, bunkering availability, and weight. The research delves into different power management system topologies, such as conventional diesel engines, ammonia, and methanol-fueled engines, along with battery hybrids. The study underscores the methodological significance of decision-making tools and anticipates that evolving regulations will drive the maritime industry towards carbon neutrality through hybrid power management systems.*

## KEY WORDS

Decarbonization; Multi-Criteria Decision-Making (MCDM); Hybrid Propulsion System; Alternative Fuel; Analytic Hierarchy Process (AHP).

## INTRODUCTION

The shipping industry has been a significant contributor to global carbon dioxide (CO<sub>2</sub>) emissions, with recent estimates indicating a 4.6% increase to 833 million tonnes in 2022 compared to 794 million tonnes in 2020 (Richardson, 2022). This rise is attributed to the combustion of approximately 203 million tonnes of fuel, primarily sourced from environmentally unfriendly fossil fuels. In response to this environmental challenge, the International Maritime Organisation (IMO) has introduced regulations under the International Convention for the Prevention of Marine Pollution (MARPOL 73/78) Annex IV as part of its decarbonization strategy (IMO, 2018). The IMO's overarching goal is to reduce annual absolute greenhouse gas (GHG) emissions from international shipping by at least 50% by 2050, compared to 2008 levels (Seddiek & Ammar, 2023). Additionally, there is a concerted effort to completely eliminate GHG emissions from the shipping industry within this century. To achieve these objectives, the IMO aims to decrease the carbon intensity emissions of global maritime transport by a minimum of 40% by 2030 and a further reduction of 70% by 2050, relative to the baseline year of 2008 (Ammar & Seddiek, 2017; IMO, 2021).

Given the prolonged lifespan of vessels, achieving these targets necessitates significant modifications to the existing fleet. Current strategies employed by the maritime sector for emission mitigation include the adoption of emissions abatement technologies, the use of marine alternative fuels, and the potential implementation of hybrid power systems (HPS) (Inal et al., 2022). This study specifically explores the use of batteries and alternative fuels such as ammonia and methanol in the power supply system of large ocean-going vessels. Advancements in battery technology, extending beyond consumer electronics and

automobiles, have prompted consideration of their application in the maritime sector. The paper delves into the energy consumption and power demands of large ocean-going merchant vessels, exploring the feasibility of incorporating batteries into the electric grid system. This integration is identified as an area where batteries and hybridization can offer significant benefits, especially as forthcoming carbon-neutral fuels are expected to incur higher costs (MAN Energy Solutions, 2019). Minimization of fuel consumption and reduction of emissions is one of the main objectives for designing the future generation of ship (Dedes et al., 2012). The development of hybrid vehicles, encompassing both terrestrial and marine applications, has emerged as a widely researched and implemented strategy to mitigate pollution within the transport sector (Chan et al., 2010). There are numerous advantages associated with the utilisation of electric hybrid systems in comparison to internal combustion engines, which pertain to both environmental and engineering considerations (Nazemian et al., 2024). The primary sources of air pollution from ships are NO<sub>x</sub>, CO<sub>2</sub>, SO<sub>2</sub>, and particulate matter. These emissions are generated either through direct combustion or as a result of chemical reactions occurring in the atmosphere. As a consequence of this, the implementation of hybrid electrical systems enables a significant decrease in pollutant emissions, as well as a substantial reduction in noise pollution (Padolecchia et al., 2023). In this context, it is imperative to thoroughly analyse power generation and power storage alternatives to identify more efficient solutions. In order to achieve an optimal and sustainable design that aligns with the ship's operation profile. Therefore, the existing scholarly literature predominantly emphasises the utilisation of batteries, supercapacitors, and flywheels as electric storage devices in conjunction with internal combustion engines and fuel cells as power generators when discussing hybridization technologies for ships (Geertsma et al., 2017; Nuchturee et al., 2020). Batteries are the dominant energy storage technology due to their superior energy density, cost-effectiveness, and extensive knowledge in various transportation sectors. They consist of electrodes, electrolytes, and separators, with performance influenced by electrode material properties (Meng et al., 2017). The selection of battery type is crucial in the maritime industry, as there are various commercially available batteries suitable for transportation. Li-ion batteries are currently preferred due to their high energy densities and extended lifetimes, which are attributed to their industrial maturity and widespread availability. Despite the potential emergence of alternative technologies, lithium-ion batteries remain the preferred choice for shipping purposes (EMSA, 2022). Study by (Geertsma et al., 2017) examines the impact of a hybrid battery-diesel electric power management system on exhaust gas emissions within the global dry bulk carrier fleet. For more information, the comparison of different types of batteries is presented in the table below.

**Table 1: Properties of different popular battery types.** (Inal et al., 2022)

Battery type	Energy density (kWh/kg)	Power density (kW/kg)	Efficiency	Lifetime(cycle)	Capital Cost(\$/kWh)
Lead-Acid	30-50 * 10 <sup>-3</sup>	75-300* 10 <sup>-3</sup>	70-90%	500-1000	70
Nickel-cadmium	50-75* 10 <sup>-3</sup>	150-300* 10 <sup>-3</sup>	60-65%	2000-2500	300
Nickel Metal Hydride	60-100* 10 <sup>-3</sup>	200-1500*10 <sup>-3</sup>	65-90%	750	300-500
Lithium-ion	100-200*10 <sup>-3</sup>	80-2000* 10 <sup>-3</sup>	85-90%	600-2000	200-700

The duration for which the battery must provide power is contingent upon the anticipated duration of unforeseen operational interruptions of the auxiliary engine. Based on empirical evidence, a battery's 15-minute duration of operation is sufficient for preventing power outages, restarting a malfunctioning auxiliary engine, and achieving optimal power output. In this particular scenario, the battery system is not to be taken as substitute for auxiliary engines, but rather as an additional system. The optimal approach, in terms of both reliability and cost-effectiveness, would involve the implementation of a solution that enables a six-hour battery operation. This duration is assumed to be adequate for resolving any potential concerns related to the auxiliary engine. The implementation of an extended battery backup system guarantees the ability to restart and restore the auxiliary engine in the event of a significant failure, thereby ensuring uninterrupted operations. Additionally, it affords maintenance personnel a sufficient duration to identify and rectify the underlying cause of the problem, thereby reducing the likelihood of a reoccurrence. Moreover, an extended battery lifespan mitigates the necessity for prompt repairs or replacements, resulting in time and resource conservation. By implementing this solution, vessel management can attain a sense of assurance, as they can be confident that their supplementary engines are adequately supported and equipped to efficiently manage unforeseen periods of inactivity. Herein, different Power Management systems with different configurations of battery hybridization and alternative fuel (Ammonia and Methanol) will be analyzed and evaluated based on decision-making process.

Ammonia and methanol are regarded as viable alternative fuels and are duly acknowledged in various power management systems. Ammonia and methanol are widely recognized as the primary candidates for alternative fuel sources, both presently and in the foreseeable future. Accordingly, different power management systems (PMS) of ship propulsion will be evaluated in this paper by combination of Conventional, Ammonia, and Methanol fuels. When evaluating each alternative fuel, the following factors are taken into account, including capital expenditures (CAPEX), risk assessment, emissions, operating

expenditures (OPEX), availability, bunkering infrastructure, and weight considerations. Various combinations of conventional fuel, alternative fuel, and hybrid systems are being considered, which are explained as follows:

1. **PMS1:** Conventional Fuel ICE.
2. **PMS2:** Conventional fuel ICE + Battery
3. **PMS3:** Ammonia ICE
4. **PMS4:** Ammonia ICE + Battery
5. **PMS5:** Methanol ICE
6. **PMS6:** Methanol ICE + Battery

This paper discusses two various combinations of ship power supply systems Traditional diesel- Mechanic propulsion (Fig.1 (a)) and semi-hybrid diesel mechanic propulsion (Fig.1 (b)).

**Figure 1: (a) Conventional diesel-mechanic propulsion system, (b) Semi-hybrid diesel mechanic propulsion system**  
(Latarche, 2021)

## METHODOLOGY

The goal of this paper is to assess compare and contrast various power management systems (PMS) utilised in maritime vessels, considering multiple criteria including capital expenditure (CAPEX), risk, emissions, operational expenditure (OPEX), availability, and weight. The objective of this study is to offer a thorough examination that can inform decision-making within the maritime sector, specifically in the selection of the most suitable PMS for a particular application of vessel. Accordingly, the study has been conducted regarding the following **steps**:

**S1. Evaluate Different PMS:** This aims to evaluate the operational efficiency and effectiveness of different power management systems (PMS) including conventional diesel engines, diesel engine-battery hybrids, ammonia ICEs, ammonia ICE-battery hybrids, methanol ICEs, and methanol ICE-battery hybrids.

**S2. Assess Criteria:** This analysis will evaluate the primary factors to consider when choosing a PMS, encompassing the initial capital expenditure (CAPEX), risk assessment through the implementation of Failure Modes, Effects, and Criticality Analysis (FMECA), emissions quantified in terms of CO<sub>2</sub> equivalents, ongoing operational expenses (OPEX), availability contingent upon fuel type and bunkering accessibility, and weight considerations.

**S3. Dedicated Calculations:** Conduct meticulous calculations for each criterion in order to determine a score for each PMS and subsequently establish a ranking based on these scores.

**S4. Apply Analytic Hierarchy Process (AHP) and MARCOS method:** Utilize the methodology known as AHP to rank the various PMS separately based on survey conduction, taking into consideration the relative relevance of each criterion. Furthermore, a dedicated calculation will be carried out using the MARCOS method on criteria and alternatives.

**S5. Compare and Contrast:** Compare the rankings derived from the dedicated calculations of MARCOS and the AHP to comprehend the effect of utilizing distinct evaluation techniques.

**S6. Provide Recommendations:** Based on the analysis, suggest to the maritime industry the most appropriate PMS for various scenarios, considering the vessel's specific requirements and constraints.

The composition of each system in EMS power plant varies with some systems employing conventional fuels, alternative fuels and hybrid configurations. Following is a summary of the six PMS systems currently under consideration:

**PMS1:** Conventional Fuel Internal Combustion Engine (ICE): This system uses conventional fuels such as LSMGO to generate power via an internal combustion engine. Currently, this is the most widely used PMS in the shipping industry.

**PMS2:** Conventional Fuel ICE + Battery: This system integrates a conventional fuel (LSMGO) internal combustion engine with a battery energy storage system. The hybrid nature of this system improves fuel economy, as the battery can store excess energy and provide additional power when required.

**PMS3:** This system uses ammonia as an internal combustion engine's fuel source and LSMGO as the pilot fuel.

**PMS4:** This system is a hybrid of an internal combustion engine powered by ammonia and LSMGO as pilot fuel with a battery storage system.

**PMS5:** This system employs methanol as an internal combustion engine's main fuel source and LSMGO as pilot fuel.

**PMS6:** This hybrid system combines an internal combustion engine fueled by methanol and LSMGO as pilot fuel with a battery storage system.

A typical configuration for an auxiliary system includes a minimum of 3 auxiliary engines. 2 engines are operating in modest loads, with another engine on standby while manoeuvring or cargo loading and unloading operations where blackouts must be avoided. This configuration permits an unexpected shutdown of one of the engines. During sailing in deep sea, 1 auxiliary engine is capable of supplying the load, the second is set to get started, and the third is undergoing maintenance. PMS1, PM3, and PMS5 do not have hybrid battery systems. These three systems are evaluated for use in important port operations with the configuration described. So, PMS1,3, and 5 will each have three engines, with two of them operating at 40% load simultaneously (Fig.2).

**Figure 2: Traditional method**

When two or more than two auxiliary engines operate at a low capacity for safety grounds, a battery has a substantial potential for savings. It can be used to mitigate sudden engine shutdowns and unforeseen events. Also, it has the capability to enhance the fuel efficiency of the auxiliary engines by selectively operating a single engine at elevated loads. The result leads to an enhancement in productivity while simultaneously decreasing operating expenses as well as repair costs. PMS 2, PMS 4, and PMS 6 have battery-hybrid systems, so in these three systems there will be two auxiliary engines, one operating at 80% capacity, second one in stop condition and battery (Fig.3).

**Figure 3: Hybrid Idea**

### Data collection of PMS scenarios for a Bulk Carrier

This study utilised data obtained from a variety of sources. This includes manufacturer data, data found in the literature, and data calculated based on established engineering principles. This section describes the methodologies used to collect data for each PMS system criterion. The ICE engines used for this study are shown in Table 2.

**Table 2: Generator engine data** (EMSA, 2022; Wärtsilä, 2023)

Power management system	Auxiliary engine	SFOC - g/kWh	Engine cost - USD/kW	Engine O&M cost USD/kW
PMS1, PMS2	Wartsila 6L25 auxiliary engine. 6-cylinder 2040kw ,900rpm	At 40% load - 198.2 At 80% load - 186.1	230	5

PMS2, PMS3, PMS4, PMS5	Wartsila 6L5DF Dual fuel Auxiliary engine, 6-cylinder 1890kW,900rpm	At 40% load - 202.1 At 80% load - 190.6	550	5.2
---------------------------	---	--	-----	-----

In both scenarios, total electric power is assumed to be 1480 kW, demanding 1560 kW from the auxiliary engine under the assumption that the generator is 95% efficient. The hotel load is assumed constant at the 560-kW required at port for operation. And the remaining power is required for port-critical activities, mainly the operation of cranes or bunker and ballast systems. In both scenarios, it is anticipated that the PMS will be operational for 1000 hours per year. For 6 hours of continuous operation in a hybrid system, the battery capacity required is 4230 kWh at a c-rate of 0.35. The Specific price of the battery in the system is taken at 500 USD/kWh, and the O&M cost is taken at 10 USD/kW (MAN Energy Solutions, 2019). Inverter installation is essential in Hybrid operation for the DC-AC conversion from the battery. The average inverter cost is 813 USD/kW (Brinsmead et al., 2015).

PMS3,4,5,6 is powered by a Wärtsilä 9L25DF engine. According to the manufacturer, this engine is already capable of running on multiple fuels and can therefore be readily upgraded to operate on future fuels like ammonia and methanol. In addition, the ratio considered for this study was influenced by Wartsila's announcement that their engine was effectively tested in full-scale operation with a blend of LSMGO (Wärtsilä, 2021).

For PMS3 and PMS 4 Fuel oil blend is: (Wärtsilä, 2021)

- GAS -> Ammonia - 70%
- Pilot fuel -> LSMGO - 30%

According to (Latarche, 2021) methanol exhibits a low ignitability when used as a fuel for internal combustion engines (ICE), as evidenced by its high ignition temperature of 470°C. Consequently, in order to ensure a consistent and stable combustion process as well as optimal engine performance, it is necessary to introduce 5% of pilot fuel, specifically LSMGO, into the combustion chamber. For PMS 5 and PMS 6 fuel oil blend is:

- GAS -> Methanol - 95%
- Pilot fuel -> LSMGO - 5%

Selective catalytic Reduction (SCR) is used as the after-treatment system for Ammonia powered PMS3 and PMS4. SCR Cost is taken 133USD/kW (EMSA, 2022).

## Calculation and Assessment of evaluation criteria

This section will elucidate the process employed for calculating and assessing the evaluation criteria. Six power plant systems of bulk carrier ship will be evaluated based on the following criteria: capital expenditure (CAPEX), operational expenditure (OPEX), risk profile, availability/bunkering, weight, and emissions. Each criterion will be assigned a weighting based on its significance to the overall performance and feasibility of the system using AHP analysis.

### CAPEX- Capital Expenditure

The capital expenditure (CAPEX) of a ship encompasses multiple components, which encompass the expenses related to the ship's asset acquisition and the financial costs associated with ship financing. In the context of ship-owners, CAPEX is typically regarded as a crucial cost component alongside OPEX within the financial statements. Numerous components, including the engine, aftertreatment system, storage tanks, and fuel supply system (FSS), are included in the fixed costs of a newly constructed vessel. The expenses incurred are not contingent upon the frequency and intensity of vessel utilization (EMSA, 2022). For the CAPEX, the cost of the engine, after-treatment system, battery, and inverter is taken into consideration as per the requirements of the PMS system.

PMS1:

CAPEX = Engine cost = 1,407,600USD

PMS2:

CAPEX= Engine cost + Battery cost + Inverter cost = 3,626,565 USD

PMS3:

CAPEX= Engine cost + SCR cost = 3,872,610 USD

PMS4:

CAPEX = Engine cost + SCR cost + Battery cost + Inverter cost = 5,269,905 USD

PMS5:

CAPEX = Engine cost = 3,118,500 USD

PMS6:

CAPEX= Engine cost + Battery cost + Inverter cost = 4,767,165 USD

### OPEX- Operational Expenditure

Operational expenditures (OPEX) encompass variable costs that are based upon the utilisation of the vessel. These costs primarily include fuel expenses, bunkering charges, maintenance, and repair costs. The daily capital and operating cost per vessel are influenced by several factors, such as crew, ship size, insurance policy, and maintenance. Several factors have been identified as influential when making investments. These factors encompass fuel prices, the geographical area in which operations are conducted, relevant regulations, the duration of time at sea, and the lifespan of the vessel (Olaniyi et al., 2018). In addition, the weather and environmental conditions encountered by a maritime vessel can have a substantial influence on its operational costs. For instance, inclement weather conditions can potentially require the consumption of extra fuel or give rise to enhanced vessel deterioration, thereby resulting in added maintenance expenses (Olaniyi et al., 2018). For the OPEX Engine O&M, Battery O&M, SCR O&M, and fuel cost are taken into consideration. Fuel cost calculations are expressed below:

Global average cost of LSMGO Fuel is 840USD/Tonne (Rotterdam Bunker Prices, 2023);

Fuel Cost Ammonia = 650USD/Tonne (EMSA, 2022);

Fuel Cost Methanol = 350USD/Tonne (Korberg et al., 2021)

PMS1:

$$\text{Fuel consumption at 40\% load} = FC_{LSMGO_{only}} = SFOC * \text{Load (40\%)} * \text{RunningHours}, = 1560 * 198.2 * 1000 * 10^{-6} = 309.19 \text{ tonnes} \text{ ,Zincir, 2022.} \quad [1]$$

$$OPEX = (FC_{LSMGO} \times \text{Fuel Cost}) + \text{Engine O\&M} = 259,721.28 \text{ USD} \quad [2]$$

PMS2:

$$\text{Fuel consumption at 80\% load} = SFOC * \text{Load (40\%)} * \text{RunningHours} = 1560 * 186.1 * 1000 * 10^{-6} = 290.316 \text{ tonnes} \quad [3]$$

$$OPEX = (FC_{LSMGO} \times \text{Fuel Cost}_{LSMGO}) + \text{Engine} + \text{Battery O\&M} = 271,315 \text{ USD} \quad [4]$$

PMS3:

$$FC_{LSMGO_{only}} = SFOC * P_{design} * \text{Load} * \text{RunningHours} \quad [5]$$

$$FR_{ammonia} = \frac{M_{ammonia} * LHV_{ammonia}}{M_{ammonia} * LHV_{ammonia} + M_{LSMGO} * LHV_{LSMGO}} \quad [6]$$

$$M_{LSMGO} * LHV_{LSMGO} = FR_{ammonia} * M_{ammonia} * LHV_{ammonia} + FR_{LSMGO} * M_{LSMGO} * LHV_{LSMGO} \quad [7]$$

Equation (5) can be used to calculate the fuel consumption of a single engine that runs solely on LSMGO for 1000 hours:

$$FC_{LSMGO_{only}} = 202.1(g/kWh) * (780 * 2) (kW) * 1000 \text{ hours} * 10^{-6} = 315 \text{ tonnes} \quad [8]$$

FR <sub>ammonia</sub>	70%
LHV <sub>ammonia</sub> (MJ/kg)	18.5
FR <sub>LSMGO</sub>	30%
LHV <sub>LSMGO</sub> (MJ/kg)	43.5

Fuel Ratios & LHV of Ammonia and LSMGO (Huang et al., 2022; Zincir, 2022).

Given that the FR<sub>LSMGO</sub> = 0.3, Equation (6) can be used to determine the ratio between the mass in tonnes consumed by ammonia (M<sub>ammonia</sub>) and the mass in tonnes consumed by LSMGO (M<sub>LSMGO</sub>). In the instance of our engine, which burns 70% NH<sub>3</sub> and 30% LSMGO as pilot fuel, the M<sub>LSMGO</sub> can be calculated as:

$$FC_{LSMGO_{only}} * FR_{LSMGO} = 315 * 0.3 = 95 \text{ tonnes.} \quad [9]$$

$$M_{ammonia} = 5.486 * M_{LSMGO} = 5.486 * 95 = 521 \text{ tonnes} \quad [10]$$

As a result, the fuel consumption for 1000 hours of main engine operation was discovered to be:

- For 1000 hours of operation, 521 tonnes of NH<sub>3</sub> are used.

- Which requires 95 tonnes of LSMGO (as pilot fuel).

$$OPEX = (FC_{LSMGO} \times Fuel\ Cost_{LSMGO}) + (FC_{Ammonia} \times Fuel\ Cost_{Ammonia}) + Engine\ O\&M\ Cost + SCR\ O\&M\ Cost = 453,577.4\ USD \quad [11]$$

#### PMS4:

Similar to Eqs (5-7) of the previous configuration for 1000 hrs operation:

$$FC_{LSMGOonly} = 190.6(g/kWh) * (1560) (kW) * 1000\ hours * 10^{-6} = 297\ tonnes \quad [12]$$

Given that the  $FR_{LSMGO} = 0.3$ , Equation (6) can be used to determine the ratio between the mass in tonnes consumed by ammonia ( $M_{ammonia}$ ) and the mass in tonnes consumed by LSMGO ( $M_{LSMGO}$ ).

In the instance of our engine, which burns 70% NH3 and 30% LSMGO as pilot fuel, the  $M_{LSMGO}$  can be calculated according to Eq (13). The ammonia consumption mass in tonne can subsequently be calculated 89 tonnes, which takes into account the various fuel ratios.

$$FC_{LSMGOonly} * FR_{LSMGO} = 297 * 0.3 = 89\ tonnes. \quad [13]$$

$$M_{ammonia} = 5.486 * M_{LSMGO} = 5.486 * 89 = 489\ tonnes \quad [14]$$

As a result, the fuel consumption for 1000 hours of main engine operation was discovered to be 489 tonnes of NH3. Which requires 89 tonnes of LSMGO (as pilot fuel).

$$OPEX = (FC_{LSMGO} \times Fuel\ Cost_{LSMGO}) + (FC_{Ammonia} \times Fuel\ Cost_{Ammonia}) + Engine\ O\&M\ Cost + SCR\ O\&M\ Cost + Battery\ O\&M\ Cost = 424,629.8\ USD \quad [15]$$

#### PMS5:

Similar to Eqs (5-7) by changing the fuel from Ammonia to methanol:

$$FC_{LSMGOonly} = SFOC * P_{design} * Load * RunningHours \quad [16]$$

$$FR_{methanol} = \frac{M_{methanol} * LHV_{methanol}}{M_{methanol} * LHV_{methanol} + M_{LSMGO} * LHV_{LSMGO}} \quad [17]$$

$$M_{LSMGO} * LHV_{LSMGO} = FR_{methanol} * M_{methanol} * LHV_{methanol} + FR_{LSMGO} * M_{LSMGO} * LHV_{LSMGO} \quad [18]$$

Equation (18) can be used to calculate the fuel consumption of a single engine that runs solely on LSMGO for 1000 hours:

$$FC_{LSMGOonly} = 202.1(g/kWh) * (1560) (kW) * 1000\ hours * 10^{-6} = 315\ tonnes \quad [19]$$

FRmethanol	95%
LHVmethanol(MJ/kg)	19.9
FRLSMGO	5%
LHVLSMGO(MJ/kg)	43.5

Fuel Ratios & LHV of Methanol and LSMGO.

Given that the  $FR_{LSMGO} = 0.3$ , Equation (6) can be used to determine the ratio between the mass in tonnes consumed by Methanol ( $M_{methanol}$ ) and the mass in tonnes consumed by LSMGO ( $M_{LSMGO}$ ). In the instance of our engine, which burns 95% Methanol and 5% LSMGO as pilot fuel, the  $M_{LSMGO}$  can be calculated by Eq (20). The methanol consumption mass in tonne can subsequently be calculated using Equation (21), which takes into account the various fuel ratios.

$$FC_{LSMGOonly} * FR_{LSMGO} = 315 * 0.05 = 15.76\ tonnes. \quad [20]$$

$$M_{methanol} = 41.53 * M_{LSMGO} = 41.53 * 15.76 = 654.6\ tonnes \quad [21]$$

As a result, the fuel consumption for 1000 hours of main engine operation was discovered to be 654.6 tonnes of methanol usage. Which requires 15.76 tonnes of LSMGO (as pilot fuel).

$$OPEX = (FC_{LSMGO} \times Fuel\ Cost_{LSMGO}) + (FC_{Methanol} \times Fuel\ Cost_{Methanol}) + Engine\ O\&M\ Cost = 271860.3\ USD \quad [22]$$

#### PMS6:

Similar to Eqs (5-7) from the previous configuration, Eq (5) can be used to calculate the fuel consumption of a single engine that runs solely on LSMGO for 1000 hours:

$$FC_{LSMGOonly} = 190.6(g/kWh) * (1560) (kW) * 1000 \text{ hours} * 10^{-6} = 297 \text{ tonnes} \quad [23]$$

Given that the  $FRLSMGO = 0.3$ , Equation (2) can be used to determine the ratio between the mass in tonnes consumed by Methanol ( $M_{methanol}$ ) and the mass in tonnes consumed by LSMGO ( $M_{LSMGO}$ ). In the instance of our engine, which burns 95% Methanol and 5% LSMGO as pilot fuel, the  $MLSMGO$  can be calculated in Eq (24). The methanol consumption mass in tonne can subsequently be calculated using Equation (25), which takes into account the various fuel ratios.

$$FC_{LSMGOonly} * FR_{LSMGO} = 297 * 0.05 = 14.85 \text{ tonnes.} \quad [24]$$

$$M_{methanol} = 41.53 * M_{LSMGO} = 41.53 * 14.85 = 614.6 \text{ tonnes} \quad [25]$$

As a result, the fuel consumption for 1000 hours of main engine operation was discovered to be:

- For 1000 hours of operation, 614.6 tonnes of methanol are used.
- Which requires 14.85 tonnes of LSMGO (as pilot fuel).

$$OPEX = (FC_{LSMGO} \times Fuel\ Cost_{LSMGO}) + (FC_{Methanol} \times Fuel\ Cost_{Methanol}) + Engine\ O\&M\ Cost \quad [26]$$

$$+ Battery\ O\&M\ Cost = 255,290.48\ USD$$

### Emissions

This study will evaluate the GHG emission of each PMS in a Tank to wake perspective, fueled by numerous fuels, including LSMGO, methanol, and ammonia. This investigation examined carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>), and nitrous oxide (N<sub>2</sub>O), the three most important greenhouse gas emissions. After carbon dioxide, CH<sub>4</sub> is the second largest contributor to greenhouse gas emissions. The vast majority of CO<sub>2</sub> emissions result from the combustion of fuels, while a negligible amount is emitted during processing. The three primary sources of CH<sub>4</sub> emissions were vented, furtive, and unburned emissions. Except for engines powered by ammonia, the contribution of N<sub>2</sub>O is minimal. Here, the greenhouse gas emissions are expressed in tonnes of CO<sub>2</sub> equivalent (CO<sub>2</sub>eq), which is shown in Table 3. The following IPCC AR5 characterization parameters were used to calculate GHG emissions in order to evaluate the warming potential over the next hundred years: 1 for CO<sub>2</sub>, 28 for CH<sub>4</sub>, and 265 for N<sub>2</sub>O (IPCC, 2023).

$$Ef(GHG) = Ef(CO_2) + 28 \times Ef(CH_4) + 265 \times Ef(N_2O) \quad [27]$$

For a medium-speed 4-stroke AE engine with:

LSMGO:

$$Ef(GHG) = 3.21 + (28 \times 5.35 \times 10^{-5}) + (265 \times 1.60 \times 10^{-4}) = 3.25 \frac{\text{ton CO}_2 - \text{eq}}{\text{ton fuel}} \quad [28]$$

Ammonia:

$$Ef(GHG) = 0 + (28 \times 0) + (265 \times 5.02 \times 10^{-3}) = 1.33 \frac{\text{ton CO}_2 - \text{eq}}{\text{ton fuel}} \quad [29]$$

Methanol:

$$Ef(GHG) = 1.38 + (28 \times 2.53 \times 10^{-5}) + (265 \times 7.59 \times 10^{-6}) = 1.38 \frac{\text{ton CO}_2 - \text{eq}}{\text{ton fuel}} \quad [30]$$

**Table 3: The engines' CO<sub>2</sub> equivalent emission factors (tons/tons of fuel) (Huang et al., 2022).**

Fuel	CO <sub>2</sub>	CH <sub>4</sub>	N <sub>2</sub> O	Total (CO <sub>2</sub> -eq)
LSMGO	3.21	$5.35 \times 10^{-5}$	$1.60 \times 10^{-4}$	3.25
Ammonia	0	0	$5.02 \times 10^{-3}$	1.33
Methanol	1.38	$2.53 \times 10^{-5}$	$7.59 \times 10^{-6}$	1.38

In our investigation of ammonia ICE and hybrid ammonia + diesel ICE, SCR is utilized to reduce N<sub>2</sub>O emissions. We assume that the SCR will contribute to a 70 percent reduction.

**Table 4: NOx Emission factor**

	Emission factor
N2O emission without SCR	1.33
N2O emission with SCR- 70% reduction	0.399

Consequently, the TTW Annual GHG Emissions have been estimated by multiplying the fuel consumptions for each scenario and shown in Table 5:

**Table 5 Emissions of each PMS**

Emissions (Ton CO2-eq)	Conventional Diesel engine	Diesel- Hybrid battery	Ammonia ICE engine	Ammonia + Diesel ICE- Hybrid	Methanol ICE	Methanol ICE+ Hybrid
	1005	944	514	485	955	900

### ***Risk***

A Failure Mode, Effects, and Criticality Analysis (FMECA) was performed in order to assess the risk of using different PMS onboard. For numerically evaluating each hazard and ranking the risk, the Risk Priority Number (RPN) indicator with the following formula has been utilised:

$$RPN = S \times P \times E \quad [31]$$

S = Severity, P = Probability, E = Ease of detection

After calculating the RPN values, a Threshold has been implemented to appropriately classify each hazard:

- Green colour, if <100 - Low risk hazard
- Yellow colour, if  $100 \leq$  medium risk hazard <180
- Red colour, if high risk hazard  $\geq 180$

For each system, potential failure modes in numerous components are identified. Here is an executive summary:

- All six systems share certain components, such as the engine (though the type of fuel varies), the alternator, the power management system, and the LSMGO bunkering procedure, and consequently share similar failure modes in these components.
- The fuel systems and safety systems differ based on whether the fuel is conventional, ammonia, or methanol, and each has its own failure mechanisms. For example, ammonia systems are susceptible to failures associated with nitrogen supply and leak detection, whereas methanol systems are susceptible to methanol pump failure or injector obstruction.
- The systems incorporating batteries, namely PMS2, PMS4, and PMS6, are equipped with supplementary components, namely the battery itself and the battery management system. These components possess essential dangers, including but not limited to battery overheating or thermal runaway, short circuit occurrences, cell degradation, and sensor malfunctions.
- It is important to note that the act of bunkering introduces various potential failure modes in all systems, and the specific nature of these failures is contingent upon the type of fuel being bunkered.

FMECA analysis for each PMS is done and the results obtained is as shown in the following risk plot.

**Figure 4: Risk plot from FMECA**

### ***Availability / Bunkering***

The research conducted an examination of thirteen prominent international ports to determine the presence of various marine fuel options and shore-side battery charging (SBC) infrastructure. The ports were strategically chosen from three regions, namely Europe, Asia, and the Americas, with each region providing a total of five ports. The marine fuel options under consideration encompassed LSMGO, Ammonia, and Methanol. The findings revealed that LSMGO was widely accessible, as it was found to be offered in all thirteen ports. The widespread use of LSMGO as a primary marine fuel in various maritime operations is evident from its ubiquity. Ammonia and Methanol were found to be accessible in eight out of the thirteen ports, indicating a discernible transition towards environmentally friendly fuel alternatives in certain regions of the globe. The aforementioned fuels were readily accessible at all European ports (with the exception of London) and Asian ports (excluding Mumbai), as well as in the cities of New York and Los Angeles within the Americas. Shore-side Battery Charging (SBC) facilities, which constitute a significant component of the maritime sector's transition towards electrification, were found to be accessible in seven out of the total thirteen ports. These facilities were accessible in all European ports, with the exception of London, as well as in Shanghai and Singapore in Asia, and in Los Angeles in the Americas.

One noteworthy observation pertained to the presence of comprehensive marine fuel and SBC facilities at the ports of Rotterdam, Hamburg, Antwerp, Shanghai, Singapore, and Los Angeles. In contrast, it should be noted that ports such as London, Mumbai, and Panama exclusively offered LSMGO. The provided data offers a concise overview of the present state of marine fuel accessibility and the level of preparedness for the implementation of electrification within the shipping sector. The aforementioned statement underscores the regional disparities in the implementation of alternative fuels and electrification within the maritime industry. Specifically, European and Asian ports tend to exhibit a more extensive range of marine fuels and shore-based charging SBC facilities in comparison to their American counterparts.

### ***Weight***

This study entails the calculation of weights for different configurations of PMS. To determine the weight of a specific PMS, technical specifications provided by the engine manufacturer have been studied. These specifications typically include information on the engine's weight, dimensions, power output, and other relevant details.

**Table 6: Engine weight data (Wärtsilä, 2023) (Latarche, 2021).**

	Wartsila 6L25	Wartsila 6L25DF
Engine Weight- in tonnes	38.3	39.6
Battery weight-system (30 kg/kWh) in tonnes	126.9	

PMS1: The present configuration employs three 6L25 engines, each weighing 38.3 metric tonnes, resulting in a cumulative engine weight of 114.9 metric tonnes.

PMS2: system achieves improved efficiency by integrating two 6L25 engines, each weighing 38.3 tonnes, along with a battery weighing 126.9 tonnes, resulting in a combined weight of 203.5 tonnes.

PMS3: system incorporates three 6L25DF engines, with each engine weighing 39.6 metric tonnes. Consequently, the total weight of the engines employed in the project amounts to 118.8 metric tonnes.

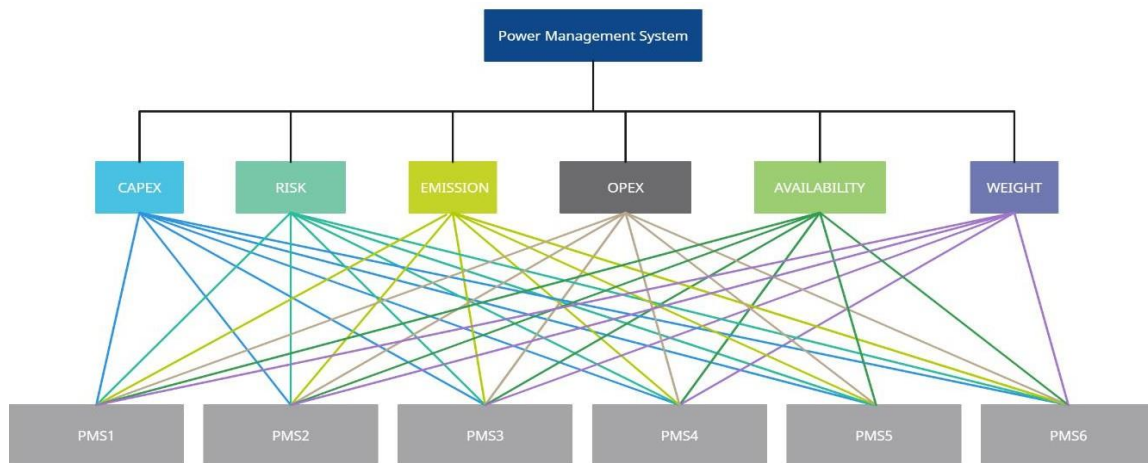

PMS4: in this configuration, combines two 6L25 engines (76.6 t) with a battery (126.9 t) to attain a total weight of 203.5 t.

PMS5: in this configuration utilises a trio of 6L25DF engines, collectively weighing 118.8 tonnes.

PMS6: this configuration utilises a hybrid PMS system consisting of two 6L25 engines weighing 76.6 tonnes each, along with a battery weighing 126.9 tonnes, resulting in a total weight of 203.5 tonnes. This weight is comparable to that of PMS2 and PMS4. The significance of the engine and battery weights in determining the overall efficiency and performance of each PMS configuration cannot be overstated. The evaluation of these weights will greatly contribute to the findings of this study

## AHP method

The Analytic Hierarchy Process (AHP) will be used to rank the PMS systems based on the importance of each criterion in terms of the overall performance and feasibility of the system. Fig.5 depicts hierarchical decision-making framework of the study regarding the goal of hybrid and alternative fuel power management systems in Ships.

**Figure 5: AHP flowchart for this study.**

The research further demonstrates its practical application by employing a questionnaire to conduct surveys among identified Decision Makers (DMs). By using pairwise comparison and AHP techniques, managers can analyze many solutions based on various factors and prioritize them based on their preferences. The survey has been conducted among key stakeholders such as maritime industry, universities, technology companies, research and development (R&D) branches and etc.

## Measurement of Alternatives and Ranking according to Compromise Solution (MARCOS) method

The Measurement of Alternatives and Ranking according to MARCOS method is a decision-making technique used in multi-criteria decision analysis (MCDA). It is designed to help decision-makers evaluate and rank a set of alternatives based on multiple criteria or objectives. The MARCOS method uses a compromise solution that balances the conflicting objectives represented by the criteria. Pairwise comparison of criteria and defining the weight of each criteria have been obtained from AHP method section. The MARCOS method is performed through the following steps (Stević et al., 2020):

**Step 1:** Creating an initial fuzzy decision-making matrix.

**Step 2:** Formation of an extended initial matrix (X). In this step, the extension of the initial matrix is performed by defining the ideal (AI) and anti-ideal (AAI) solution.

**Step 3:** Normalization of the extended initial matrix (N).

**Step 4:** Determination of the weighted matrix (V). The weighted matrix V is obtained by multiplying the normalized matrix N with the weight coefficients of the criterion.

**Step 5:** Calculation of the utility degree of alternatives  $K_i$ .

**Step 6:** Determination of the utility function of alternatives  $f(K_i)$ .

**Step 7:** Ranking the alternatives based on the final values of utility functions.

The MARCOS method provides a structured approach that the best alternative is the one that is closest to the ideal and at the same time furthest from the anti-ideal reference. It aids decision-makers in identifying trade-offs and making informed choices aligned with their preferences and objectives.

## RESULTS AND DISCUSSION

### Survey and AHP results

The following report analyses six PMS options for ocean-going vessels: This pairwise comparison matrix in Table 7 illustrates, according to the evaluation, how each criterion (CAPEX, RISK, Emission, OPEX, Availability, and Weight) compares to each other in terms of importance. This matrix is used to determine the relative weights of the criteria, which are then used to rank the alternatives (in this case, the Power Management Systems). Priority weights are computed by normalising and then aggregating the values in each column and row.

**Table 7: Pairwise comparison of criteria**

	CAPEX	RISK	Emission	OPEX	Availability	Weight
CAPEX	1.00	5.00	0.20	1.00	5.00	7.00
RISK	0.20	1.00	0.20	0.33	3.00	5.00
Emission	5.00	5.00	1.00	5.00	7.00	9.00
OPEX	1.00	3.00	0.20	1.00	5.00	7.00
Availability	0.20	0.33	0.14	0.20	1.00	3.00
Weight	0.14	0.20	0.11	0.14	0.33	1.00

The resulting weights reflect the relative significance of each decision-making criterion. These weights are then used to perform a weighted evaluation of the alternatives, which ultimately results in the alternatives' final ranking. By calculating the priority vector using the pairwise comparison matrix, the priority of each alternative is determined, along with its rank. as shown in the table 8.

**Table 8 Priority of each alternative**

	Priority vector	Priority (%)	RANK
CAPEX	0.195	19.46	2
RISK	0.091	9.06	4
Emission	0.468	46.78	1
OPEX	0.172	17.17	3
Availability	0.049	4.89	5
Weight	0.026	2.64	6

About 47 percent of criteria preference devotes to emission reduction, which shows the most important parameter of propulsion system selection among ship operators and designers. CAPEX and OPEX are second and third rank in the survey in about equal priority. The following matrices show the alternatives for each criterion.

**Table 9 Alternatives for criterion CAPEX**

Alternatives	PMS1	PMS2	PMS3	PMS4	PMS5	PMS6
PMS1	1.00	5.00	5.00	9.00	3.00	7.00

**Figure 6: Mean prioritize of alternatives by percentage.**

**Table 16: PMS alternatives ranking.**

Power system	Alt. num.	Rank
PMS1: Conventional Fuel ICE	3.259	5
PMS2: Conventional fuel ICE + Battery	2.903	6
PMS3: Ammonia ICE	6.985	2
PMS4: Ammonia ICE + Battery	9.068	1
PMS5: Methanol ICE	3.342	4
PMS6: Methanol ICE + Battery	4.197	3

According to AHP analysis results in Table 16, one may conclude hybridised system of ICE engines with battery (PMS 4) can be the best option among alternatives. The availability and cost of Ammonia as an alternative fuel make it appealing among stakeholders and can be a possible option for marine fuel in the future of the shipping industry. In the next section, another Multi-Criteria Decision-Making (MCDM) process will be carried out based on available data and dedicated calculations.

## Criteria Evaluation for MARCOS Analysis

The specialised calculations provide a comprehensive evaluation of each power management system based on the values for each criterion. In the present section, these calculations are presented independently for each criterion, providing a clear overview of the performance of each PMS in each criterion. The sections that follow detail the calculations performed for each criterion. Measurement of Alternatives and Ranking according to Compromise Solution (MARCOS) method will be applied to alternatives to rank them and compare them with AHP method.

### CAPEX

Based on the cost of the systems and their installation, the CAPEX for each PMS was computed. The following are the results:

$$(If\ CAPEX = \$\ 0\ then\ Score = 100\ @If\ CAPEX = \$\ 8\ mil\ then\ Score = 0) \quad [32]$$

**Table 17: CAPEX Results**

Alternatives	USD	Score
PMS1 (Conventional Diesel Engine)	\$1407600	82.41
PMS2 (Diesel Engine-Battery Hybrid)	\$3626565	54.67
PMS3 (Ammonia ICE)	\$3872610	51.59
PMS4 (Ammonia ICE-Battery Hybrid)	\$5269905	34.13
PMS5 (Methanol ICE)	\$3118500	61.02
PMS6 (Methanol ICE-Battery Hybrid)	\$4767165	40.41

The conventional diesel engine system, PMS1, has the lowest CAPEX, whereas the most advanced and advanced system, the ammonia ICE-battery hybrid system, PMS4, has the highest CAPEX. The remaining systems range between these two extremes.

### RISK

Calculated using Failure Modes, Effects, and Criticality Analysis (FMECA), The risk values for each PMS are as follows: To determine these normalised values, all RPN for each FMECA analysis are added together. The PMS1 had the lowest risk score, with a value of 3,459. This was likely due to its long-standing use and continuous improvements. The PMS4, received the maximum risk score of 5816. The risk scores for the remaining systems, PMS2, PMS3, PMS5, and PMS6, were 4456, 4735, 4604, and 5195, respectively, due to the incorporation of alternative fuels and hybrid technologies. Comparing these risk scores assists in determining the tradeoffs involved in selecting an appropriate PMS for ocean-going vessels.

**Table 18: Risk Results (Total of RPN values)**

Alternatives	RISK	Score
PMS1 (Conventional Diesel Engine)	3459	50.59
PMS2 (Diesel Engine-Battery Hybrid)	4456	36.35
PMS3 (Ammonia ICE)	4735	32.36
PMS4 (Ammonia ICE-Battery Hybrid)	5816	16.92
PMS5 (Methanol ICE)	4604	34.23
PMS6 (Methanol ICE-Battery Hybrid)	5195	25.79

Conditions considered,

$$(If \text{ RISK} = 1 \text{ then Score} = 100 @ If \text{ RISK} = 7000 \text{ then Score} = 0) \quad [33]$$

**Table 19: Risk analysis**

	High	Medium	Low	
	RED	Yellow	Green	Total
PMS1	8	10	5	23
PMS2	11	12	6	29
PMS3	12	11	7	30
PMS4	16	13	7	36
PMS5	11	12	7	30
PMS6	13	14	6	33

### **Emission**

These are the calculated emission values for every PMS in terms of carbon dioxide equivalents (CO2 eq):

**Table 20 Emissions Results**

Alternatives	Emission	Score
PMS1 (Conventional Diesel Engine)	1004	16.26
PMS2 (Diesel Engine-Battery Hybrid)	943	21.37
PMS3 (Ammonia ICE)	514	57.13
PMS4 (Ammonia ICE-Battery Hybrid)	485	59.57
PMS5 (Methanol ICE)	954	20.44
PMS6 (Methanol ICE-Battery Hybrid)	900	24.97

Conditions considered,

$$(If \text{ Emission} = 0 \text{ then Score} = 100 @ If \text{ Emission} = 1200 \text{ then Score} = 0) \quad [34]$$

The PMS1 had a high CO2 eq emission value of 1004,87 tonnes CO2 eq, indicating a substantial contribution to greenhouse gas emissions. At 485.16 tonnes CO2 equivalent, the PMS4 had the lowest emission value, highlighting the potential environmental benefits of using ammonia, a carbon-free propellant, and a battery hybrid system. Other systems, PMS2, PMS3, PMS5, and PMS6, demonstrated lower emissions, demonstrating the potential of alternative fuels and hybrid technologies to reduce the environmental impact of ocean-going vessels.

### **OPEX**

OPEX represents the continual expenses associated with the PMS's operation and maintenance. The cost of fuel has the greatest impact on the OPEX. The following table shows the OPEX for each PMS:

**Table 21: OPEX results**

Alternatives	USD	Score
PMS1 (Conventional Diesel Engine)	\$ 290321	51.61
PMS2 (Diesel Engine-Battery Hybrid)	\$ 271315	54.78
PMS3 (Ammonia ICE)	\$ 453577	24.40
PMS4 (Ammonia ICE-Battery Hybrid)	\$ 424629	29.23
PMS5 (Methanol ICE)	\$ 271860	54.69

Conditions considered,

$$(If\ OPEX = 0\ then\ Score = 100@If\ OPEX = 600000\ then\ Score = 0) \quad [35]$$

The cost of fuel has a significant impact on the OPEX values. Alternative fuels such as ammonia and methanol are not widely available and are more expensive than conventional fuels such as LSMGO. The highest OPEX for PMS3 is 453,577.36, indicating that ammonia-fueled systems incur greater operating expenses. PMS4 has 424,629.80, indicating that battery systems incur additional costs. At 255,290.48 USD, PMS6 has the lowest OPEX, demonstrating economic efficacy. Other systems have intermediate OPEX values, emphasising trade-offs between ongoing operational expenses and fuel expenses. The following figure shows the graphical representation of the OPEX.

### Availability/Bunkering

The data on bunkering availability illustrates the availability of various fuel types at thirteen global ports. LSMGO is commonly used in the maritime industry, while alternative fuels such as ammonia and methanol are available in eight of thirteen ports. Seven out of thirteen ports offer shoreside battery charging (SBC) facilities, indicating the development of electric power infrastructure in the maritime industry but limited availability relative to traditional fuels. These bunkering availability statistics illustrate the current state of fuel infrastructure in the world's main ports, indicating that alternative fuels and electric power are becoming more prevalent but still lag behind traditional fuels such as LSMGO. This could have a negative effect on the viability and operational flexibility of ships powered by alternative fuels or hybrid systems.

**Table 22: Availability/Bunkering evaluation based on operational ports.**

	Ports	LSMGO	Ammonia	Methanol	SBC
1	Rotterdam	✓	✓	✓	✓
2	Hamburg	✓	✓	✓	✓
3	London	✓			
4	Antwerp	✓	✓	✓	✓
5	Barcelona	✓			✓
6	Shanghai	✓	✓	✓	✓
7	Singapore	✓	✓	✓	✓
8	Ulsan	✓	✓	✓	
9	Dubai	✓		✓	
10	Mumbai	✓			
11	New York	✓	✓	✓	
12	Los Angeles	✓	✓		✓
13	Panama	✓			
	Total	13	8	8	7

**Table 23: Availability/Bunkering results.**

Alternatives	Bunkering	Availability	Score
PMS1 (Conventional Diesel Engine)	LSMGO	13.00	90.91

PMS2 (Diesel Engine-Battery Hybrid)	LSMGO + SBC	13.70	95.80
PMS3 (Ammonia ICE)	Ammonia (70%)+LSMGO (30%)	9.50	66.43
PMS4 (Ammonia ICE-Battery Hybrid)	Ammonia (70%) +LSMGO (30%) + SBC	10.20	71.33
PMS5 (Methanol ICE)	Methanol (95%) +LSMGO (5%)	8.25	57.69
PMS6 (Methanol ICE-Battery Hybrid)	Methanol (95%) +LSMGO (5%) + SBC	8.95	62.59

Conditions considered,

SBC is given a 10% extra weightage in hybrid PMS.

$$(If\ Availability = 14.3\ then\ Score = 100@If\ Availability = 0\ then\ Score = 0) \quad [36]$$

### Weight

The PMS1, PMS3, and PMS5 all utilise three engines with total weights of 114.9 tonnes, 118.8 tonnes, and 118.8 tonnes. The remaining three systems PMS2, PMS4, and PMS6 are hybrid systems that include a battery weighing 126.9 tonnes. The total weight of these systems was determined by adding the weight of the two engines (79.2 tonnes) to the weight of the battery, resulting in a total weight of 206.1 tonnes for each system. The PMS's weight is a crucial factor in the decision-making process, as it impacts the performance of the vessel, its fuel efficiency, and the space required for the PMS.

**Table 24: Weight assessment results.**

Alternatives	Tonnes	Score
PMS1 (Conventional Diesel Engine)	115	77.35
PMS2 (Diesel Engine-Battery Hybrid)	206	23.42
PMS3 (Ammonia ICE)	119	75.04
PMS4 (Ammonia ICE-Battery Hybrid)	206	23.42
PMS5 (Methanol ICE)	119	75.04
PMS6 (Methanol ICE-Battery Hybrid)	206	23.42

Conditions considered,

$$(If\ Weight = 77\ then\ Score = 100@If\ Weight = 246\ then\ Score = 0) \quad [37]$$

Based on these calculations, each PMS can be evaluated and compared to determine the most suitable system considering the specific needs and constraints of the vessel.

### MARCOS Analysis

After closely evaluating each PMS across the selected criteria using specialised calculations, the following ranking was determined by using MARCOS method. The MARCOS method is used for ranking alternatives based on multiple criteria while seeking a compromise solution. In order to determine the rank of each PMS, the values derived from the calculations are converted into unitless numbers and expressed as scores ranging from 1 to 100. All MARCOS process will be depicted in Tables 25 to 29.

**Table 25: Criteria comparison and weight implementation.**

<b>PMS4</b>	0.74	0.26	0.65	<b>2</b>
<b>PMS5</b>	0.74	0.26	0.54	<b>4</b>
<b>PMS6</b>	0.74	0.26	0.50	<b>6</b>

**Table 30: MARCOS analysis result.**

<b>Power system</b>	<b>Rank</b>
PMS1: Conventional Fuel ICE	<b>3</b>
PMS2: Conventional fuel ICE + Battery	<b>5</b>
PMS3: Ammonia ICE	<b>1</b>
PMS4: Ammonia ICE + Battery	<b>2</b>
PMS5: Methanol ICE	<b>4</b>
PMS6: Methanol ICE + Battery	<b>6</b>

As a result of the MARCOS method, PMS3 has been chosen as the first-rank PMS alternative for under-studied bulk carrier ship propulsion systems. The main difference between MARCOS results with AHP is the position of PMS3 and PMS4 in rank first and second, which are substituting each other. The reason for PMS3's advantage against PMS4 is two main parameters Risk and Weight.

## CONCLUSIONS

This study delivered a thorough look at how well different power management systems (PMS) for vessels work, how much they cost, and what risks they pose. Using MARCOS method on dedicated calculations and the Analytic Hierarchy Process (AHP), important criteria of decision-making process have been evaluated. The dedicated calculations conducted involved comprehensive evaluations of various systems, considering the present circumstances, available data, and associated costs. The anticipated future developments, which were accomplished through the application of the Analytic Hierarchy Process (AHP), facilitated the comparison of each criterion and alternative from the perspective of a marine expert, aligning them with desired future outcomes. Based on the current circumstances that were taken into the calculations, the ammonia ICE (PMS3) emerged as the top option due to its lower pollution, acceptable operational costs, and reduced risk, closely followed by the ammonia ICE-battery hybrid (PMS4). However, when future scenarios are considered and criteria are prioritised using the AHP method, the rankings change, and the ammonia ICE-battery hybrid (PMS4) becomes the leading contender. This demonstrates the significant potential of ammonia as an alternative fuel and hybrid system to address the crucial challenge of reducing emissions when given priority. In the AHP classification, the standalone ammonia ICE system (PMS3) holds a firm second place, further demonstrating the potential of ammonia-fueled systems. In third place, the methanol ICE-battery hybrid (PMS6) is also a compelling future option, demonstrating the potential versatility of methanol fuel and hybrid systems.

The PMS5 and PMS6 systems that use methanol stand out as good choices to think about now and in the future. Their high carbon emissions, on the other hand, are a big problem. Innovations like onboard carbon capture units to reduce TTW emissions and the use of "green methanol" could reduce this pollution, making methanol-fueled systems more practical. In the same way, a machine that runs on ammonia could have a lot less pollution over its whole time if it used green ammonia in well to tank emissions. This study points out that infrastructure for alternative fuels and shoreside battery charging (SBC) at ports is one of the most important things to think about. As the company advances towards more environmentally friendly methods, there should be more of this kind of equipment. As technology improves, the costs of alternative fuels and the costs of buying the appropriate engine and safety systems are likely to go down in the future. This makes the case for using hybrid systems and alternative fuels even stronger, which could make them the best choice for future marine activities. Here are some conclusions about why dedicated calculations using the MARCOS method and AHP methods may have produced different rankings, as well as the strengths and weaknesses of each method.

## DATA ACCESS STATEMENT

Research data must be shared via data repositories. The publisher, TU Delft OPEN Publishing, requires authors to cite any publicly accessible research data in their reference list and will verify this as a condition of publication. The publisher, TU Delft OPEN Publishing, encourages research data to be made accessible under open licenses that permit reuse freely. References to datasets (data citations) must include a persistent identifier (such as a DOI). The publisher, TU Delft OPEN Publishing, does not enforce particular licenses for research data, where research data are deposited in third party repositories.

## CONTRIBUTION STATEMENT

**Author 1:** Conceptualization; data curation; methodology; validation; writing – original draft. **Author 2:** conceptualization; supervision; writing – review and editing. **Author 3:** conceptualization, data curation, formal analysis, investigation, writing – original draft.

# The impact of hydro generation on board large sailing yachts

Marijn van der Plas<sup>1,\*</sup>, Wick Hillege<sup>2</sup> and Peter de Vos<sup>3</sup>

## ABSTRACT

*In response to the leading narrative of increasing sustainability in the yachting sector, a research collaboration is started between the Delft University of Technology and Dykstra Naval Architects (DNA) to examine the potential use of hydro generation on board large sailing yachts. By harvesting energy from the water flow when a yacht is sailing, diesel generator use can be limited, reducing overall emissions. However, it is a challenge to quickly identify the impact of a chosen hydro generation system on the overall design during the early stages of yacht design. A design method, with a primary focus on the propeller, is therefore developed to quantify this impact. This allows the designer to explore various hydro generation systems in an early design stage. This paper describes the developed method and presents results from a case study to provide insight into the applicability of the method.*

## KEY WORDS

Hydro generation; Sailing; Ship design; Sustainability

## INTRODUCTION

The yachting industry is growing, as is the idea of sustainable yachting. Sailing yachts can limit emissions from the yachting sector with their ability to transit without using fossil fuels. However, a modern sailing yacht does require electricity to run its hotel, navigation, and sailing systems during sailing. The main engine or a dedicated engine-generator set usually provides this electricity. Alternative solutions for this exist. This paper focuses on one of these alternatives: hydro generation.

Hydro generation is the process of extracting momentum from a water flow to generate electricity. On board a sailing yacht this is achieved using the propulsion propeller or a separate dedicated turbine. This concept is realized in, among others, sailing yachts Black Pearl, Perseverance, and Project Zero, the latter currently under construction at Vitters Shipyards. The implementation of hydro generation serves two purposes: economic and ecological improvement, i.e. installing a hydro generation system limits the use of fossil fuel onboard, decreases related costs, and limits fuel-related emissions. However, it does give rise to several challenges that need to be overcome. These challenges find their origin in the required balance between the inevitable increase in system weight and size relative to, for example, emission reduction.

Today's approach towards analyzing a hydro generation system is characterized by detailed propeller calculations combined with refined flow analysis to converge to the optimum configuration. This approach requires detailed knowledge about the

yacht's lines plan and chosen propulsion system making it unsuitable to use in the early stages of yacht design. The study presented here aims to overcome this difficulty by only utilizing first principles and main particulars. The method developed for this study allows the designer to efficiently investigate the impact of various configurations on the overall design, safeguarding the necessary flexibility.

The design method considers the impact of six major variables that influence hydro generation. The first three variables concern size and include the propeller diameter, battery capacity, and sail area. The remaining variables relate to operational and design choices and include decisions on energy consumption, fixed or controllable pitch propellers, and generation in the first or third quadrant of the propeller diagram. A case study for an ocean crossing with a sailing yacht aiming to limit fuel consumption demonstrates the influence of these design decisions. It shows that this method can support major design choices whilst having limited knowledge about the final design.

## THEORY

Since this method is intended for an early-stage design assessment the calculations are very general. The energy balance is analyzed using only main dimensions and rough propeller data.

### Turbine physics

A hydro turbine is designed to extract energy from a fluid flow and convert it to useful work. Since the turbine under consideration here is placed in an open flow, under a hull, the available power in the flow depends on the cross-sectional area, speed, and density of the fluid only:

$$P_{flow} = \frac{1}{2} \rho V_a^2 \cdot \dot{V} \quad (1)$$

$$P_{flow} = \frac{1}{2} \rho V_a^3 \cdot A_0 \quad (2)$$

Where in this case,  $\rho$  is the density of seawater,  $V_a$  is the advance velocity of the propeller, and  $A_0$  is the propeller disc area. The efficiency of a turbine is often defined in literature by the fraction of the output of the turbine (in useful work) divided by the energy supplied to it; in case of a classical hydro turbine, this is the power present in the flow. For a turbine mounted on a moving object (the yacht), the energy supplied to it is not the power present in the flow, but rather the power required to move it through the water, so effectively, the drag of the unit multiplied by its speed through the water. The ratio between the power in the flow versus the output power is however significant property of the turbine, and is referred to as the power coefficient ( $C_p$ ) in this paper, this in analogy to the power rating of wind turbines:

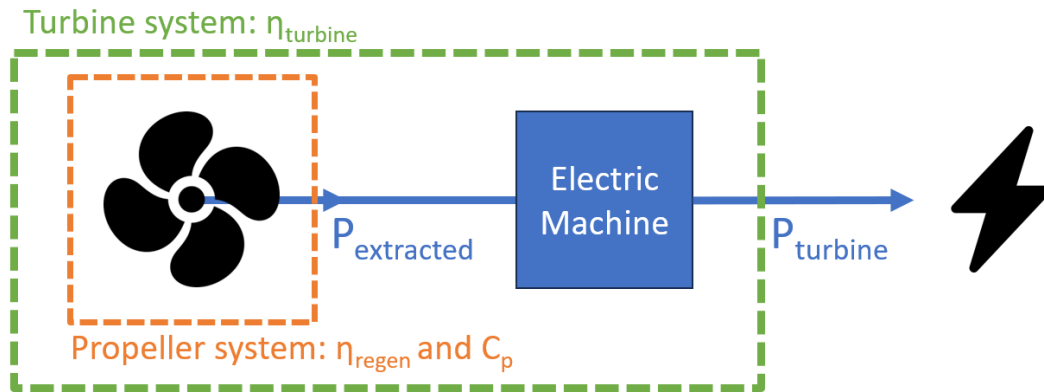

$$C_p = \frac{P_{extracted}}{P_{flow}} = \frac{P_{extracted}}{\frac{1}{2} \cdot \rho \cdot V_a^3 \cdot A_0} \quad (3)$$

$$P_{extracted} = C_p \cdot P_{flow} = C_p \cdot \frac{1}{2} \cdot \rho \cdot V_a^3 \cdot A_0 \quad (4)$$

The ratio between the useful power and the supplied power is, in analogy with common propeller theory, defined as the output power divided by the input power:

$$\eta_{regen} = \frac{P_{extracted}}{T \cdot V_a} = \frac{Q \cdot \omega}{T \cdot V_a} \quad (5)$$

Where  $T$  normally stands for thrust of the propeller, which in this case means the drag of the propeller in turbine mode as described above. Note that the extracted power here is defined at the propeller shaft, i.e. mechanical losses and conversion efficiencies are not incorporated in  $\eta_{regen}$  and  $C_p$ , as is depicted below.

**Figure 1:** System definition for hydro generation systems

## Turbines on sailing yachts

Every modern sailing yacht is fitted with a propeller for mechanical propulsion. With some adjustments and additions, this propeller can also function as a hydro generator. However, a propeller adds momentum to a flow, and a turbine is designed to extract the maximum energy from the available flow momentum. These are fundamentally different objectives combined with different physics. Propellers will generate a contracting flow and turbines an expanding flow. Furthermore, the flow around the blade is dissimilar for turbines and propellers. For propellers, lift is generated in the forward direction to deliver propulsion. For turbines, this lift is generated backwards resulting in drag. This is achieved by altering the angle of attack on the propeller blades. The main problem is the required shape. The shape differs for an optimal propeller from that of an optimal turbine. There are two adjustments that (partially) overcome this problem, either by adjusting the pitch of the blades, the flow direction, or both.

### *Fixed and controllable pitch propellers*

Propellers can roughly be divided into two groups, fixed-pitch propellers (FPP) and controllable-pitch propellers (CPP). When considering an FPP, the pitch of the blades cannot be adjusted. The propeller is designed to work well in one operating point, likely a design point in propulsion. Outside this point, the propeller will not operate optimally and efficiency is compromised. Modern sailing yachts however operate at more than one operating point being propulsion, motor sailing, and free sailing. This requires a certain flexibility in different pitch settings. For this reason, the second propeller type, a CPP, is mostly applied on modern sailing yachts. Additional benefits of a CPP arise when considering hydro generation. During hydro generation, a sailing yacht is slowed down depending on the amount of energy extracted from the flow. Knowing this it can be reasoned that a CPP allows for more efficient hydro generation as the blade's pitch can be adjusted to meet the changing flow speed whilst tuning to the desired system energy output. This characteristic makes a CPP more suitable for hydro generation when compared to an FPP as it allows for better balancing the desired energy extracted with the desired sailing speed.

## Generation quadrants

In this study the definition by Kuiper (1991) is adopted for the four propeller quadrants, it describes the transition between each quadrant as a function of the hydrodynamic pitch angle  $\beta$ . Several points of interest occur when increasing  $\beta$  for a fixed blade profile. In figure 2, points of interest on a fixed blade are shown:

**Figure 2:** Four quadrants and the hydrodynamic pitch angles on a blade

## FORCE BALANCE

During the simulations, the equations of motion are solved in 1 degree of freedom, x-direction only. For this, a force balance is defined for the conditions of motoring, free sailing, and for hydro generating. The latter is discussed in more detail below and shown mathematically in equation 6. The left-hand side of this equation represents the energy input in the system, driving force by the sails or propeller (not touched upon in this paper), whereas the right-hand side represents the energy output or loss.

When hydro generating, the total resistance comprises four parts: the hull resistance, the additional resistance due to side force, the resistance caused by the propeller blades ( $R_{prop,generation}$ ), and the propeller related structure resistance ( $R_{structure}$ ), equation 6.

$$F_{driving} = R_{hull} + R_{side} + R_{prop,generation} + R_{structure} \quad (6)$$

During the simulations the hull resistance and resistance due to side force are calculated adopting the relations developed

with the Delft Systematic Yacht Hull Series (DSYHS) as described by Keuning and Sonnenberg (1998). To determine the additional resistance due to hydro generation new formulations are derived. To better understand these formulations an understanding of feathered drag is necessary.

Feathered drag is the resistance of the propeller, in feathered condition, including surrounding structures. The presumption for this calculation is that the propeller blades are pitched into a setting where the least resistance occurs. Feathered drag is determined by multiplying a Prismatic Parameter (PiPa) with the pressure of water flow through the propeller area:

$$R_{feathered} = PiPa \cdot p_{flow} \quad [N] \quad (7)$$

$$= \left( \left( \frac{A_e}{A_0} \cdot A_0 \right) \cdot C_d \cdot \frac{A_p}{A_d} \right) \cdot \left( \frac{1}{2} \cdot \rho \cdot V_a^2 \right) \quad [N] \quad (8)$$

This formula encompasses all submerged propulsion system parts, such as hull bossing, shaft, struts, shaft brackets, and the propeller itself. The formula is based on the propeller area. It uses a coefficient  $C_d$  for the drag and a factor of  $\frac{A_p}{A_d}$  to account for the difference between the developed area and the projected area of the propeller. Coefficient  $C_d$  for a feathered propeller is taken as 0.3 based on the findings of MacKenzie and Forrester (2008). The factor  $\frac{A_p}{A_d}$  is based on formula 9 by Gerr (1989), adopting an average  $\frac{P}{D}$  of 1.

$$\frac{A_p}{A_d} = 1.0125 - \left( 0.1 \cdot \frac{P}{D} \right) - \left( 0.0625 \cdot \frac{P}{D} \right)^2 \quad [-] \quad (9)$$

To determine the total resistance during generation a distinction between drag caused by the structure and drag caused by the propeller is necessary as propeller drag varies with the propeller setting. It can be shown that roughly 50% of the total feathered resistance can be attributed to the structure, equation 10. Further research in this area is recommended to refine this ratio.

$$R_{structure} \approx \frac{1}{2} R_{feathered} \quad (10)$$

The remaining resistance contribution is the resistance caused by the propeller blades during generation. For this, propeller curves in the first and third quadrant are constructed based on the chosen propeller geometry. To construct the propeller curves the polynomials describing the B4-70 propeller family are used as published by MARIN, van Lammeren et al. (1969). The outcome presents itself in  $K_t$  and  $K_q$  values for different hydrodynamic pitch ( $\beta$ ) angles and  $\frac{P}{D}$  values. Matching the  $K_t$  value to the selected propeller setting allows for calculating the propeller blade drag.

The force balance described above is used to determine the possible output of a specific hydro generation setup for various environmental conditions. For this, a performance prediction program is developed of which results are shown in figure 3.

Figure 3 indicates in white the conditions when there is not enough or too much wind. It is for these wind angles and wind speeds that the yacht will not sail and her main engine(s) are used to provide the necessary driving force to allow travel at transit speed. Transit speed is the desired minimum speed at which a yacht can perform a transit, this speed is based on the yacht's length. The grey area in the graph represents a free sailing condition, i.e. when the desired transit speed can be reached under sail power alone and the engines are turned off. However, hydro generation does not occur yet, as this would result in the transit speed dropping below a preset limit. The colored part of the graph represents the hydro generation condition where the limit of the transit speed is surpassed under sail power alone. The excess energy can now be harvested through hydro generation.

**Figure 3:** System energy output for the first quadrant

## Hotel Load

The yacht's energy demand, or hotel load, is calculated adopting the method developed by Van Eesteren Barros and YETI van Eesteren Barros (2022). The yacht's operational profile is hereby taken into account. Following on board measurements and interviews with captains and crews, the values calculated via the YETI approach were deemed to be high, especially for sailing yachts. To better match the on board measured values a multiplication factor as a function of the yacht's waterline length is determined. For this a second-degree polynomial was drawn through the available data, resulting in a multiplication factor of roughly 0.42.

## CASE STUDY

The goal is to perform a fuel-minimizing ocean passage. This means that the hotel load, modeled as a constant average, is compensated by utilizing hydro generation during the crossing where possible. A common ocean crossing for many big-class yachts is from the Mediterranean to the Caribbean once the European summer has ended. In this scenario, the sailing yacht leaves Gibraltar with a full battery and sets sail for the West Indies. The yacht's battery life is monitored for multiple crossings adopting a prediction for the chance of motoring, free sailing, and hydro generation. A crossing is considered a success if the crossing is completed without additional use of the diesel generator to supply the hotel load. A success rate is determined by dividing the number of successful crossings by the absolute number of crossings. For this case study five energy management rules are set to which the yacht adheres during each crossing.

- The engine covers the hotel load if turned on. The battery is not charged in this situation.
- The engine is used if the yacht cannot reach 80% transit speed using sails only.
- If 120% transit speed is reached under sail power alone, hydro generation is initiated. Transit speed is derived using the yacht's waterline length ( $l_{wl}$ ) in meters, and relations shown in equation 11.
- Energy is supplied via the main engine, generators, and hydro generation only.
- A diesel generator supplies the hotel load if the battery state of charge reaches zero, and hydro generation is not possible.

$$F_n = \frac{V_{transit}}{\sqrt{g \cdot l_{wl}}} [-] \quad \text{in which:} \quad F_n = 0.3 - 0.1 \cdot \left( \frac{l_{wl}}{150m} \right) [-] \quad (11)$$

Typically, a crossing would be planned based on the weather, resulting in the best route. In this case study the crossing starts at fixed time intervals, regardless of the weather. Also, the great circle route is sailed, even if a longer distance passage would be faster. Predicting the wind that a vessel might encounter on this route is done through a weather mapping calculation developed by DNA. This weather mapping calculation determines a probabilistic distribution of prevailing wind speed and direction along that particular route based on historical weather data. To create the distribution used for this study the crossing is completed 190 times in a straight line at transit speed. The crossing is executed between October and November, the usual time for a crossing like this. A crossing is completed every ten days using wind data from 1979 to 2009. All data is summarized in a wind probability matrix with wind speed and wind direction on its axis.

## Event distribution

The information displayed in figure 3 shows the energy output for various wind direction and speed combinations. It also shows the conditions for which, motoring, free-sailing, and hydro generation occur. By multiplying this data with the wind probability matrix a probability distribution for motoring (A), free-sailing (B), and hydro generation (C) can be calculated. For this case the event distribution equals roughly, 30% motoring, 50% free sailing, and 20% hydro generating, 5. Each event is considered independent.

Adopting the chances for an event to occur, a route is simulated using a randomizing function. A route is characterized by a series of events where a new event occurs every three hours of the crossing. In other words, one time step lasts three hours. The battery state of charge is monitored over the entire crossing.

The success of one crossing does not guarantee future crossings to be successful as well, due to the underlying probability distribution. In other words, for the case of one crossing the sample does not represent the population. By simulating multiple crossings and monitoring their results, an overall success rate is determined that is representative of the population's success rate. For a population-representative sample, the distribution of the events is to be representative to the original distribution. Within such a sample, there might be crossings where almost the entire distance could be sailed, and there might be crossings with no sailing at all. An additional benefit of completing multiple crossings is the elimination of the dependency on how the events follow one another. To check whether the sample created is representative for the population a control mechanism is modeled that verifies if the acquired distribution of events, figure 5, adequately represents the input distribution. If not more crossings are calculated to extend the sample.

For each unsuccessful crossing, the number of hours a backup diesel generator was run is calculated and stored. A distribution of the sample is formed for the sum of backup generator hours per crossing. Figure 4 is an example of such a distribution. The distribution represents 100,000 crossings of the Atlantic with a notional sailing yacht using the calculated event distribution (30-50-20) in 300 hours. Note that the event distribution is design-specific. This sailing yacht has a hotel load

of 15 kW, an average hydro generation capacity of 30 kW, and a 700 kWh battery. The total success rate for a generator-less crossing is 1.51%. On average the diesel generator is running for 94 hours.

**Figure 4:** Sample distribution of generator hours,  $n = 100.000$

**Figure 5:** Sample event probability distribution,  $n = 100.000$

## Baseline

A 31-meter sailing yacht is set as a baseline for this case study. She is equipped with a shaft line mounted CPP that hydro generates in the first quadrant. The CPP allows four settings: feathering, maximizing  $\eta_{regen}$ , middle, and maximizing  $C_p$ . The design is characterized by a battery size of 200 kWh and a propeller with a diameter of 0.9 meters. The yacht runs an average hotel load of 26.2 kW. All simulations are done for  $1 \cdot 10^6$  crossings.

The combined results of the crossings are shown for generator usage in figure 6. The success rate of this example is 0%, which indicates that the current design is under no conditions able to cross the ocean without running the diesel generator. On average, the diesel generator runs for about 232 hours during a crossing. From this baseline, design changes are introduced to the propeller, battery, and other factors such as the hotel load. In the following section, the impact of various changes on the expected average diesel generator running hours is shown.

Figure 6: Baseline diesel generator usage

## RESULTS

Several design changes are introduced to the baseline. These are a propeller diameter increase of 10%, a battery capacity increase of 100%, and a hotel load decrease of 30%. One variable is changed at a time in the baseline design after which its impact on average diesel generator usage is discussed. The reason for choosing above mentioned design alterations is that they do not require extensive changes to a yacht's design allowing for easy retrofitting if desired.

### Propeller variation

The baseline’s propeller measures at 0.9 meters which is increased to 0.99 meters. A larger change is deemed unrealistic without significant design changes. A larger propeller will result in more power output at the cost of additional resistance. This relationship is shown in figure 7. The impact on generator running hours is calculated and it is shown that increasing propeller size with 10% will lead to a decrease in diesel generator running hours of 5 hours. The chance for a successful crossing is not changed and remains 0%.

**Figure 7:** The effect of 10% increase in propeller diameter variation on the delivered power output.

**Figure 8:** The effect of 10% increase in propeller diameter on average generator running hours.

Battery variation

Increasing the battery size by 100% leads to an increase in light ship weight of about 2%, based on phosphate batteries adopting a weight density of  $0.133 \frac{kWh}{kg}$ , Verma and Kumar (2021). During the early design stage such a weight increase is considered within reason to implement. Calculations show that increasing the battery size will lead to a 21-hour decrease in average diesel generator usage, shown in figure 9. The chance for a successful crossing is not changed and remains 0%.

Figure 9: The effect of 100% increase in battery size on average diesel generator usage.

Hotel load variation

The final change deemed reasonable within the yacht’s design without any significant design changes is a decrease in the hotel load. This can be achieved by incorporating more efficient systems together with better insulation. For the current design, a 30% decrease in average hotel load is considered feasible. A decrease of 30% of the hotel load reduces the generator hours from the baseline to 208 hours, indicating a 23-hour decrease, roughly equal to doubling the battery size. The chance for a successful crossing is not changed and remains 0%.

Figure 10: The effect of decreasing average hotel load with 30% on average diesel generator running hours.

## Combined

The effect of combining above mentioned design alterations, i.e. implementing all at once, is also studied. It was found that changing the three variables at the same time shows a decrease in generator usage of 41%, as plotted in figure 11. A chance that the crossing succeeds is recorded at 0.02%, indicating that a crossing without any fuel consumption is possible, but not very probable. When compared to the other individual solutions it is found the combination of design alterations leads to a greater reduction in diesel generator hour usage than the sum of its parts, table 1.

**Table 1:** The effect of design alterations on average diesel generator usage.

	Baseline	Propeller	Battery Capacity	Hotel Load	Combined
Average generator running hours	231	226	210	208	139
Success Rate	0%	0%	0%	0%	0.02%
Diesel generator hours w.r.t Baseline	0	-5	-21	-23	-92

**Figure 11:** The effect of combined design changes on the average diesel generator running hours.

## CONCLUSION

Hydro generation is expected to go from a niche to a common feature on sailing yachts in the coming years. A method is developed that allows for an exploration of various hydro generation components in the early design stage. This practical approach will assist yacht designers in designing more sustainable sailing yachts. Its applicability is shown by three examples for which a decrease in hotel load is found most effective in reducing the diesel generator running hours. For each design alteration, a total of 1 million routes were sailed to quantify its effect. The simulations were carried out using main particulars and first principles only. The design alterations proposed did not materialize in a significant increase of the success rate. Each design alteration did lead to a decrease in average diesel generator running hours; indicating less emissions.

The case study is concluded by combining the three design alterations and implementing them simultaneously. The calcu-

lations show this combination to be more effective than the sum of its parts. The 41% decrease in diesel generator running hours is 1.7 times larger than the sum of the separate solutions, which amounts to 22%. It suggests that the effect of one design alteration can benefit other alterations and act as a multiplier. The nature of this multiplier effect how it affects the outcome of the success rate, and whether it differs for different design change combinations, requires further research. This multiplier effect shows that it pays off to implement multiple small adjustments to a design rather than focusing on one major design change when considering hydro generation. A zero fuel crossing, as presented in the case study, is difficult to achieve by applying adjustments to an existing yacht. Using the design method during the initial design process helps to make this achievement more realistic on a new sailing yacht.

## RECOMMENDATIONS

During this study, several assumptions and simplifications were made. It is recommended to further investigate these assumptions to improve the developed method.

- The current approach to determining the hotel load relies heavily on a database comprised mainly of motor yachts, hence it was chosen to correct for this with an average ratio based on on-board measurements. An improvement in the estimate for hotel loads of sailing yachts is therefore recommended. This can be achieved by using a database of sailing yachts within the design range of the method, and cross-reference with full-scale measurement data.
- At this moment the force and energy balance is considered for the yacht sailing in an upright condition. However, it is well known that sailing yachts tend to sail with heel and leeway. The effect of this on the performance of the hydro generation systems is to be further investigated.

# Quantifying Flexibility for a Ship Power and Energy System Design

D. Platenberg<sup>1</sup>, J. S. Chalfant<sup>2\*</sup>, W. Seering<sup>3</sup>

## ABSTRACT

*The pace of technology maturation and the uncertainty in magnitude and characteristics of future load types on Navy ships drive the need for robust power and energy system architectures that can adapt to future perturbations in requirements. The Naval design community needs a consistent method for evaluating ship system flexibility in the early design stages when informed decision making provides the greatest opportunity to influence the system's performance and lifecycle cost. The research presented herein develops quantitative, measurable metrics and applies them to applicable case studies for Naval power and energy system flexibility: the capability of the system to accommodate change in response to perturbations in requirements.*

## KEY WORDS

Ship Design; Flexibility; Metrics;

## INTRODUCTION AND BACKGROUND

Naval ship design is a complex system-of-systems activity that balances the operational requirements, physical constraints, and logical connectivity of individual systems into an integrated platform. For a surface combatant, missions ranging from ballistic missile defense to antisubmarine warfare drive the required combat system, consisting of sensors, processing, communication, payload, and ordinance. To enable these mission systems, the ship must provide a stable, responsive power and energy system.

The U.S. Navy surface fleet is in a transition period and faces challenges related to the recapitalization of aging ships, the rate of technology change and uncertainty of the combat systems of the future, and the significant cost of investment to design and build new ship classes. The fleet as it exists today reflects a series of decisions based on the global geo-political environment dating back to the 1980s. Most of the Navy's destroyer and cruiser assets were designed and built following the end of the Cold War to host the top-of-the-line combat system technology of that era, the Aegis combat system, and the SPY-1D radar. Today, forty years later, they are approaching the end of their service lives, and the Navy needs new ships designed for the next fifty years of fleet operations.

At the same time, the rate of technology change has increased uncertainty in requirements for the major combat system elements of the future. System value is defined by its ability to affordably maintain mission relevance within an evolving operational context. The maturation of developmental mission system technologies, with new and increased electrical power demands, are driving requirements for emergent properties, or "ilities," for the naval power and energy system beyond the typical functional requirements. The need to understand and characterize these properties is further amplified by service life requirements of thirty to forty years per platform.

Affordability requirements dictate the need to conduct cost versus capability trade studies early in the design process. System metrics are necessary to quantify performance measures and provide the insight required to "right size" the system-of-system (SoS) architectures. The cost constraints of the recent Research and Development (R&D) and Acquisition environment, along with the timelines to develop and test new power and energy system designs, necessitates a robust evaluation of the design

space to determine a dominant solution. Power and energy system metrics based on the required “ilities” provide the system designer a basis of differentiation between options within a large design space.

Platenberg (2024) presents the findings from a robust literature review of system of systems “ility” requirements and relationships, and methods for differentiating between preferred solutions within a design tradespace. The research was used to develop a hierarchy of “ility” relationships for the naval power and energy system and to generate a framework for decomposing top level requirements and ility-based requirements into metrics for identifying a dominant architecture within an early-stage design tradespace. The framework considers the physical, logical, and operational aspects of the architecture to generate a set of perturbations that are likely to impact the system’s ability to maintain value over its lifecycle. A deep dive into Flexibility, a common “ility” of interest, is presented here with four case studies using proposed metrics for power and energy system flexibility. This work is intended to present metrics that can be integrated within early-stage design tools for generating and evaluating the naval power and energy system.

## **The Naval Power and Energy System**

The power and energy system of a Navy ship is responsible for providing propulsion and shipboard electrical power required to conduct the platform mission requirements. Today’s surface fleet primarily consists of ships with power and energy (P&E) system architectures that decouple propulsion and power generation functions through the implementation of dedicated propulsion turbines connected directly to the propeller shafts and separate ship service generators installed to provide distributed shipboard electrical power. This type of mechanical-electrical configuration has been a favorable and cost-effective design over the last century, as the demand for propulsion power has significantly outweighed the demand for combat system power. The DDG-51 class, for example, has approximately 78 MW of dedicated propulsion power on shaft, compared to 9 MW of separate ship service power.

The Navy’s most recent class of destroyers, the Zumwalt class, introduced an alternative power and energy system architecture, the Integrated Power System (IPS), where all power generated onboard is shared between propulsion load demands and distributed electrical power demands, including mission system loads. The ability for this ship to share full power across all platform functions is enabled by the inclusion of electric propulsion motors, enhanced power distribution, and power controls.

Performance characteristics of the P&E system can be traced to the physical, logical, and operational characteristics of the sub-module configuration. It is important to decompose desired functional and non-functional requirements to the lowest level of measurable capability, as they can often be met by a variety of architectural configurations. For example, an IPS architecture provides increased flexible power capacity when compared to a traditional mechanical architecture based on the total installed power residing within the power generation module, vice split between the power generation and propulsion modules as in a mechanical architecture. However, alternative measures of flexibility, such as the ability to service high-magnitude-short-duration pulse load types, may be architecture agnostic and instead may depend more directly on the configuration of a particular sub-module, such as the energy storage module. When comparing alternatives, the designer needs to consider total integrated P&E system capability and the dependencies between applicable modules.

Design decisions are made at the system and subsystem levels throughout the Navy’s ship design process to satisfy overarching performance and cost requirements. The permutation of architectural options within each subsystem domain creates a potential solution space of a high order of magnitude that is challenging to evaluate. Beyond the ability to meet predetermined requirements and specifications, additional performance metrics for non-functional requirements are necessary to evaluate and rank design options within the tradespace.

## **Development of Metrics for Ilties**

Platenberg (2024) presents a hierarchy of ility relationships for the naval power and energy system and proposes a framework for decomposing top level requirements and ility-based requirements into metrics for identifying a dominant architecture within an early-stage design tradespace. The framework considers the physical, logical, and operational aspects of the architecture to generate a set of perturbations that are likely to impact the system’s ability to maintain value over its lifecycle. Potential “preparations” that can mitigate perturbations are examined. Selection of preferred architectures requires a balance between uncertainty, performance, cost, and complexity to “right-size” the system.

The framework for development of metrics pertaining to ilties proceeds through six distinct steps:

1. Define the emergent system property of interest.
2. Characterize the system attributes in terms of their physical, logical, and operational architectures. Define the system boundary and required interfaces within the system logical model.
3. Establish a design tradespace of feasible solutions, defined by the lower-level system attributes of each option.
4. Identify a comprehensive set of potential perturbations impacting the emergent system property of interest.

5. Link potential preparations to the set of perturbations to verify the robustness of the potential design solution space. Decompose preparations into their base attributes within the physical, logical, and operational views of the system.
6. For perturbations of interest, generate design metrics for measuring system value under the influence of change caused by the given perturbation. Utilize the system physical, logical, and operational attributes to identify independent and dependent variables.

This framework was used to develop specific metrics for use in evaluating flexibility of a ship power and energy system; these metrics are described in the remainder of this paper.

## LITERATURE REVIEW

A literature review was conducted to survey the existing body of knowledge related to “ilities”, especially flexibility, in the design of complex systems-of-systems. The design community was found to use the term “ility” with a range of similar definitions, as summarized below.

**Ilities.** Beginning with a broad exploration of ilities for complex system of systems, several common themes and definitions were found throughout the published material reviewed. The primary objective of defining ilities centers on maintaining system value over time. This need arises from an identified difference between functional requirements used to define the current system's purpose and ilities used to measure the system's ability to respond to change. A temporal aspect of change is prevalent throughout the literature, including lifecycle performance and value discussions. However, there appears to be conflicting terminology used to articulate these purposes. One commonly discovered conflict is the overlap between the definition of ilities and metrics.

(Ricci, Fitzgerald, Ross, & Rhodes, 2014) define a system-of-systems' ilities by the lifecycle value properties that enable a system to “sustain value delivery over time by responding to exogenous changes in the operational environment.” They suggest a temporal aspect of the ility, where the value provided isn't realized until after the system is in operation. This aspect differs from traditional functional requirements, which are set to determine the initial primary value of the system. The authors outline a System of System Architecting with Ilities (SAI) method that presents an example set of evaluation metrics for comparing design alternatives that include “optionability” alongside quantitative criteria such as cost and several uses. They go on to describe the need to evaluate SoS architecture alternatives against various metrics, including “value metrics,” such as attributes and costs, and “ility metrics,” which are determined by evaluating the impact of shifts in system context or requirements from one moment in time to another.

(Chin, Yau, Kok Wah, & Khiang, 2013) describe ilities as “attributes that characterize a system's ability to respond to changes, both foreseeable and unforeseeable.” They are presented as non-functional requirements necessary to ensure value delivery over the lifecycle of a system of systems. The authors make a point to acknowledge the cost of implementing ilities and the potential conflict between certain ilities that would require tradeoff decision-making within the architecture. These considerations emphasize the need for a balanced design approach considering the broader system context and requirements.

(Doerry & Amy, 2019) discuss key requirements for surface combatant power and propulsion system design. The authors present a mixed discussion of three prioritized metrics (size, weight, cost) and ilities (flexibility and survivability) that greatly influence the metrics. They identify drivers of requirement implementation as a mix of metrics and ilities: projected future mission system loads, which is a metric, and system survivability criteria, including CONOPS, which is an ility.

(Guariniello & DeLaurentis, 2014) call out an essential role played by metrics in their definition of ilities as the impact of functional and developmental dependencies “on metrics that characterize global properties of a system of systems over its lifespan.” They suggest that metrics represent capability at the individual system level but do not directly translate to the system of systems level. Higher level metrics at the SoS level are called ilities.

**Design Metrics.** To evaluate alternative power and energy system architectures, (Smart, et al., 2017) identified the need for metrics to distinguish between design alternatives. The study explored the impact of new technologies and alternative topologies. Several metrics were available within the designated design tool, S3D, including weight, volume, component count, and a fuel load-range calculation. The authors proposed several future areas for development within early-stage design tools, including various performance metrics.

(Toshon, et al., 2017) present a method for executing Set-Based Design within the shipboard power systems using metrics available in early-stage design tools. The authors discuss a 5 MW Modular Multilevel Converter (MMC) topology and identify pertinent metrics related to the choice of thermal facilities, power density, and cabinet sizing as selection criteria for preferred architectures.

(McNabb, et al., 2019) present a case study for quantifying the value of a particular electric-ship architecture within a broader tradespace using a methodical approach for implementing architectural variations in a baseline model within a robust design simulation environment. The example presented measured baseline performance metrics, displacement, speed, and range variation.

(Chalfant, Hanthorn, & Chrysostomidis, 2012) discuss several metrics typically used in early-stage P&E system design analysis of alternatives, such as weight, volume, fuel efficiency, and losses (based on location, size, and loading). They present an additional survivability metric, which relies on input data from loads, defined services, connectors, and their associated locations. These metrics and their underlying variables were identified within existing design tools, as they are required for defining the system's physical architectures and functional capabilities.

**Options, Perturbations and Preparations.** A reoccurring set of terminology was found throughout the literature review of systemilities. To establish a common vernacular, the various approaches for implementingilities to maintain system value commonly refer to “options in design,” “perturbations,” and “preparations.” To design for anility and to preserve system value, the term perturbation is used to characterize an influence on the system that necessitates change. Design options are inherent capabilities in the design to accommodate future changes. They provide the system owner the option or right to implement the change later in the system's life once the need is identified (right to take action). Preparations refer to the specific architectural features or capabilities planned into the design to enable the system to positively respond to the perturbation (maintain value, value at cost, effectiveness).

(Ricci, Fitzgerald, Ross, & Rhodes, 2014) define perturbations as “unintended (i.e., imposed) state changes in a system’s design, context, or stakeholder needs that could jeopardize value delivery;” and an option as “the ability to execute a design decision or feature at any point in the lifecycle that will change or prevent change to the SoS, to respond to variations in the operational context and in stakeholder preferences.” The authors further decompose options into change options, which enable a change in the design in response to a perturbation, and resistance options, which enhance the system’s ability to resist change.

(Mekdeci, Ross, Rhodes, & Hastings, 2012) decompose perturbations into disturbances and disruptions in their “Taxonomy of Perturbations.” Disturbances and disruptions are defined as types of perturbances, with the distinction that disturbances occur over some period of time, but disruptions are nearly instantaneous.

**System Views and Context.** The naval power and energy system is a complex multidimensional system of systems, including architectures that perform various duties regarding the generation and supply of electrical power, cooling, and mechanical utilities, among others. (Brefort, et al., 2018) present a framework for analyzing distributed systems of naval ship design by decomposing the system characteristics into three primary architectures: physical, logical, and operational. Relationships between interconnected and interdependent systems are discussed in terms of their spatial, functional, and temporal characteristics. The authors present this framework with survivability specifically in mind but outline the applicability to other desired system characteristics. The primary architectures are defined as follows:

- Physical architecture represents the spatial and physical characteristics of the system and its environment.
- The logical architecture describes the functional characteristics of the system and the linkages between each component of the system, focusing on the multidisciplinary nature of the system.
- The operational architecture describes the temporal behavior of a system, including human-system interactions.

These overlapping areas combine information from each primary architecture to provide a deeper understanding of the design space: the physical and logical architectures produce a physical solution; the physical and operational architectures produce physical behaviors; and the logical and operational architectures produce the functional utilization. All three together produce the system response. This framework underpins our approach to defining flexibility metrics and the associated perturbations and preparations.

**Flexibility.** Flexibility was found to be a predominant ility considered throughout the literature review. Flexibility is frequently presented alongside the classic ilities of survivability and safety as a mechanism for easily enabling system change in response to various types of perturbations. Within the naval power and energy system community, the desire for system flexibility is clear; however, only a single accepted approach for implementation currently exists. Unlike survivability, where industry, government, and Navy-specific guidance has been issued to define system requirements, flexibility is still in the early stages of definition and implementation. This is partially due to the broad scope of requirements and system attributes commonly categorized as flexibility. Whereas the definition of survivability is widely accepted as being decomposed into susceptibility, vulnerability, and recoverability, the literature on flexibility ranges from intrinsic design properties to real options for stakeholder value.

(Chin, Yau, Kok Wah, & Khiang, 2013) define flexibility as “the degree of ease of effecting change(s) to the SoS, in response to external or internal changes, to maintain its mission effectiveness.” They suggest that there are two different types of

flexibility – operational: the ability to transition between different modes of operation, and design: the design attribute that enables the system to incorporate changes more easily. Agility, adaptability, and scalability are considered subsets of flexibility.

(Doerry, 2014) identifies eight methods for global ship flexibility and how the electrical power distribution system should be considered within each approach. These flexibility approaches include physical shipboard arrangements of equipment to align with hull features and electrical zones, sizing of longitudinal electrical distribution busses, sizing of power cabling, use of interface standards for support equipment, use of modular equipment, use of commercial equipment, and incorporation of energy storage methods. Doerry specifically highlights the importance of flexibility in the electrical distribution system for servicing future electric weapon systems with significantly higher power ratings and load type demands and proposes several interfaces to be developed, including required power type, amount of power required, ramp rates, power quality, quality of service requirements, and monitoring and control conditions.

(Hein, 2022) defines flexibility as “the measure of a ship’s ability to be upgraded quickly and cheaply to efficiently respond to a known or unknown perturbation.” His thesis develops a framework for identifying and characterizing flexibility in design through cause-effect mapping.

(Doerry & Koenig, 2017) propose a framework for identifying what types and quantities of flexibility will “increase the ability of the ship to be quickly and economically reconfigured in the future.” They acknowledge the temporal aspect of the required change as either a temporary mission capability or permanent reconfiguration. Their paper discusses modularity, adaptability, and flexibility as pertaining to specific types of technologies that can be incorporated, each with an independent impact on overall system affordability. The need for flexibility over the platform’s service life is based on potential extensive unknown requirement changes, including high power and new variant combat and mission systems. The overarching framework is based on the principles of Real Options analysis, where design options are considered with respect to their cost per value delivered. In early-stage design and requirements formulation, this type of analysis is valuable for forecasting potential changes to the system requirements and evaluating cost-effective means for responding in the future, but it requires upfront investment in the design. The authors define a tradespace of type and quantity of modular and adaptable technologies, considering cost impacts in terms of weight/space/design effort. These technologies for a flexible ship are proposed considering future system locations, power capacity, sufficient power conversion and distribution, and cooling capacity to support future systems.

(Page J. , 2012) discusses the value of flexibility options in the early-stage design of naval warships instead of options on a project or design. The author argues that Real Options analysis and Net Present Value (NPV) need to be modified to evaluate capital projects (without revenue) and options in design based on needs, cost, and capability. The author identifies power generation and power distribution as top design considerations for historical ship platform upgrade enabling considerations, following general arrangements. Given the Navy’s budgeting constraints that limit investment in new capabilities through the development of new ship classes, a framework is presented using an Overall Measure of Effectiveness based on a Choice Model for how capability can be added to a single ship class over time. The example compares an inflexible (current Navy) platform to a notional modular platform with several flexible preparations. The author suggests extending this framework to the subsystem-level or SoS-level analysis. The paper also suggests that the flexible platform has lower upfront acquisition costs, contrary to many discussions of the cost of flexibility.

(McCauley, Hannapel, Bassler, & Koleser, 2016) introduce the “SWAP Boxes” concept to decouple the ship payload (combat system) from the platform. This decoupling is intended to counter the observed tendency within Navy design programs to quickly lock in design requirements to reduce design time and constrain the ship's weight to control cost. The authors state that flexibility and modularity are two concepts: “flexibility is the ship design capability to accommodate combat system growth, and the ability to insert new technologies into the ship throughout the lifecycle of the individual ship and its class. Modularity is the platform’s ability to accept a system as a self-contained unit with interface standards.” They define flexibility as a function of four criteria: design flexibility, construction modularity, mission modularity, and mission flexibility. Some key benefits of implementing the SWAP Box approach are the ability to apply targeted system margins versus top-level margins and the ability to conduct sensitivity analysis against the maturity of the intended systems. For impact on the power and energy system, SWAP Box parameters would encompass the mission-related loads used to size distributed systems; however, the method is not obviously applicable to the design of the power and energy system architecture itself.

(Richards, Ross, Hastings, & Rhodes, 2009), in their discussion of various perspectives for defining survivability, introduces the ilities flexibility and robustness as “temporal system properties that specify the degree to which systems can maintain or even improve function in the presence of change.” The authors emphasize that ilities are dynamic, based on changes to system needs, the system itself, or the system context.

(Doerry & Moniri, 2013) cite the need for improved survivability and reliability of naval power and energy systems as the systems evolve from traditional low-voltage systems to meet the demands of new high-power combat systems.

**Ility Relationships.** The collection of research presented in the literature review points to a common definition of ilities as emergent systems properties that impact the system's ability to maintain value over time. Ilities are not primary functional requirements, such as those defined in an Initial Capabilities Document or Capability Development Document that define the system's purpose, but rather, are attributes used to measure the system's ability to respond to change. Emergence refers to the resulting function or capability when multiple elements of a decomposed system architecture are integrated together. While the design community agrees on the perceived value in analyzing ilities, system architects and decision makers need a consistent method for prioritizing and quantifying ility requirements. U.S. Navy guidance identifies the need to assess such ilities as reliability, maintainability, sustainability, flexibility, and vulnerability. The Ship Specifications will typically detail the expected producibility, operability, and maintainability of the ship. However, these proprieties are typically measured within the late stages of design, once the ability to influence the system architecture has passed. Upfront understanding of the dependencies and relationships between ilities and functional requirements will enable the designer to identify more robust solutions when making architectural decision in the early stages of design.

While survivability is widely accepted as being decomposed into susceptibility, vulnerability, and recoverability, the literature on flexibility ranges from intrinsic design properties to real options for stakeholder value. Informally, in the field of Marine Engineering, the two ilities are interchangeably used to describe the ability to maintain system performance; however, a key distinguishing difference in application comes from the origin of the perturbation on the system, and the identification of enabling system attributes. A perturbation requiring system survivability is posed by a purposeful threat to degrade system performance, whereas flexibility perturbations are based on the own-system competitive performance or stakeholder desired capability. Survivability most closely relates to the short-duration sub-type of flexibility, due to the nature of real-time, finite duration disturbance.

## FLEXIBILITY DEFINITION FOR SHIP DESIGN

Flexibility is an ility that frequently appears in the discussion of complex systems-of-systems' attributes and requirements but lacks a clear and consistent definition. From the literature review in Section 0, several authors have identified common characteristics of flexible systems within the context of Naval Architecture and ship design, but at varying levels of specificity. (Chin, Yau, Kok Wah, & Khiang, 2013) addressed a comprehensive maritime system of systems, relating flexibility to the degree of ease of effecting change to maintain mission effectiveness in response to external or internal perturbations. At the platform level, (Doerry & Koenig, 2017) have expanded the definition of "ease" to include a measure of speed, timeliness, and cost, and (Hein, 2022) identifies that the perturbations may be either anticipated or unknown at the time of making the required design decisions that determine the platform's capability. (McCauley, Hannapel, Bassler, & Koleser, 2016) identified the mission system as the driver of platform flexibility, which (Schank, et al., 2016) relates to the ability to change physical platform boundaries by providing excess space and flexible infrastructure.

From the commercial energy industry perspective, the International Energy Agency (IEA) defines power system flexibility as "the ability to respond in a timely manner to variations in electricity supply and demand" (Gutierrez Tavarez, 2019). This industry definition of flexibility can be tailored to the shipboard naval power and energy system application and used to develop metrics for early-stage design evaluation.

The definition of flexibility used in this work is as follows:

*Flexibility is the capability of a system to accommodate change in response to perturbations in requirements.*

The utility in application of flexibility depends on the defined system boundary and the distinction between near-term and long-term impacts. Requirements, such as Top-Level Requirements or system specifications, refer to the measurable needs of the stakeholders. The requirements can be organized into the system's physical, logical, and operational context to better understand the design drivers and determine the enabling design characteristics.

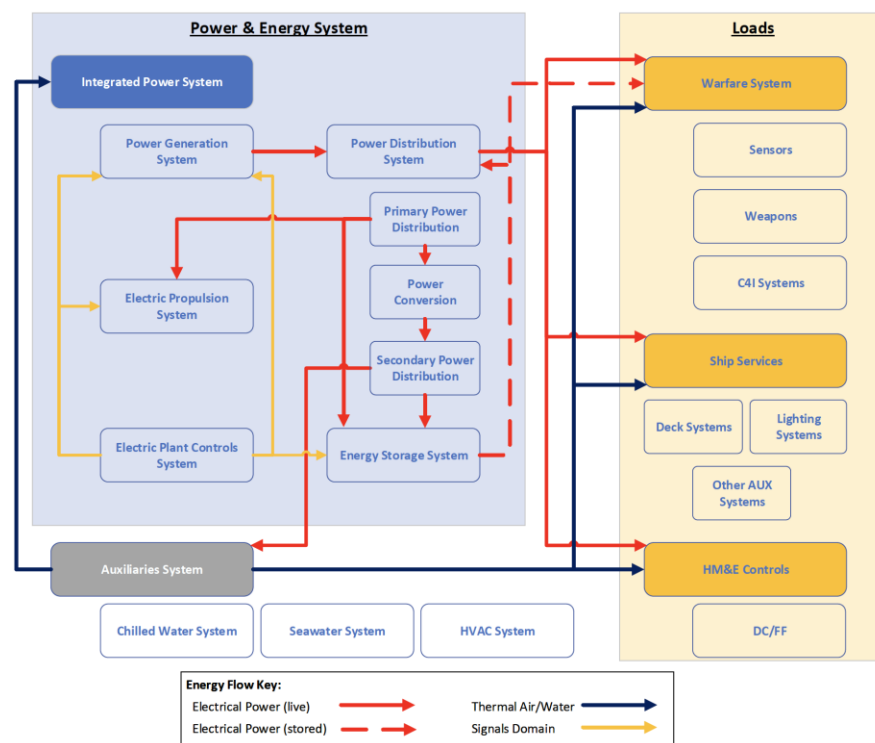

For the naval power and energy (P&E) system, flexibility is quantified within the system boundary, in response to perturbations from new and changing loads requiring power (**demand**) or changes at the source of an energy flow (**supply**). The following discussion defines the power and energy system within the physical-logical-operational capability construct introduced by (Brefort, et al., 2018). Together, these system views link the "right power, right location, right time, and right conditions" (Doerry, 2014).

**Physical.** The physical view relates to the spatial configuration of the system and the physical attributes of the individual subsystems and components. The P&E system is a distributed system that spans the full extent of the ship and comprises many components typically listed in a Machinery Equipment List (MEL). In this view, the system can be depicted as a series of nodes representing each component or enclosed subsystem. Each node is assigned a location using a coordinate system to establish

integration within the whole ship architecture and to define node locations in relation to each other. The metrics used to measure the system's physical requirements and characteristics include measures of distance and each component's physical attributes, including space, weight, power, and cooling (SWAP-C).

Flexibility within the physical view is system configuration driven. The selection of components that comprise the power and energy system and their integration within the ship platform determine the potential system flexibility. The component capacities are measured against the system requirements for supply and demand. Options for implementing flexibility within system attributes include provision of traditional Service Life Allowance margins on SWAP-C, the installation of excess capacity (e.g., installed power generation) beyond initial platform requirements, and defining system interface standards for future subsystem integration. Spatially, the P&E system architecture should be arranged to align with hull features and electrical zones. Options for implementing physical-spatial flexibility include designing reconfigurable spaces, providing access and outfitting paths, or reserving excess arrangeable area within the defined hull compartmentation. Modularity, the design feature that enables the swapping or plug-and-play capability of various system sub-modules within a defined location and interface standard, is defined within the physical view.

**Logical.** The logical view describes the functional characteristics of the system and the relationships between system components that enable emergent capability. The power and energy system is multidisciplinary, with components connected across the mechanical, electrical, thermal, and signals domains. Figure 1 depicts the flow of electrical power, thermal auxiliaries (water and air), and data across the electrical, thermal, and signals domains for a representative Integrated Power System architecture. In the IPS configuration, as described in Section 0, the propulsion module is considered within the power and energy system, vice as an external load. In the logical view, linkages are identified to connect the individual subsystem or component nodes established in the physical view. Each linkage requires a direction, type, and magnitude to represent a flow within a designated domain.

**Figure 1: Power and Energy System Logical Model for an Integrated Power System (IPS) for a Combatant**

Flexibility within the logical view focuses on the system's ability to provide the required linkages between supply and demand elements within each functional domain when the system realizes future perturbations in requirements. The power and energy system includes a network of distributed systems to enable flows within each domain. The functional flexibility of these systems often centers on the conversion and distribution of the flows and the type of compatible supply and demand elements. To facilitate system sizing and design decision-making, the SWAP Box method introduced by (McCauley, Hannapel, Bassler, & Koleser, 2016) can be used to represent unknown future elements requiring a range of potential P&E system services. The logical view also provides insight into the ability to reconfigure the system in response to realized perturbations.

**Operational.** The operational view defines the temporal behavior of the system required to accomplish a given mission, including the sequencing of system functions. This view relates a given architecture's physical and logical aspects to the system performance, often referred to as a Measure of Performance. Typical design requirements define the functional capability desired within a particular operating scenario. The time scale of a scenario can range from instantaneous system response to multiyear outlays, such as forecasting of technology maturation and integration. For the power and energy system, these requirements can target specific capabilities of components within each of the specified domains (supply side) or be derived from higher-level platform performance requirements (demand side), such as those related to platform energy consumption.

Operational flexibility is differentiated between requirements for instantaneous response to real-time changes in running conditions beyond the design requirements, and the reconfiguration of the system in response to an emerging requirement change over a large timescale (order of magnitude in years). The various combinations of the demand loads (combat system, ship service, and propulsion loads) requiring service and energy flows within each domain define operational scenarios for the power and energy system. Examples of operational flexibility include the ability to debit power from one category of load to service another, the use of energy storage in response to real-time operational changes or service interruptions, and the ability to incorporate future combat system elements with unique load profiles, such as pulse loads.

## **METRICS FOR FLEXIBILITY**

Design metrics are quantitative or qualitative measures of a system's characterization and value. In the early stages of design, metrics are formulated to assess a system's ability to achieve design requirements and other desired capabilities, includingilities. When evaluating a large multi-attribute tradespace of potential system architectures, alternative designs are compared using metrics to understand the design trade-off and determine the preferred or non-dominated designs. A typical tradespace exploration will evaluate primary and secondary performance measures against cost requirements to uncover trends in system configurations within the open design tradespace.

Attributes of a system within the physical, logical, and operational views serve as the base elements for capability metrics. Forilities such as flexibility, any measure of performance can be traced to the physical attributes of the elements comprising the system; however, the logical and operational properties of these elements within the broader system configuration are required to achieve the desired emergent capability. Flexibility, as the capability to make changes within the system in response to perturbations, requires upfront consideration of how an architecture will respond within each design domain.

For U.S. Navy ship design, flexibility has been traditionally addressed using the Service Life Allowance (SLA) requirement, which equates each vessel's intended years in service to measures of future growth and fatigue capacities based on historical trends such as weight growth and increases in electrical load demands over time. The Navy's design authority, Naval Sea Systems Command (NAVSEA), decomposes SLA into the specific design domains of space, weight, power, and cooling (SWAP-C). These allowances are used to inform the design of the power and energy system and auxiliary systems, size the hullform, and design the hull structure. For the power and energy system, SLA represents flexibility by gross capacity, but doesn't address the necessary decomposition to the subsystem level such as preparations needed within the power distribution and energy storage modules to ensure the intended future capability is achievable.

The following sections identify metrics for evaluating flexibility of the power and energy system within early-stage design space exploration activities. The distinguishing factor of early-stage design is the relatively low amount of design-specific information available to specify a system architecture. Designers and decision makers will typically start with an initial machinery equipment list of components that drive acquisition cost and determine gross system capacity, such as prime movers, generators, power converters and transformers. Sizing and quantities of these components are balanced against first order estimates of load demands based on historical regression or ratiocination, known demands of required mission equipment, and initial system layouts within a conceptual ship stack-up arrangement. The following process traces perturbations to three categories of system flexibility requirements: power capacity, distributable power, and energy storage. Metrics for characterizing capability in each category are proposed using physical-logical-operational system attributes. These metrics should be considered within the overall design space exploration and weighed against functional requirement performance, other ility attributes, and system cost to identify the preferred, "right-sized," solutions.

## **Power Capacity**

Flexible power capacity is dependent on the physical attributes of the power generation subsystem and the design ratings of its components. Within the operational view, flexible power capacity depends on the supply's specified running conditions from the power generation subsystem and demand from the mission system and ship service elements. While the overall power and energy system may be sized based on the prescribed Service Life Allowance requirement, the definition of operating conditions provides a realistic measure of the system's ability to accommodate future potential loads. For an IPS system, power flexibility is determined by the ship's power generation subsystem sizing criteria, including a requirements-driven loading condition. Sufficient power generation is required to energize electric propulsion motors, provide ship service power, and operate onboard

mission systems. The requirements-driven loading condition specifies the combination of ship speed and mission system electrical loads requiring simultaneous power supply. Typically, the power generation sizing requirement will specify the propulsion load required to ensure sustained speed, as this is the highest order of magnitude load onboard the ship. The corresponding mission system electrical load depends on the platform's intended use, which may require the ship to operate the most stressing mission load at sustained speed or a representative average of the daily loads experienced.

**Flexible Power Capacity (FPC) Metric.** Equation (1) defines flexibility power capacity (FPC) as the sum of the total distributable power available ( $P_{DST}$ ), based on generation and distribution subsystem capacities; minus the sum of all required loads ( $L_{REQ}$ ) within the system sizing criteria used for the calculation, such as the 24-hour average load or maximum-margined electrical load; divided by the total power installed ( $P_{tot}$ ). Distributable power includes energy generated onboard that is available for mission systems and ship services, whereas, depending on the architecture topology, the total installed power includes all energy generated. For example, in an IPS architecture the distributable power may be equal to the total installed power, but a mechanical architecture will have separate ship service power generation and dedicated propulsion diesels or gas turbines directly connected to the shaft line, so distributable power will be significantly lower than total installed power. The FPC metric provides a relative measure of flexibility for alternative architectures that meet similar mission requirements and should not be used to compare platforms of drastically different initial load requirements. For those types of high-level material solution considerations, a measure of total excess capacity in megawatts is more appropriate. Case Study 1 outlines the differences in applying this metric for different power and energy system architectures.

$$FPC = \frac{P_{DST} - L_{REQ}}{P_{tot}} \quad (1)$$

**Debitable Power Flexibility (DPF) Metric.** A second metric for the employment of flexible power capacity within an IPS architecture, where the total power generated is required to service the propulsion as well as the mission and ship service loads, is debitable power flexibility (DPF). Whereas the FPC Metric considers elements of the system's physical architecture in a defined loading condition, the Debitable Power Flexibility metric considers the operational architecture capability for applicable system topologies across a range of operational loading conditions, defined by combinations of load requirements. Debitable Power is the ability of the IPS system to prioritize the loads receiving power, effectively debiting power from one load category to service another. Because the largest magnitude load by category is the propulsion load at sustained speed ( $L_{ps}$ ), the debitable power load available ( $L_{avail}$ ) is the propulsion load used to size the propulsion subsystem ( $L_{pREQ}$ ) less the propulsion load required to make a minimum acceptable mission speed ( $L_{pmin}$ ); thus,  $L_{avail} = L_{pREQ} - L_{pmin}$ . The DPF is then the minimum of the new additional load demand above the initial design requirement ( $L_{add}$ ) and the debitable power load available, divided by the new load demand; see equation (2). Case Study 2 will discuss the sensitivity of IPS power flexibility against the selected sizing criteria propulsion and mission loads.

$$DPF = \frac{\min(L_{add}, L_{avail})}{L_{add}} \quad (2)$$

An observed phenomenon when using this metric to compare power and energy systems in ship concepts of varying hullform efficiencies is that a less efficient hull requires larger installed power capacity to achieve the same top-end speed, thus providing a larger debitable power load available when propulsion requirements are reduced to the minimum acceptable speed. This perceived benefit, however, only sometimes leads to system selection within a tradespace when balanced against other attributes, such as cost. Right-sizing the power generation subsystem to align with the desired operating modes leads to a preferred architecture.

### Case 1: Flexible Power Capacity Metric

The following examples demonstrate the application of the Flexible Power Capacity metric, equation (1), for three different power and energy system architectures: an Integrated Power System (IPS), a Hybrid power system, and a Mechanical propulsion system with separate ship service power generation. Within each architecture, the sensitivity to specified load conditions is demonstrated by varying the load criteria for ship service and mission elements between the max-margined and 24-hour average electrical load cases and the propulsion loads between the sustained speed and economical transit (cruise) conditions. Additionally, each demand load is evaluated at the initial delivery and end-of-service life conditions to demonstrate increases in demand over time.

For the basis of this analysis, a notional ship concept was leveraged from the NAVSEA Design Data Sheet (DDS 200-2) for 'Calculation of Surface Ship Annual Energy Usage and Cost' (2012). The concept has a design service life of 20 years, requiring a 15% power SLA. Table 1 shows the electrical loads for each design operating condition, including 50% of the SLA. Economical transit is conducted at 16 knots, surge to theater requires 30 knots, and the underway-mission propulsion load is based on a prescribed speed-time profile from DDS 200-2.

**Table 1: Electric Load Conditions at various temperatures and operational scenarios (NAVSEA, 2012)**

Temperature (°F)	In port - Shore Power (kW)	Underway - Economical Transit (kW)	Underway - Surge to Theater (kW)	Underway - Mission (kW)
10	1,000	3,000	3,000	4,800
59	500	1,800	1,800	3,200
100	900	2,400	2,400	4,000
Propulsion Load	-	7,100	46,800	7,208

Three representative ships were created using the same hullform, mission system loads, and propulsion requirements, but with three different P&E system topologies: IPS, Hybrid, and Mechanical. The DDS 200-2 representative ship concept was leveraged for the Integrated Power System, consisting of three Large Gas Turbine Generators (LTG), two Small Gas Turbine Generators (STG), and two electric Propulsion Motor Modules (PMM). For this basis of comparison, the hybrid and mechanical architecture alternatives were created to provide comparable power for propulsion and mission loads, as shown in Table 2. In the IPS concept, PMMs are sized to achieve the design sustained speed of 30 knots at eighty percent of the maximum continuous rating (MCR). The power generation subsystem, consisting of LTGs and STGs, is sized to provide sufficient power for the sustained speed condition plus the mission load at the end of service life (EOSL), accounting for motor efficiencies and power transmission losses. For the hybrid concept, the propulsion subsystem consists of PMMs, sized to achieve the economical transit speed of 16 knots, plus two propulsion gas turbines (PGT) directly coupled one to each shaft in an ‘Or’ configuration, such that the PMMs and PGTs do not combine to achieve sustained speed, and the required propulsion demand is supplied by one or the other. The hybrid power generation subsystem is sized to provide full power to the PMMs and mission loads at EOSL. Lastly, the mechanical concept propulsion subsystem consists of four PGTs, two per shaft, and the power generation subsystem is sized to provide mission loads at EOSL with one generator offline for redundancy, referred to as the (N-1) requirement. This (N-1) requirement is not required for IPS or hybrid architectures due to the order of magnitude greater amount of distributable power capacity installed which enables the system to debit propulsion load to compensate for a generator casualty.

**Table 2: Major Machinery Equipment Lists**

IPS			Hybrid (Or)		Mechanical	
	Unit Count	Total kW	Unit Count	Total kW	Unit Count	Total kW
Large Turbine Generator (LTG)	3	72,000	0	-	0	-
Small Turbine Generator (STG)	2	6,000	5	15,000	3	9,000
Propulsion Motor Module (PMM)	2	60,000	2	8,000	0	-
Propulsion Gas Turbine (PGT)	0	-	2	60,000	4	76,000
Condition Driving Installed Power Generation	Sustained Speed Propulsion (30kt) + mission at EOSL		Max Electric Propulsion (16kt) + mission at EOSL		Mission at EOSL (N-1)	
Power Generation Required	-	67,370	-	12,938	-	5,136
Total Installed Power	5	78,000	7	75,000	7	85,000

**IPS architecture case.** In the IPS architecture, it is assumed that the full amount of power generated can be distributed throughout the ship for propulsion or ship mission loads; thus, the Power Distributable ( $P_{DST}$ ) is equal to ( $P_{tot}$ ) at 78 MW. In reality, there may be restrictions on the amount of power that can be distributed across a single bus, limiting the power available for non-propulsion loads based on the specific distribution architecture. The load required ( $L_{REQ}$ ) is dependent on the specific combination of propulsion and mission load demands, and the amount of service life consumed. Table 3 determines the Flexible Power Capacity for the IPS architecture at sustained speed while operating in two different modes: the underway-mission at 10°F condition, requiring the maximum margined electrical load, and the underway-economical at 10°F condition, requiring the 24-hour average electrical load. Each load combination will evolve over the ship’s service life as SLA is consumed and propulsion efficiency reductions are realized. The “at delivery” load required includes the propulsion shaft horsepower required with a 94% PMM efficiency at sustained speed and the stated mission load without SLA. The “at the end of service life (EOSL)” load applies an additional 25% growth factor to the propulsion SHP for hull fouling and plant degradation and a 15% growth factor to the mission loads for consumed SLA. Table 3 also provides the Flexible Power Capacity calculations for the same load conditions at cruise speed, where the PMM efficiency is 91%.

**Hybrid architecture case.** For the hybrid architecture, where the electric propulsion PMMs are required to cover a smaller portion of the propulsion speed-power curve than the IPS, the distributable power ( $P_{DST}$ ) is significantly less, at 15 MW. In this configuration, propulsion power at the top end of the speed-power curve is provided by a dedicated PGT on each shaft, which are accounted for in the  $P_{tot}$  of 75 MW. In operating conditions with high-speed requirements, the PGTs are online to provide propulsion load, and the  $L_{REQ}$  only reflects the ship mission loads. In conditions with speeds up to 16 knots, the  $L_{REQ}$  includes the power for the electric propulsion PMMs in addition to the ship mission loads. Table 4 demonstrates the differences between

loading conditions requiring PGT and PMM propulsion service. In each example,  $L_{REQ}$  is calculated at the max-margined and twenty-four-hour average loads at delivery and at the end of service life, as evaluated in the IPS case. A 94% PMM efficiency factor is applied to the propulsion load in all cruise conditions (16 knots), and a 25% hull fouling and plant degradation factor is applied to the end of service life evaluations.

**Table 3: IPS at Sustained Speed and Cruise Speed**

IPS: Sustained Speed				IPS: Cruise Speed

**Mechanical architecture case.** In the mechanical architecture case, electrical power distribution capacity ( $P_{DST}$ ) is not required for any portion of the propulsion load and, therefore, is sized solely based on the ship service and mission loads. The propulsion demand, an order of magnitude greater than the max margined electric load, is serviced by dedicated PGTs and included in the total installed power ( $P_{tot}$ ). The load required ( $L_{REQ}$ ) is calculated at the max margined and twenty-four-hour average loads at delivery and at the end of service life, as evaluated in the IPS and hybrid cases. The mechanical power flexibility, Table 5, is calculated based on the same loading requirements as the sustained speed hybrid case, using PGT propulsion power.

**Table 5: Mechanical (not propulsion dependent)**

Mechanical: Not Propulsion Dependent				
	Max Margined Load at Delivery (w/o SLA)	Max Margined Load at EOSL (w/ SLA)	24 HR AVG at Delivery (w/o SLA)	24 HR AVG at EOSL (w/ SLA)

**Discussion.** When setting a flexible power capacity requirement, the selection of determinant loading conditions should be based on the platform's intended use and CONOPS. The comparison of cases above provides the requirement owner additional context into the differences between resulting architectures that a particular set of requirements will drive the designer to select. Evaluation of the FPC metric within a full-scale design space exploration will link the ability performance of the P&E system topologies to the physical attributes of their integrated platform, such as overall dimensions, displacement, and cost to better identify the preferred solution. Figure 2 depicts the flexible power capacity for each IPS, hybrid, and mechanical architecture considered across the range of potential loading requirements. Each of the eight loading conditions are plotted for the IPS and hybrid architectures, along with the four mechanical load cases. The flexibility metrics are plotted against a normalized balance of power required and power available to service the requirement due to the significant differences in capacities for integrated versus separated power systems. This normalization demonstrates the magnitude of power required for each individual load case versus the physical architecture capacity installed.

The IPS example architecture has installed capacity beyond the minimum requirement for end-of-service life based on the selected combination of LTGs and STGs. The plant lineup identified in DDS 200-2 (NAVSEA, 2012) targeted increased energy efficiency at each operating condition, requiring a mix of low- and high-power-rated turbines aligned to the required load combinations. This configuration provides flexible power capacity in each evaluation condition, including the most stressing case: sustained speed plus maximum-margined electrical load with full consumption of SLA. The IPS example has five times the amount of distributable power as the hybrid example and thirteen times the amount of the mechanical example. When evaluated for Flexible Power Capacity, including consideration of total installed power and propulsion plus ship service loads in each condition, the IPS example scored one and a half times greater than the FPC values of the hybrid PGT-propulsion on average across the four loading conditions, and eleven times greater on average than the FPC values of the mechanical architecture.

**Figure 2: Flexible Power Capacity (FPC) Metrics for IPS, Hybrid, and Mechanical examples versus normalized power capacity, load case required over distributable power**

Of interest, the case results determined that the hybrid architecture FPC flexibility is higher at high speeds, while the IPS architecture FPC flexibility is higher at low speeds. In the ‘Or’ condition with PMMs online (up to 8 MW), the hybrid architecture’s measure of flexibility is significantly reduced from the flexible power capacity while using PGTs, as the electric propulsion consumes over half of the available power for distribution. It should be noted, however, that there may be limitations in minimum operating speeds for scenarios able to utilize the flexible power capacity of the PGT-only operating conditions based on the minimum RPM of the propulsion gas turbines and the shaft-propeller design.

The mechanical case requires the greatest amount of installed power of the three architectures, as the required loads for mission and propulsion are isolated to dedicated power supplies, resulting in the lowest amount of distributable power. Additionally, despite the mechanical concept requiring the installation of a redundant/backup ship service power generation to satisfy the (N-1) requirement, the third STG does not contribute to the distributable power.

## Case 2: IPS Debitable Power Flexibility Metric

This case utilizes the notional IPS ship concept from DDS 200-2 (NAVSEA, 2012), as described in Case 1, to demonstrate the debitable power flexibility metric. Two variants of the IPS architecture, with a 30-knot and 27-knot sustained speed requirement ( $L_{PREQ}$ ) respectively, are compared to isolate the impacts associated with a given architecture’s sizing criteria for required propulsion load. The debitable power metric for each variant is evaluated for a 1-knot and 5-knot speed reduction in the minimum propulsion load required ( $L_{pmin}$ ), at both initial delivery and end-of-service life conditions. Three sets of new load demands above the initial design requirement ( $L_{add}$ ) are then used to represent a range of future mission system requirements.

Table 6 demonstrates the debitable power flexibility (DPF) for the 30-knot IPS architecture, given 1-knot and 5-knot speed reductions for minimum acceptable propulsion load at delivery and EOSL conditions. The additional 25% propulsion factor applied for the EOSL condition reduces the debitable power load available ( $L_{avail}$ ) by 11 MW in the 1-knot reduction case and 7 MW in the 5-knot reduction case. This results in lower DPF values when assessed against the 15 MW load for the 1-knot

reduction case and the 30 MW load for both 1- and 5-knot reduction cases. In all minimum acceptable propulsion conditions, the 30-knot IPS architecture easily accommodates the 2 MW additional load case. The 5-knot speed reduction significantly increases debitable power load availability, a 94% increase in the delivery condition, and a 340% increase in the EOSL condition.

**Table 6: Debitable Power 30 knot IPS**

	1 Knot Reduction				5 Knot Reduction			
	Propulsion Condition	kW	Propulsion Condition	kW	Propulsion Condition	kW	Propulsion Condition	kW
LpREQ	30kt, 100% MCR	62,234	30kt, 100% MCR	62,234	30kt, 100% MCR	62,234	30kt, 100% MCR	62,234
Lpmin	29kt, Delivery	45,014	29kt, EOSL	56,268	25kt, Delivery	28,812	25kt, EOSL	36,015
Lavail		17,220		5,966		33,422		26,219
	Ladd (kW)	DPF	Ladd (kW)	DPF	Ladd (kW)	DPF	Ladd (kW)	DPF
Load 1	2,000	1.00	2,000	1.00	2,000	1.00	2,000	1.00
Load 2	15,000	1.00	15,000	0.40	15,000	1.00	15,000	1.00
Load 3	30,000	0.57	30,000	0.20	30,000	1.00	30,000	0.87

The 27-knot sustained speed variant of the notional IPS architecture assumes the same speed-power curve performance of the hull, but the reduced top-end speed requires less total installed power. Table 7 demonstrates the debitable power flexibility for the 27-knot IPS architecture, given 1-knot and 5-knot speed reductions for minimum acceptable propulsion load at delivery and EOSL conditions. Based on the lower speed requirements, which correspond to significantly lower resistance and propulsion demand along the speed-power curve, this concept has less debitable power load available in both speed reduction conditions. Compared to the 30-knot concept, the available loads are 20-25% lower for the 27-knot concept cases. Despite the differences in the magnitude of the loads available in all conditions, the relationship between available load at delivery and EOSL conditions holds for the 27-knot concepts, with a 98% increase for the 1-knot reduction and a 330% increase in the 5-knot reduction cases. In summary, the 27-knot concept scored lower debitable power flexibility in all cases and failed to provide the available load threshold for the 15 MW load case 2 in the 1-knot reduction at delivery case, while the 30-knot IPS concept was able to provide sufficient flexible power in the all cases.

**Table 7: Debitable Power 27 knot IPS**

	1 Knot Reduction				5 Knot Reduction			
	Propulsion Condition	kW	Propulsion Condition	kW	Propulsion Condition	kW	Propulsion Condition	kW
LpREQ	27kt, 100% MCR	45,495	27kt, 100% MCR	45,495	27kt, 100% MCR	45,495	27kt, 100% MCR	45,495
Lpmin	26kt, Delivery	32,535	26kt, EOSL	40,669	22kt, Delivery	19,830	22kt, EOSL	24,787
Lavail		12,959		4,826		25,665		20,708
	Ladd (kW)	DPF	Ladd (kW)	DPF	Ladd (kW)	DPF	Ladd (kW)	DPF
Load 1	2,000	1.00	2,000	1.00	2,000	1.00	2,000	1.00
Load 2	15,000	0.86	15,000	0.32	15,000	1.00	15,000	1.00
Load 3	30,000	0.43	30,000	0.16	30,000	0.86	30,000	0.69

Whereas the flexible power capacity metric considers the architecture-specific installed power generation and electrical loading conditions, the debitable power flexibility metric focuses solely on the demand load conditions, given an established system sizing criterion. Figure 3 graphically displays the increase in available load as the propulsion load is debited for the 27 and 30 knot concepts in their EOSL state. Each curve represents the flexible power available at the given speed, as evaluated in the cases in Tables 13-16. Horizontal grey lines are placed at the three evaluation loads for 2, 15, and 30 MW. Where the dashed horizontal lines are above the L-avail curve, the debitable power flexibility is less than one, with scores decreasing as the distance between the two increases. Vertical arrows are drawn at the speed reductions of 1 and 5 knots, as evaluated above.

The debitable power flexibility metrics for each of the eight conditions are plotted in Figure 4 against the three added load requirements (2, 15, and 30 MW). The figure depicts the point at which each case is no longer able to satisfy the additional load when DPF drops below one. The 30kt IPS concept outscores the 27kt concept in each combination of delivery/EOSL and -1/-5 knot minimum propulsion load due to the exponential shape of the speed power curve. The higher the sustained speed required, the greater the available load when the minimum propulsion load is identified along the exponential curve. Additionally, as expected, we see that the 5 knot reductions for minimum propulsion load provide the largest available load and DPF values in each condition. Lastly, the impact of expected fact of life growth in propulsion load to achieve the minimum acceptable speed at EOSL reduces the available load and DPF for the 15 and 20 MW added loads in each case.

**Figure 3: Flexible Power – Load Available at Speed**

**Figure 4: Debitable Power Flexibility versus Load Available for example speed delta cases**

## Distributable Power

Power distribution system flexibility is required to connect generation capacity to the component-specific load demands throughout the ship. Distribution includes the ship-wide transmission of energy flows and energy conversion into the voltage and quality required by the end users, as shown in the logical view, Figure 1. The physical configuration of the distribution system relies on the maximum distribution capacity, available voltage types and ratings, and the spatial considerations of where the loads are located on the ship, which are typically bound by the assignment of electrical zones. Load requirements will vary within each zone, depending on the interface needed for each individual end user. Therefore, power flexibility depends on each zone's local conversion and distribution capabilities.

**Power Distribution System Flexibility (PDSF) Metric.** The power distribution system flexibility metric utilizes an ‘evaluation loading set’ to represent the types of interfaces and the classification of potential future load demands within an individual zone. An evaluation loading set is a compilation of potential future load elements, beyond the initial system design requirements for demand services at delivery plus any required service life allowances. The set can be generated to include a variety of load characteristics required for service from the power and energy system to provide, such as voltage type, voltage rating, and power draw. Because propulsion load demands for an IPS ship significantly outweigh the mission and ship service loads in any zone, they are considered separately from the distribution evaluation loading set. Table 8 demonstrates five evaluation loading conditions based on four potential future mission elements and one representative set of their combination.

Each load element is differentiated by voltage type and power demand. The ~1000 VDC demands are typical of high-power mission systems like radar and laser weapons and may draw directly from the primary power distribution bus. Other low voltage demands, such as onboard computing and thermal auxiliary systems, require in-zone power conversion and distribution within the secondary power distribution system. In an early-stage design tradespace exploration, the full permutation of single

elements and their combinations can be used to determine a simple and indicative metric for distributable power flexibility. Further along in the design process, ship configuration details such as general arrangements and locations of mission stations are established, and the evaluation loading set should be tailored to reflect the revised open tradespace or uncertainty for a given zone.

**Table 8: Example distribution system ‘evaluation loading sets’ for potential future load demands**

Voltage Type:	1000 VDC	800-650 VAC	450 VAC
Load Condition (N)	Element* (Power - kW)	Element (Power - kW)	Element (Power - kW)
N1	Laser (1200)	Base Load (500)	Base Load (2000)
N2	Radar (1000)	Base Load (500)	Base Load (2000)
N3	EW (1500)	Base Load (500)	Base Load (2000)
N4	NA	Base Load (500) Energy Magazine (1000)	Base Load (2000)
N5	Laser (1200) Radar (1000) EW (1500)	Base Load (500) Energy Magazine (1000)	Base Load (2000)

\*Electric loads for mission system elements of interest taken from (Smart et al., 2017)

The distribution capacity within a zone depends on the sizing of the primary power distribution system, which brings medium voltage power from the onboard generators, and the secondary power distribution system, which converts medium voltage power to lower voltages and currents directly compatible with end users’ demand. The power distribution system can be configured in a variety of topologies, such as a radial bus, distributed, or zonal system, with each option having tradeoffs in space, weight, cost, and performance. The flexibility of a ship’s power distribution system (*PDSF*), Equation (3), is the average distribution flexibility: the sum of the distribution flexibility in each zone ( $DST_{zone}$ ), divided by the total number of zones ( $N_{zones}$ ). Equation (4) determines each zone’s flexibility score by assessing the in-zone distribution capability to satisfy the set of load conditions (N). If the zone has sufficient capacity in all defined assessment criteria categories, ( $N_j$ ) will be scored as a 1, otherwise, if the distribution architecture cannot satisfy any one of the categories in the load condition, it will receive a 0. This approach provides a measure of the platform’s distribution flexibility, regardless of the total number of electrical zones, as described below.

$$PDSF = \frac{\sum_0^{zone(i)} DST_{zone}}{N_{zones}} \quad (3)$$

$$DST_{zone} = \frac{N_1 + N_2 + N_3 + \dots + N_j}{N_{tot}} \quad (4)$$

Flexibility can be incorporated (and purchased) as capacity within the design at the initial delivery of the system, or through design preparations that enable future upgrades to the system when needed. The configuration of the primary and secondary power distribution (ring, distributed, zonal, or other) controls the inherent capabilities of the system that impact flexibility, as measured in equation (4). Table 9 provides three examples of power distribution system features that enable flexibility by increasing the total number of potential load cases either at initial system delivery or as a future reconfiguration. The case study provided below compares a split ring and a zonal distribution system architecture at different stages of the design specification process and at different points in the platform’s service life.

**Table 9. Examples of flexible distribution system features**

Flexible Electrical Distribution	Impact
<b>Dedicated electrical power distribution bus for expected high power loads.</b>	Increases the number of potential load cases by enabling new mission system elements to be installed in any zone, with reduced dependence on in-zone power conversion capacity.
<b>Use of high-temperature superconducting cable – variable current, temperature dependent.</b>	Can increase the power distributed to the zone by decreasing the cable temperature without adding new cables. Requires additional cooling. (Note: not necessarily available instantaneously, design preparations needed)
<b>Use of programmable and/or modular power conversion and power electronics:</b> - Power Electronic Building Blocks - Integrated Power Node Centers	Reduces the total number of power conversion elements. Provides the ability to customize conversion within any given zone to the needs of future end-users using existing or common distribution equipment.

### Case 3: Power Distribution System Flexibility Metric

This case demonstrates how to build an evaluation loading set and use it to assess power distribution system flexibility in P&E system architectures. The case study uses a common evaluation loading set to compare four variants:

- **Conventional split ring bus architecture (early-stage design):** based on the ESRDC 10,000-ton IPS ship concept (Smart, et al., 2017)
- **Ring bus alternative (later design stage):** a variant of the ESRDC concept case is presented to demonstrate the maturation of the evaluation criteria as the design space for potential future loads is reduced.
- **Zonal distribution architecture (base model):** based on the Integrated Fight-Through Power (IFTP) concept described in the ‘Next Generation Integrated Power System (NGIPS) Roadmap’ (Doerry, 2007)
- **Zonal alternative (future block upgrade):** a variant of the NGIPS concept is used to demonstrate the increase in flexibility associated with a future upgrade to the initial base architecture.

The evaluation loading set is built as a full permutation of the individual element loads in Table 10, which include the base loads required at delivery plus the potential future mission systems that the platform may be required to host in the future. The voltage types and power ratings for this evaluation set are notional, based on the payload list identified in (Smart, et al., 2017), and do not represent any actual Navy system values. Elements listed with multiple power ratings, separated by a comma, represent different configurations the future system may reflect in the future. Various options per element type may represent uncertainty of element rating or quantity. The two baseload LVAC options reflect potential differences across multiple zones of the ship at delivery. Inclusion of zero kW element loads enables the evaluation set to account for potential zone requirements that do not include the given mission element. A full permutation of these load elements generates 1,728 evaluation conditions; each of these evaluation conditions is assessed against each zone in the given distribution system architecture to determine the distribution score for that zone, then zonal scores are combined for an overall PDSF metric. To simplify the assessment of a given electrical distribution zone, the applicable loads for each set are summed by voltage type category, in this case as 1000V Medium Voltage Direct Current (MVDC), between 650-800V of either Alternating or Direct Current (MVAC/MVDC), or 450V Low Voltage Alternating Current (LVAC). For example, the 300th permutation consists of:

[500 kW MVAC/DC Base Load, 1500 kW LVAC Base Load, 200 kW MVAC/DC Energy Magazine, 600 kW MVDC Laser, 0 kW MVAC/DC Processing, 0 kW MVAC/DC VLS, 1700 kW MVDC Radar, 4000 kW MVDC SEWIP, 450 kW MVAC/DC Sonar]

which sums to [6,300 kW MVDC, 1,150 kW MVAC/DC, 1500 kW LVAC]. The full set of permutations is available in Platenberg (2024).

**Table 10: Evaluation Load Set Elements**

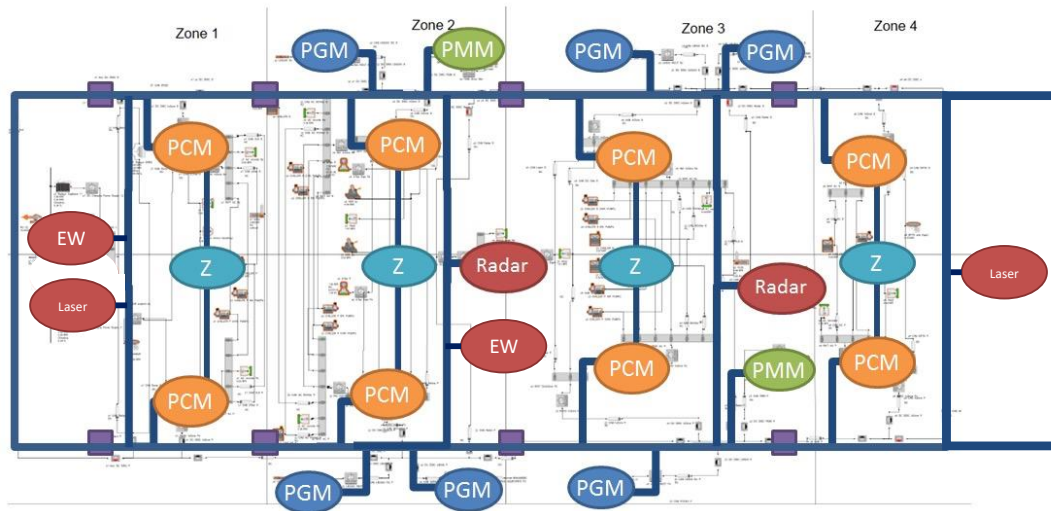

Voltage Type:	MVDC (direct feed)	MVAC/MVDC	LVAC
Element	Power (kW)	Power (kW)	Power (kW)
Base Load	NA	500	1500, 2000
Energy Magazine	NA	0, 200, 1000, 2000	NA
Laser	0, 600, 1200	NA	NA
Processing Equipment	NA	0, 200	NA
Missile Launcher	NA	0, 400	NA
Radar	0, 1700, 3300	NA	NA
Electronic Warfare (EW)	0, 2000, 4000	NA	NA
Sonar	NA	0, 450	NA

**Variant 1: Ring Bus (early-stage design evaluation).** The conventional split-ring-bus architecture, shown in Figure 5, is based on the (Smart, et al., 2017) 10,000-ton IPS concept, with four electrical distribution zones, a primary power distribution system voltage of 10 kVDC, and dual paths of power on port and starboard sides of the ship through the fully connected ring bus. Power generation modules (PGMs) and propulsion motor modules (PMMs) are connected directly to the ring bus via appropriate converters or drives. The baseline architecture included dedicated converters for high power loads to connect two Radars and one Railgun to the primary distribution bus; however, for this case and the evaluation load set, the topology was modified to replace the Railgun converter with converters for the EW and Laser elements in Zone 1, add a second EW converter in Zone 2, and add a second Laser converter in Zone 4. The power conversion modules (PCMs) represent converters and inverters within each zone, connecting all other loads to the port and starboard bus. The sizing of these converters was taken directly from the ESRDC concept, and the total distribution capacity by zone is summarized in Table 11.

Each of the four electrical zones was assessed independently for its ability to satisfy the 1,728 potential future electrical loading conditions (N) in the evaluation set. If the zone had sufficient capacity in each of the three voltage categories, then a score of 1 was recorded for that Nth condition, otherwise, if there was insufficient capacity in any one of the three categories, a score

of 0 was recorded. The sum of the 1,728 N-scores divided by the total number of N load conditions determined the zone's flexibility metric ( $DST_{zone}$ ), as shown in Table 11. The average of the four zones scores determined a total power distribution system flexibility score ( $PDSF$ ) of 0.31.

**Figure 5: Conventional Split Ring Bus Distribution Architecture Topology. Based on (Smart, et al., 2017).**

In each of the four zones, the limiting distribution category is the MVDC converter ratings for the dedicated mission elements. In a design space exploration activity, this finding might lead the designer to investigate the ability of the potential future elements to bring additional dedicated converters when needed for installation in the future, along with verification of the architecture's total flexible power capacity.

**Table 11: Conventional Split Ring Bus Distribution Capacity by Zone and voltage category; with each zones distribution flexibility score considering the full evaluation loading set permutation.**

	Zone 1 (kW)	Zone 2 (kW)	Zone 3 (kW)	Zone 4 (kW)
MVDC (direct feed)	3,200	3,700	3,300	1,200
MVAC/MVDC	8,000	17,800	12,400	5,800
LVAC	4,200	5,800	7,000	3,100
<b><math>DST_{zone}</math></b>	0.33	0.41	0.37	0.11

\*Distribution capacity based on (Smart et al., 2017)

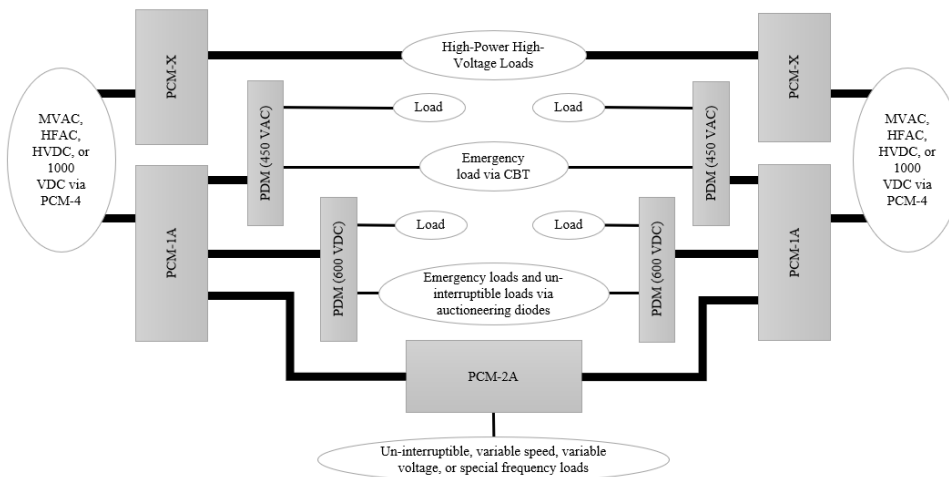

**Variant 2: Ring Bus (later stage design evaluation).** To simulate the progression from a distribution flexibility analysis of an early-stage concept design to a more mature preliminary design baseline, the conventional ring bus architecture was used for a second flexibility evaluation. In this case, the design space for potential zone requirements is narrowed and the evaluation loading set is tailored to the requirements for each zone. Table 12 provides the refined requirements for evaluation loading set criteria applicable to Zones 1-4. Zone 1, the forward-most zone on the ship, is designated responsibility for the Sonar, due to shaping of the hullform and location of the sonar dome. Radar requirements are allocated to the zones 2 and 3, which are covered by the deckhouse for mounting the equipment topside. The Laser tradespace is unchanged; however, the energy magazine requirements are reduced to 1 MW and locations based in zones 2-4. The resulting flexibility score improvements are shown in Table 12, and the total power distribution system flexibility score ( $PDSF$ ) improves to 0.64. Note that zone 1 scores a 1.0, as the evaluation loading set requirements were narrowed to match the MVDC converter for the mission elements as intended.

**Variants 3 and 4: IFTP (Base Model and Block Future upgrade).** The zonal distribution architecture is based on the Integrated Fight-Through Power concept described in the Next Generation Integrated Power System Roadmap (Doerry, 2007), with a notional in-zone topology depicted in Figure 6. For this case, the zonal electrical distribution system concept consists of 4 electrical zones, with a series of Power Conversion Modules (PCM) types to convert power within each zone. A PCM-4 serves as a transformer rectifier to convert MVAC power from the power generation module to 1000 VDC for distribution across the ship. Within each-zone, PCM-1As convert 1000 VDC power to a variety of MVDC voltages based on user needs. PCM-2As then convert 750-800 VDC power from the PCM-1A into LVAC in-zone demands. Additionally, for this concept, a notional PCM-X is connected to the 1000 VDC bus in each zone to service high power MVDC loads throughout the ship. It is

assumed that the rating of each PCM is scalable based on the number of modular subcomponents included: Ship Service Inverter Modules (SSIM) or Converter Modules (SSCM).

**Table 12: Refined Requirements Evaluation Loading Criteria**

	Zone 1	Zone 2	Zone 3	Zone 4
MVDC (direct feed) Limiting Criteria	0x Radar 1x EW Unit 1x Max Laser	1x Radar Unit 1x EW Unit 1x Max Laser	1x Radar Unit 1x EW Unit 1x Max Laser	0x Radar 1x EW Unit 1x Max Laser

**Figure 6: NGIPS Roadmap "Potential Future IFTP" In-Zone Topology, based on (Doerry, 2007)**

Two variants of the zonal IFTP concept were evaluated to demonstrate the different flexibility scoring associated with a base model architecture as initially delivered, and a block future architecture, including some planned upgrades to the distribution system. These two zonal IFTP variants are consistent with this approach, as the base model architecture including design preparations in the form of planned PCM growth capacity to accommodate additional SSIM/SSCMs in the future, when needed. The base model is delivered with 5.5 MW of PCM-X, 12 MW of PCM-1A, and 10 MW of PCM-2A capacity, and design preparations for 22 MW of PCM-X and 4 MW of PCM-1A SSCM/SSIMs. Table 13 indicates the PCM capacity for the base model configuration by zone, with the associated zone's flexibility metric ( $DST_{zone}$ ). The total power distribution system flexibility score ( $PDSF$ ) for this configuration is 0.14. However, once the maximum PCM capacity is installed in the block future configuration, also shown in Table 13, the total  $PDSF$  score improves to 0.85.

**Table 13: Zonal IFTP Distribution Capacity by Zone, Base Model and Future Distribution**

	Base Model				Future Distribution				
	Zone 1 (kW)	Zone 2 (kW)	Zone 3 (kW)	Zone 4 (kW)	Zone 1 (kW)	Zone 2 (kW)	Zone 3 (kW)	Zone 4 (kW)	Total DST Capacity (kW)
PCM-X	0	2,000	3,500	0	6,875	6,875	6,875	6,875	27,500
PCM-1A	3,000	3,000	3,000	3,000	4,000	4,000	4,000	4,000	16,000
PCM-2A	2,500	2,500	2,500	2,500	2,500	2,500	2,500	2,500	10,000
<b><i>DST<sub>zone</sub></i></b>	0.03	0.16	0.32	0.03	0.85	0.85	0.85	0.85	0.85

The four architecture variants' power distribution system flexibility metrics and individual zone flexibility scores are plotted in Figure 7. Each architecture was modeled with four electrical zones, with varying distribution and conversion capacities in

each zone, across the MVDC, MVDC/MVAC, and LVAC assessment categories. The ring bus variants, each with the same distribution and conversion capacities, are shown in blue. The early-stage design assessment utilized the full permutation of the evaluation loads sets, whereas the later-stage design assessment tailored the evaluation loads based on other known design decisions to reduce the range of potential future load options desired in each zone. This maturation of design data resulted in a 100% increase in PDSF for the ring-bus architecture. The IFTP base model and block future variants are plotted in yellow, to demonstrate the increase in distribution flexibility provided by including preparations in the design to accommodate future (long-term) perturbations in required load demands. The ship concept for these IFTP variants remains constant other than the installation of additional distribution and conversion modules in the block future, to represent in-line upgrades at the same maintenance availability where the new load demand end-users are installed. In a design space exploration activity, a large number of representative architectures can be defined by their individual zone characteristics, and assessed against a common set of evaluation loads to identify the feasible options. In this limited example, the IFTP option is preferred based on the lower upfront cost of the architecture and the ability to achieve the higher power distribution system flexibility in the future, when the long-term perturbations are realized.

**Figure 7: Power Distribution System Flexibility (PDSF) and individual zone (DSTzone) scores**

## CONCLUSIONS

This paper develops measures of power and energy system flexibility; this specific ility was chosen based on the frequency of its appearance in the literature review and interest within the broader naval design community. Flexibility is defined as the capability of the system to accommodate change in response to perturbations in requirements. For the naval power and energy system, flexibility is quantified within the system boundary, in response to perturbations from new and changing loads requiring power or changes at the source of an energy flow. Three case studies were conducted to develop metrics for Flexible Power Capacity, Debitable Power Flexibility, and Distributable Power Flexibility.

The maturation of developmental mission system technologies with new and increased electrical power demands are driving requirements for emergent properties, beyond the typical functional requirements. The U.S. Navy surface fleet is currently facing challenges related to the rate of technology change and uncertainty of the combat systems of the future, and the significant cost of investment to design and build new ship classes. Uncertainties impact the system's ability to affordably maintain mission relevance within an evolving operational context. Affordability constraints within the Navy acquisition environment, and the timelines for designing new and modified classes of ships, emphasize the need to make informed decisions in early-stage design.

## Related and Future Work

Additional metrics were developed in conjunction with this work. Interested readers are referred to Platenberg (2024) for a description and case study of an energy storage system flexibility metric, and for a Real Options Analysis that balances system performance and cost to "right size" the P&E system at delivery with preparations in the design to react to future uncertainty.

The Navy and academic community should pursue validating and implementing the metrics presented here for power and energy system flexibility within the Smart Ship System Design (S3D) program and integrating with the standard early-stage design tools within the Leading Edge Architecture for Prototyping Systems (LEAPS) toolkit.

# Optimization of Ship Design for the Effect of Wind Propulsion

Timoleon Plessas<sup>1,\*</sup> and Apostolos Papanikolaou<sup>2</sup>

## ABSTRACT

*International regulations as well as strong market demand for zero-emission transport call for a radical change in the shipping industry. One very promising zero-emission propulsion system for shipping is wind propulsion. In this context, the EU-funded Orcele Wind project (<https://cordis.europa.eu/project/id/101096673>) aims at using wind as the main source of ship propulsion and to demonstrate the effectiveness and viability of Wind Assisted Propulsion Systems (WAPS) by a retrofitting and new building demonstrator. In this paper, we explore the effect of wing sails on the concept design of a VLCC tanker in the frame of a newly parametric ship design optimization procedure.*

## KEY WORDS

Ship Design; Parametric Optimization; Wind Propulsion; Wing Sails; WAPS; Case Study

## INTRODUCTION

The International Windship Association (IWSA) has declared 2021-2030 the ‘Decade of Wind Propulsion’ and the European Maritime Safety Agency (EMSA) recently issued a related report (EMSA, 2023) concluding that “wind-assisted propulsion is considered to have potential for the shipping industry”. Thus, the maritime industry seems to be returning to its roots by experimenting with Wind Assisted Propulsion Systems (WAPS) in its effort to drastically cut its carbon footprint. The numerous regulatory requirements related to Green House Gas (GHG) emissions (IMO 2022) and the increased costs and problems with logistics of *green* fuels make wind propulsion a promising alternative for achieving the required environmental goals, to comply with related regulations and to reduce operational costs. Wind as an energy source offers numerous advantages for the shipping industry: it is freely available and future-proof, independent from the supply and price fluctuations of combustible and of alternative fuels. In addition, wind is a predictable energy source with zero emissions, which does not require new shore infrastructures and associated logistic systems. It is also one of the few technologies potentially offering double-digit fuel and emission savings.

Numerous recent studies have focused on the modeling and the simulation of wind assisted propulsion systems (e.g. Rosander & Bloch 2000; Bentin et al 2018; Talluri et al 2018), while potential fuel savings have been demonstrated by 3-DOF (Viola et al 2015; Ma et al 2023) and 4-DOF (Tillig & Ringsberg 2019) simulation methods. Although the main focus has been given to the performance prediction of vessels equipped with Wind Assisted Propulsion Systems (WAPS), *the effect of WAPS on ship design optimization* has not been yet systematically examined, namely *traditional ship design concepts* are being equipped with WAPS in the way of retrofitting and their performance is examined/optimized, even if they are newbuildings.

In this paper we present the development of a parametric ship design optimization framework to identify possible differences in the main dimensions and characteristics of ships, when considering the effect of WAPS, starting with the concept design of ships with fitted wing sails. It is noted that until now, the fitting of WAPS to ships has been as a retrofitting to an existing design, even in cases of newbuildings. For this, we developed and implemented a new methodology in MATLAB (Mathworks, 2023). It enables the fast simulation of the effect of alternative WAPS on the design of ships of various types and sizes, the identification of trends for the main ship design characteristics (main dimensions, hull form, main engine and propeller characteristics), while using only few input parameters and while all pertinent major design constraints are taken in to account. The developed method and s/w tool are herein applied to the design of a VLCC tanker with WAPS (here: generic wing sails) to demonstrate the applicability and limits of the presented approach.

## WIND POWERED SHIP PROPULSION SIMULATION MODEL

Focusing on the concept design of ships with WAPS, a simplified one degree of freedom (1-DOF) hydrodynamic/maneuvering simulation model is utilized to conclude on the effect of WAPS on ship design. The main differences between a 1-DOF model (surge, movement in longitudinal direction) and a 4-DOF model (surge, sway, yaw and roll movement) are the consideration of the hydrodynamic forces that occur due to the added rudder resistance to maintain the required course and the drift resistance, which is the added resistance due to the fact that the vessel sails at a drift angle which results in a non-symmetrical flow around the hull. Regarding the effect of roll motion, a simplified way to compensate for the lack of consideration of the roll movement in the simulation is to examine the caused heel angle hydrostatically, meaning that the static heel is estimated based on the generated sail side force. Also, the effect of the heel angle on the projected sail area and the height of the center of effort is considered. Of course, this is a simplified approach that ignores the dynamic phenomena of a complete maneuvering model of ship's hydrodynamics (Papanikolaou et al, 2016); thus, it needs to be used with caution in cases where large heel angles are expected and when the hydrodynamic effect of hull appendages (bilge keel, sideboards, bottom daggerboards etc.) is significant. Tillig and Ringsberg (2019) showed in a case study on the utilization of WAPS for a tanker operating on a route in the Baltic Sea (from Gothenburg to St. Petersburg) that the difference in estimating the fuel consumption for wind assisted vessels with 1 DOF model compared to a 4 DOF model ranges from 2% (for smaller sail areas – e.g. 300 m<sup>2</sup>) to 7% (for larger sail areas – e.g. 900 m<sup>2</sup>), with the 4 DOF model giving more conservative predictions in terms of savings.

Following this reasoning and for the purpose of optimizing ship's concept design, a one degree of freedom (1-DOF), quasi-steady model has been developed and coded for simulating and optimizing a ship operating in a pre-defined route with available weather data information. The developed model takes into account the interaction between hull, propeller, engine and sail, simulates and balances all forces in surge direction and estimates the power and fuel consumption needed for completing a scheduled voyage. In addition, the developed model allows the communication (exchange of data) between MATLAB and NAPA software packages (Figure 1). This enables the conduct of a more detailed analysis for each generated design alternative, which includes lightship & loading conditions determination, intact stability criteria assessment, environmental regulations assessment (e.g., oil outflow compliance for tankers) and overall performance analysis. The user can choose if NAPA should be utilized during the optimization. Alternatively, simplified calculations can be conducted within MATLAB without the need of NAPA, which may provide less details but it significantly speeds up the optimization procedure. Indicatively, when calling NAPA a single simulation takes approximately 40 seconds, whereas computations using semi-empirical formulas within MATLAB take approximately 1 second on a conventional computer. The results presented in this study were conducted using only MATLAB internal routines.

Figure 1. MATLAB code: Interaction between vessel modules

The developed simulation tool consists of three basic modules: “input creation”, “simulation” and “output”. The “Input creation” module is responsible for creating all the necessary input (power curves, engine curves, stability and weight relationships and calculations, etc.) while considering the input (selected) design variables (see subsection “Design Variables” for more information). Within this module it is possible to call NAPA for conducting more detailed weight, performance and stability calculations. Once all necessary input files are created, the “simulation” module estimates all acting hydrodynamic and aerodynamic forces and simulates the sailing of the vessel on the selected route considering the available weather information (wind and waves). Finally, the “output” module is responsible for printing the resulting figures and tables.

In the examined case study, the voyage is a typical tanker route between Corpus Christi (USA) to Rotterdam (Netherlands) (Figure 2). The voyage is subdivided into 12 legs and it is assumed that it is a round trip voyage, thus the vessel returns in ballast condition using the same route, therefore 24 voyage legs are considered in total (12 for laden condition and 12 for ballast condition). For each leg all ensuing parameters are estimated twice: once taking into account the effect of the wing sails and once as if the wing sails did not exist, for a fixed speed. This allows an instant comparison of the effect of wing sail on the required thrust to propel the ship and forms the foundation of the optimization process where the effect of the fitted wing sail on ship design is examined.

Figure 2. Selected Route

It is evident that the performance of fitted WAPS strongly depends on the route and the prevailing wind direction and strength, which are varying with location, time and season of the year. Thus, the shortest route between departure and arrival point is not necessarily the optimal one and traditional routing optimization procedures and software tools need to account for the best wind potential of the investigated route. An optimal routing methodology, which enables the operational energy savings to be assessed on various trading routes across the globe, has been developed by SSPA/RISE. The methodology considers the need for the vessel to fit into a logistics system regarding arrival time and lateness and considers European Centre for Medium-Range Weather Forecasts (ECMWF) weather data captured during the last decade (Werner 2021). This methodology is being utilized in the Orcelle project and supports the present study.

## Wing Sail Characteristics

The main focus of the present methodology is development of tools in order to assess impact of WAPS on ship design in the frame of a design concept optimisation procedure. The herein examined wing sails system is based on a simplified, generic arrangement of symmetrical NACA airfoils (Abbott & Von Doenhoff 1959), which differs significantly from the *Orcelle Oceanbird* concept (Oceanbird 2024), whose sail consists of an optimized main wing and a controllable flap. This approach allows the development of the necessary WAPS simulation tools independently of the development and actual efficiency of

the Oceanbird concept, which will be integrated into the developed simulation tools in the future, while it is expected that its efficiency in terms of generated lift (and thrust) will be significantly higher.

Based on the above reasoning, the herein examined WAPS consists of eight rigid wing sails of an approximate height of 80 m and average chord length of 23 m. The assumed wing profile is a NACA0015 airfoil with a modified trailing edge. Each sail has sail area 1,844 m<sup>2</sup>, mean chord length of 23 m and aspect ratio of 3.47 (Malmek et al 2020). The developed MATLAB simulation code has the flexibility to ultimately consider a variation of the number of fitted wing sails, their arrangement, size and wing profile. Also, alternative WAPS (different types of wing sails and rotors) may be considered, assuming the availability of aerodynamic data for the estimation of the induced lift and drag forces.

In the present case study, some assumptions regarding the position and the interaction of the wing sails are made in order to simplify the problem, reduce computational time and reduce the parameters of the optimization problem. Sail position (longitudinally and crosswise) is crucial for maximizing the effectiveness of the wings. However, for the 1-DOF model the exact position of the sails is not examined, thus it is implied that there is a feasible/optimized sail arrangement that maximizes the generated wind thrust and minimizes the effect of drift angle and rudder resistance for maintaining the required course and complies with all necessary requirements (e.g. bridge visibility, ship structural strength etc.) (Bordogna et al 2018).

In cases where the generated sail force is sufficient to move the vessel at the desired speed (100% wind generated thrust), there are various options regarding the operation of the propeller such as windmilling, feathering or harvesting (Gypa, 2023). For the optimization problem, harvesting the energy of the rotating propeller is herein not examined and the added resistance from the windmilling/feathering propeller is not taken into account.

### Estimation of Forces

The developed model simulates the longitudinal/surge forces, so the voyage is divided into legs with constant speed and environmental conditions and for each leg, equation [1] is solved to estimate the thrust of the propeller.

$$X_{CW} + X_{AW} + X_W + X_S + T = 0 \quad [1]$$

where

$X_{CW}$  is the calm water resistance (N) which is calculated using the Holtrop & Mennen method (Holtrop & Mennen 1982; Holtrop 1984), properly calibrated to predict the calm water resistance of the reference vessel.

$X_{AW}$  is the added resistance due to waves (N) which is calculated using the semi-empirical SNNM method (Liu & Papanikolaou 2020)

$X_W$  is the wind resistance (N) of ship's superstructure, which is estimated according to ISO 15016 (International Organization for Standardization 2015)

$X_S$  is the generated sail force (N) for the assumed wing sails, which is calculated from tabulated aerodynamic forces provided by RISE Research Institutes of Sweden (personal communication)

$T$  is the propeller thrust (N)

### Vessel performance comparison with and without sails

The developed tool is capable of simulating the whole voyage with detailed calculations for each leg and a direct comparison between the same design with and without sails. Below some indicative figures are presented that compare the results of the various modules (hull, engine, propeller and sail). The figures refer to the 4<sup>th</sup> leg of the selected voyage for the reference vessel (Figure 3).

Figure 3. Leg 4

### Forces

For each leg, all the forces are calculated (Figure 4) and the percentages of propulsion and resistance forces depicted in Figure 5.

Figure 4. Estimated Forces for leg 4

**Figure 5. Force Percentages for leg 4**

### **Hull**

The calm water resistance of the vessel is plotted in Figure 6, along with the operational points. Speed is fixed to 12 knots.

**Figure 6. Speed vs Resistance**  
(Colored points refer to leg 4. Transparent points refer to the rest of the legs)

### **Main Engine**

The engine layout diagram, along with the calculated operational points for all legs are shown in Figure 7 and the Specific Fuel Oil Consumption (SFOC) is shown in Figure 8. It should be noted that an assumption is made that the engine is always in operation (zero brake power is not allowed). In practice, operational points with very low engine loads (Reche-Vilanova et al 2023) need to be addressed with an operational strategy (e.g. increase vessel speed, trim sails etc.) in order to avoid operating at such low loads (and very high SFOC). During the herein conducted optimization, this is not taken into consideration because in the examined case study the majority of the operational points do not require very low engine loads, therefore the effect of an operational strategy for these cases does not have a significant impact on the optimization output.

**Figure 7. Engine layout diagram**  
(Colored points refer to leg 4. Transparent points refer to the rest of the legs)

**Figure 8. Power vs Specific Fuel Oil Consumption (SFOC)**  
(Colored points refer to leg 4. Transparent points refer to the rest of the legs)

### *Propeller*

The examined Fixed Pitch Propeller (FPP) is modeled based on the polynomials of the Wageningen B-series (Lammeren et al 1969 and Oosterveld & Van Oossanen 1975). Propeller efficiency is estimated for the various operating points (Figure 9) and a check is conducted to ensure that we do not have extensive cavitation (Figure 10)

**Figure 9. Propeller Efficiency**  
(Colored points refer to leg 4. Transparent points refer to the rest of the legs)

**Figure 10. Checking for cavitation (Carlton 2007)**  
(Colored points refer to leg 4. Transparent points refer to the rest of the legs)

### *Wing Sail*

Regarding the wing sail, the forces are calculated based on the apparent wind speed, apparent wind angle and lift/drag characteristics of the ensuing wing profile (Figure 11).

Figure 11. Wing Sails Thrust (8 Wing Sails) depending on wind angle and wind speed

## DESIGN OPTIMIZATION METHODOLOGY

A customized optimization problem for the design of ships with WAPS has been defined and appropriate methodology developed to handle the wind assisted propulsion problem. The output of the optimization process is the optimum combination of hull, engine and propeller that minimize the objective function, while including the effect of the examined WAPS. The MATLAB coded optimization module is capable of conducting both single- and multi-objective optimization studies and the main optimization process is sketched in Figure 12. The herein presented study focuses on a single-objective optimization problem. Below, some details regarding the optimization process are briefly mentioned.

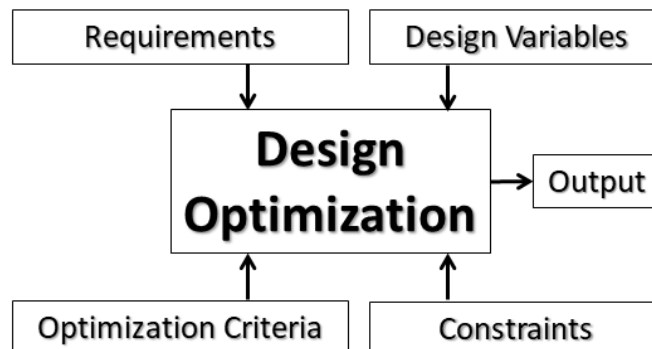

Figure 12. Generic design optimization process (Papanikolaou, 2014)

### Optimization Algorithm Selection

Due to the nonlinear nature of the problem, a combination of optimization algorithms is utilized, both heuristic (genetic algorithm) and deterministic (sequential quadratic programming), in order to ensure that convergence to a global optimum solution and avoid possible local minimal solutions.

### Design Space Exploration

In order to ensure that we have explored the design space sufficiently, a large number of initial designs is populated using the SOBOL sequence (Bratley & Fox 1988). A SOBOL sequence is a probabilistic sampling scheme that covers the design space more evenly compared with a pseudorandom number source. It increases the diversity of the population and leads to better

optimization results (Agushaka & Ezugwu 2022). In the examined case study 5,000 designs are generated and the best 50 feasible designs are used as initial population in the genetic algorithm.

Figure 13. 5,000 Initial Designs Using Sobol Sequence

### Heuristic Optimization Algorithm

The global optimization algorithm that is utilized is the genetic algorithm (Mathworks 2023). We optimize for 500 generations with each generation containing 50 individuals. The 50 “fittest” designs from the design space exploration process are used as initial population.

Figure 14. Genetic Algorithm Progress Example

### Deterministic Optimization Algorithm

After the global optimization algorithm finishes, a deterministic optimization algorithm is utilized, namely Sequential Quadratic Programming (SQP). The initial value of the deterministic optimization algorithm is the output of the Heuristic Algorithm, thus optimizing further the design.

Figure 15. SQP Optimization Algorithm Iterations Example

## IMPLEMENTATION

The developed WAPS simulation tool is implemented within the earlier defined design optimization methodology to approach the wind-assisted design optimization problem holistically (Figure 15). Some details regarding the implementation of the methodology are briefly outlined below.

### Design Variables

In the herein presented application study, we consider 8 ship design variables: Length (L), Breadth (B), Depth (D), Draft (T), Block Coefficient (CB), Engine BHP/type (selected from a list), propeller pitch ratio (P/D) and propeller expanded area ratio ( $A_E/A_0$ ). Due to the nature of the employed genetic algorithm that is used for optimization, it is more efficient to handle all design variables as integers (discrete optimization). For L, B, D and T we keep 2 decimals, thus  $L_{integer} = L \cdot 100$ ,  $B_{integer} = B \cdot 100$  etc. and for CB, P/D and  $A_E/A_0$  we keep 3 decimals  $CB_{integer} = CB \cdot 1000$  etc. The engine selection parameter is also an integer number that defines which engine has been selected from the provided engine list. This technique significantly speeds up the optimization process and allows a wider examination of the design space.

Once the genetic algorithm has completed the optimization process, the deterministic optimization algorithm uses the optimum result of the genetic algorithm to conduct a continuous optimization process, thus no longer treating the design variables as integers. This is due to the nature of the employed continuous optimization algorithm and allows the fine-tuning of the already optimized design by a genetic algorithm.

### Objective Function

The objective function used in the present case study is the minimization of annual fuel oil consumption of the main engine (and indirectly of the associated GHG emissions). The fuel consumption per roundtrip is estimated for the provided weather conditions and then the annual consumption is estimated taking into consideration the activity of the reference vessel (yearly percentage of laden and ballast sailing time) and the number of roundtrip voyages that can be achieved yearly. It is noted that there is no restrictions in the implemented optimisation method and code to include more objective functions (multi-objective optimization possible)

### Constraints

The set design optimization problem considers 15 constraints, which ensure that the derived results are feasible. More specifically, the constraints include limits for the DWT, limits for the form coefficients and main dimension ratios in order to ensure that the generated designs are meaningful and do not much deviate from relevant data of existing vessels (Papanikolaou 2014), they ensure that the propeller operates within engine limits with minimum cavitation (Burrill &

Emerson 1978), and the compliance with regulations regarding freeboard (IMO 1966) and minimum propulsion power (IMO 2021). A minimum metacentric height (GM) of 3 meters is also required as an initial check of the intact stability of the vessel. It should be noted that the EEDI constraint (IMO 2022) is herein excluded due to lack of information regarding the calculation of the possible reduction factor for the installed WAPS (presently under consideration at IMO).

The set constraints for the VLCC tanker considered in the following are summarized below:

1. Min. DWT  $\geq 270000$  tons
2. Max. DWT  $\leq 330000$  tons
3. Engine Limit Constraint
4. Less than approximately 5% cavitation at the propeller
5.  $0.79 \leq CB \leq 0.88$
6.  $0.992 \leq CM \leq 0.996$
7.  $0.88 \leq CWL \leq 0.94$
8.  $0.835 \leq CP \leq 0.855$
9.  $5.1 \leq L/B \leq 6.8$
10.  $2.4 \leq B/T \leq 3.2$
11.  $10.5 \leq L/D \leq 14$
12. IMO Minimum Power Requirement
13. Freeboard Constraint
14.  $GM \geq 3$  m
15.  $0.2 \cdot T \leq \text{Propeller Diameter} \leq 0.55 \cdot T$

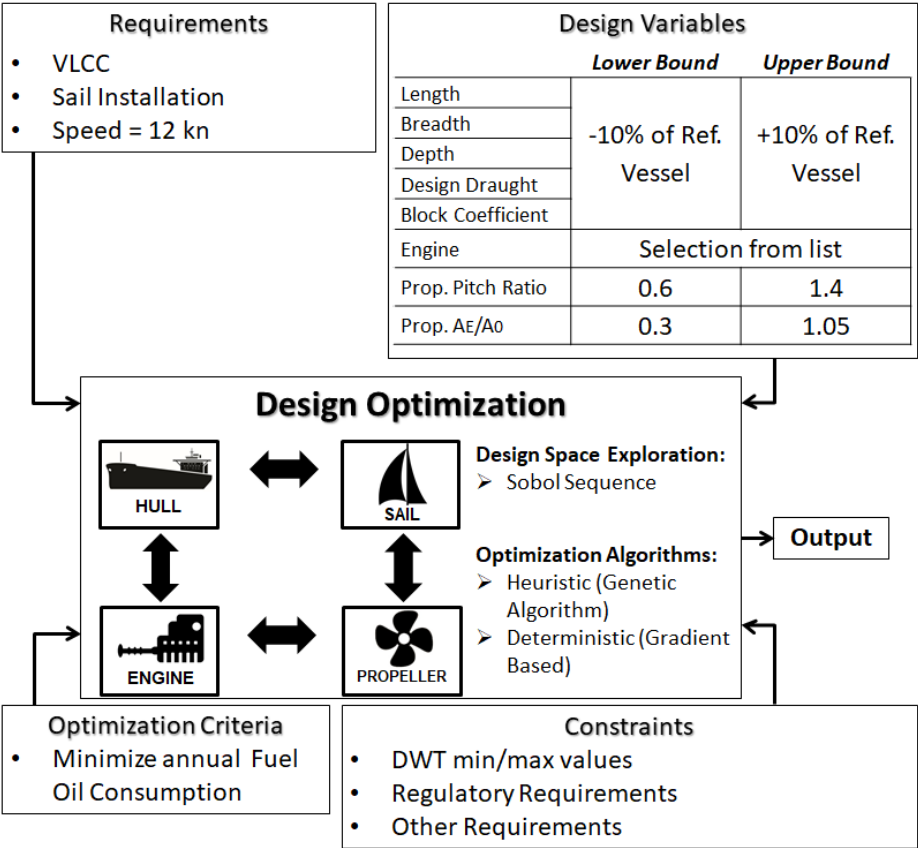

Figure 16. WAPS optimization process for VLCC case study

## CASE STUDY

### Reference Vessel

The reference vessel is an existing VLCC tanker. The main particulars of the reference vessel are presented in Table 1.

**Table 1. Main particulars of reference vessel**

Length B.P.	322.00 m
Breadth Mld.	60.00 m
Depth Mld.	29.40 m
Design Draught	20.50 m

### Selected route and weather characteristics

The selected route for the case study is a common route from Corpus Christi (USA) to Rotterdam (Figure 2). The weather characteristics per leg were provided by the ORCELLE partner StormGEO and contain ERA5 data from 1980 to 2022. ERA5 (Hersbach et al. 2020) is the fifth generation atmospheric reanalysis of the global climate, produced by the Copernicus Climate Change Service (C3S) at ECMWF. In Table 2 the mean values of the provided data are presented. Seasonal changes in weather can also be taken into consideration but for the examined case study the weather information is herein considered constant.

**Table 2. Weather information for the selected route**

leg	Latitude	Longitude	TWS (kn)	TWA (deg)	Wave Height (m)	Wave Period (s)
1	26	-88.25	11.5	277.4	1.1	5.8
2	24.75	-79.75	11.0	276.6	0.9	5.4
3	25.75	-77	11.3	285.1	1.2	8.2
4	28.5	-72	11.8	310.7	1.7	8.7
5	32.25	-64.5	13.4	44.5	1.8	8.7
6	36.75	-56	16.3	64.4	2.5	9.2
7	40	-49	16.9	70.3	2.8	9.7
8	42	-45	17.8	75.3	3.0	9.8
9	43.75	-40.5	18.0	73.6	3.1	10.0
10	46	-33	18.1	70.0	3.3	10.3
11	47.75	-25.75	17.9	72.7	3.3	10.5
12	49.75	-6.5	15.7	86.2	2.5	10.4

It should be noted that the possible fitting of WAPS goes hand in hand with weather routing optimization, thus the examined conventional route (not optimized for prevailing winds) significantly underestimates the potential savings (Werner et al 2023).

### Results

The results from the optimization algorithm are presented in Table 3 and a comparison of the main dimensions of the initial population (feasible and infeasible), the reference vessel (with and without sails) and the optimum vessel is presented in Figure 17

Table 3. Optimization Results

	Reference Vessel (without sail)	Optimized Vessel (with sail)	Difference (%)
L (m)	322	338.4	+5%
B (m)	60	54	-10%
D (m)	29.4	32.23	+10%
T (m)	20.5	22.12	+8%
CB	0.796	0.78	-2%
Main Engine MCR (kW)	25600	26437.61	+3%
Main Engine RPM at MCR (RPM)	60.9	63.5	+4%
Prop. P/D	0.803	0.787	-2%
Prop. AE/A0	1.05	0.459	-56%
Disp. (m3)	315264	315264	0%
DWT (t)	276902	276902	0%
Estimated Annual Main Engine Fuel Cons. (t)	13003	9666.6	-26%

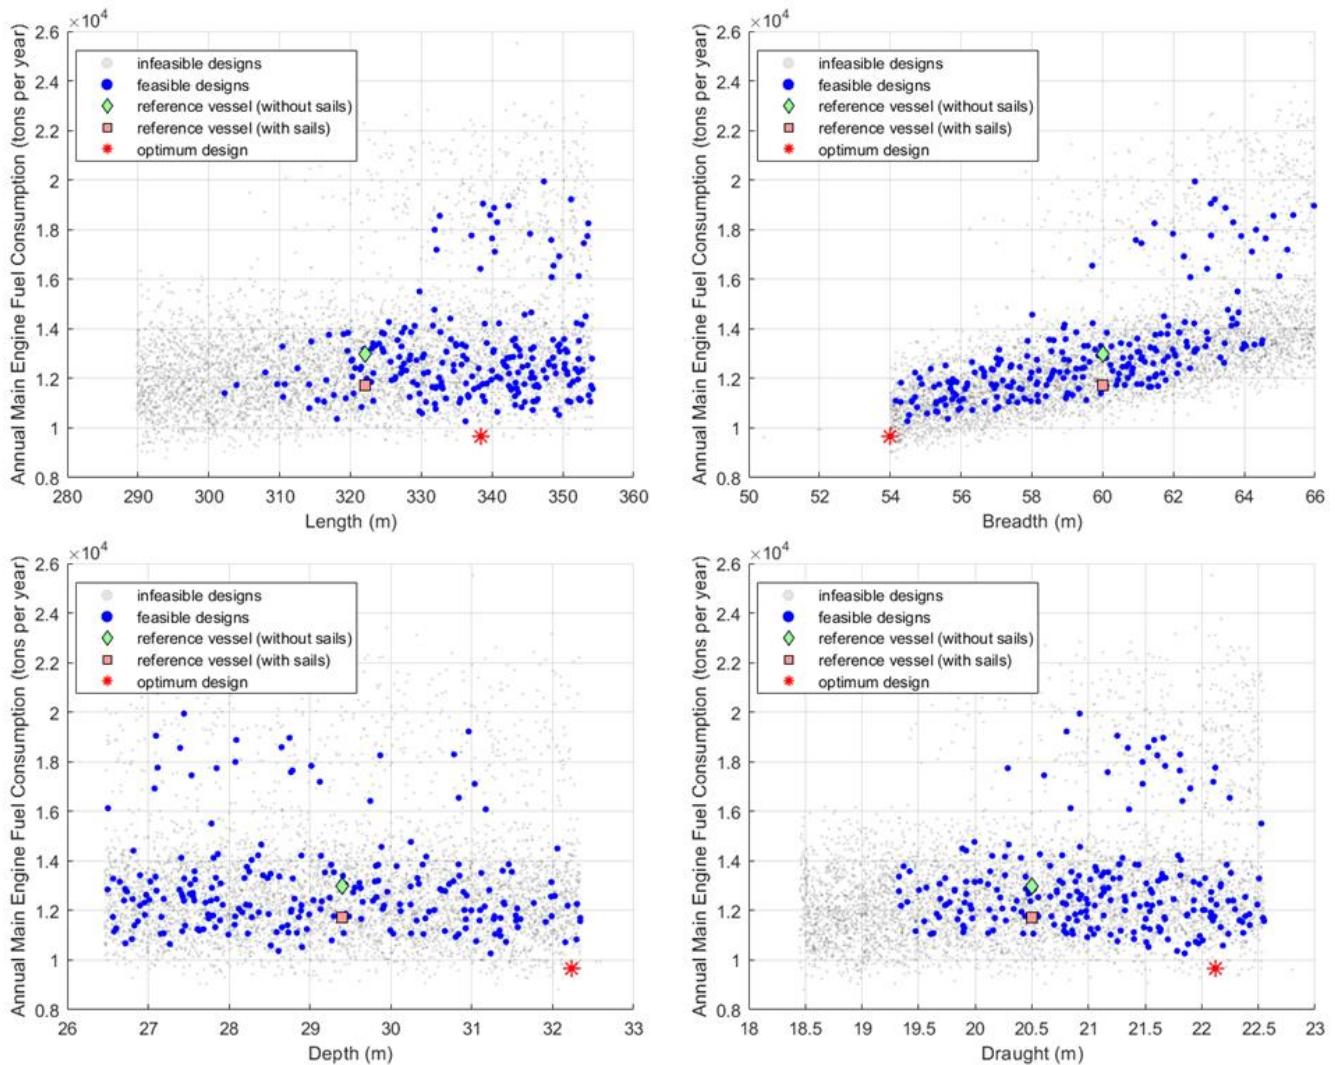

Figure 17. Comparing Main Dimensions of Explored Designs

In Figure 17 It can be observed that during the design exploration phase, a large number of infeasible designs is generated (grey points), which emphasizes the effect of the set constraints and the need of a sufficiently large and evenly-distributed

initial population in order to ensure that the optimization algorithm converges to the global optimum. In Table 3, it can be observed that the conducted optimization resulted in a vessel with the same DWT but longer, with smaller breadth and larger draught. The reduction of the annual fuel consumption compared to the reference vessel is about 26%. It is also interesting to note that if the present wing sail system were installed at the reference vessel (retrofitting), the estimated annual Main Engine consumption would be 11728 tons, thus we would have still a reduction of 17.5% that is attributed to the changed design characteristics. It should be finally noted that the effect of WAPS on ship's main dimensions can be expected to be more drastic for other ship types and sizes, considering that the wind potential may be assumed the same for all ships operating on the same route, but its effect on ship's propulsion and motions is directly dependent on ship's size (displacement) and on the magnitude of the generated wind thrust compared to ship's hydrodynamic (and air) resistance.

## SUMMARY & CONCLUSIONS

In the present paper, we developed a new simulation tool for the assessment of the performance of ships equipped with WAPS, allowing the exploration of the effect of the wing sails on the concept design of ships with wing sails in the frame of a multi-parametric ship design optimisation procedure. The developed simulation tool has been applied to a VLCC tanker design case study. Several useful conclusions maybe drawn from the conducted research:

1. There are numerous ship design and operational parameters that have major effect on ship design, when the ship is fitted with WAPS, such as ship's main dimensions, engine and propeller characteristics, route, speed, size/number/arrangement of wing sails, logistics, WAPS alternatives etc. and all of them need to be included in a ship design optimization procedure.
2. The main characteristics of the resulting optimized VLCC tanker with WAPS significantly differ from those of traditional VLCC designs w/o WAPS. It may be expected that differences will be more pronounced for smaller vessels and other ship types (volume vs. deadweight carriers).
3. The predicted fuel saving and associated reduction of GHG emission of 26% for a VLCC tanker are remarkable. These savings may appear too optimistic, because of the limited accuracy of the employed 1DOF hydrodynamic modeling. However, using an optimized route with respect to wind potential, instead of the shorted root and advanced technology wing sails, like the Oceanbird concept, instead of the herein used NACA wing profiles, it may be expected that the encouraging outcome of this study is fully justified.
4. Way ahead: further investigation of the effect of WAPS by
  - a. proceeding to ship's preliminary design (by use of, e.g., the NAPA® naval architectural software platform)
  - b. applying the present concept design approach to other ship types and sizes
  - c. using more advanced hydro- and aero dynamic models (3 and 4DOF maneuvering models, inclusion of Oceanbird wing sail characteristics, effect seakeeping on the sails and on the resistance/thrust estimations).

It seems evident only a holistic approach to the wind-assisted ship design process will reveal the true and full potential of wind assisted propulsion in shipping and facilitate its acceptance by the maritime industry.

## CONTRIBUTION STATEMENT

**TP:** Conceptualization; data curation, methodology; writing – original draft. **AP:** conceptualization; supervision; writing – review and editing.

## ACKNOWLEDGEMENTS

The support of this research by the European Com-mission research project ORCELLE WIND under the European Union's Horizon research and innovation program under grant agreement n° 101096673 is acknowledged. The European Commission and the authors shall not in any way be liable or responsible for the use of any knowledge, information or data presented, or of the consequences thereof. The authors also acknowledge the support the ORCELLE WIND project partners SSPA/RISE and StormGeo for the provision of aerodynamic data on wing sails performance and weather data pertaining to the presented case study, respectively. The provision of comparative ship data for the conducted case study by THENAMARIS is also acknowledged.

# Nuclear fusion as unlimited power source for ships

E.S. van Rhee<sup>1\*</sup>, J.P.K.W. Frankemölle<sup>2,3</sup> and E.L. Scheffers<sup>1</sup>

## ABSTRACT

*Every now and then, every marine engineer dreams of a compact, lightweight and inexhaustible energy source to power large ships across the seven seas. Nuclear fusion of deuterium and tritium promises to be a safe, compact, carbon-free, and inexhaustible energy source. Even though it will take decades before conventional power plants may be replaced with nuclear fusion, the concept of nuclear fusion for marine propulsion has already been put on the table by commercial parties. This research investigates the potential of nuclear fusion onboard ships. The design investigates putting the smallest imaginable magnetic confinement reactor, ARC, on a ship. The only commercial ship requiring significant amounts of power is the Queen Mary 2. The large power output of ARC (200 MWe) is one of the major issues of putting a fusion reactor on a ship. Other issues may include intact stability, structural design and influences of vibrations on the fusion reactor. All in all, we found that a fusion reactor onboard a ship is unlikely to be feasible in the near future.*

## KEY WORDS

Nuclear Fusion; Nuclear ships; Powerful ships; Conceptual Design; Retrofit Design

## INTRODUCTION

Like many other domains, the maritime industry needs to dramatically decrease its harmful emissions by 2050 (International Maritime Organization, 2023). Sustainable powering of ships is the key to reducing emissions during the ship's operational life cycle. Therefore, research into alternative fuels is essential to reach the emission goals. Those fuels range from hydrogen, hydrogen-based fuels such as methanol and ammonia, to nuclear-driven ships (Houtkoop et al., 2022). However, none of these fuels are a perfect match for maritime applications, as all have their drawbacks. Hydrogen has a low volumetric energy density and is extremely flammable (Van Rhee et al., 2023). Both methanol and ammonia are toxic. Additionally, methanol still generates carbon emissions, and ammonia is hard to combust (Van Rhee et al., 2023). Nuclear-powered ships currently refer to ships powered by fission reactors. While nuclear fission reactors are a proven technology, their use in commercial ships remains limited. Not only are nuclear-powered ships expensive, but the risks of meltdowns and long-lived radioactive waste have also slowed their adoption for marine power generation (Wang et al., 2023).

Nuclear fusion represents an alternative to nuclear fission, which can potentially mitigate many of the risks associated with conventional nuclear technology. While atoms are split in the nuclear fission process, the principle of nuclear fusion is to glue two atoms together. The most conventional form of nuclear fusion uses the deuterium–tritium (D–T) reaction:

From left to right, the fusion of a deuterium atom (a hydrogen atom with an extra neutron, also noted as hydrogen-2) with a tritium (a hydrogen atom with two extra neutrons, also noted as hydrogen-3) yields an alpha particle (a helium atom, also noted as helium-4), a neutron and 17.6 MeV of energy split amongst the reaction products (Freidberg, 2007). Deuterium (hydrogen-2) is stable, and can be found naturally. Conversely, tritium (hydrogen-3) has a half-life of 12.3 years and decays to helium-3 under beta minus emission (Bé et al., 2006). Tritium needs to be generated on-site through a second nuclear reaction: neutron capture of lithium-6 and lithium-7, the neutron being supplied by the D–T reaction (equation 1).

So the only fuel a fusion-powered ship would have to carry would be deuterium and lithium, two light-weight isotopes. A ship would require only little fuel to travel far because D–T fusion has an energy density of approximately 340E6 MJ/kg. Table 1 gives a comparison of the energy density of different fuels. Nuclear fusion fuels have the highest energy density. The difference in the energy densities of nuclear fusion and conventional marine diesel oil is extremely large. The amount of fuel that has to be bunkered for nuclear fusion is negligibly small compared to conventional fuels.

**Table 1:** Energy densities of different fuels (Freidberg, 2007; Aronietis et al., 2016)

Fuel	Energy density [MJ/kg]
Deuterium-tritium fusion	340 000 000
Fission (U-235)	88 000 000
Pure hydrogen	120
Heavy Fuel Oil	40

Nuclear fusion is an interesting ship fuel source, as it is safe, carbon-free and virtually inexhaustible. Ships powered by fusion would only need to be refuelled rarely and can thus have a higher up-time. Additionally, these ships would not only be carbon-free, but their only emissions would be helium, which is not considered a greenhouse gas or harmful. Moreover, fusion-driven ships would theoretically have a significantly larger range than fossil-fuel ships.

However, nuclear fusion is still under development. Currently, a reactor is being built in France, ITER, which aims to generate ten times more energy than is required to operate it. While ITER should hopefully be up and running by the late 2020s, it will be another fifteen years before it makes its first D–T fusion reactions (Lopes Cardozo, 2019). EUROfusion, the European fusion research consortium, aims to deploy the first European demonstration power plant (DEMO) by 2060 (Lopes Cardozo, 2019). An economy of scale will likely not be achievable before 2100 (Lopes Cardozo, 2019). These plans all focus on land-based fusion power plants. Nonetheless, looking at fusion reactors on ships is still interesting, especially since companies are already advocating for fusion power on ships (Lockheed Martin, n.d.; DNV, 2021). Lockheed Martin (n.d.) not only promotes fusion on ships, but they also deem it to be one of the first applications of so-called compact fusion. DNV (2021), on the other hand, have made a preliminary calculation of placing a fusion reactor on a ship, based on a reactor designed by General Fusion. It is likely, that the main motivation for placing nuclear fusion reactors on ships is the resulting large range, combined with low fuel costs and no carbon emissions.

This paper aims to get insight into the implications of putting a nuclear fusion reactor onboard a ship from a design perspective. For this study, we decided to place a selected nuclear power plant onboard an existing ship, which provides a certain base in dimensions, mission and requirements. The selection of this ship is based on its suitability and adaptability for a nuclear fusion power plant. To structure our thinking, we loosely performed one iteration of the design spiral (Evans, 1959). We did not assume this would yield an exhaustive overview of all the pros and cons of nuclear fusion on a ship. However, we did feel it would give sufficient scoping to our research.

This work is structured as follows. First, we describe the basics of nuclear fusion (Section "Basics of nuclear fusion"). This section describes the plant’s working process, basic design characteristics, and constraints. This theory is followed by an overview of design considerations and related challenges, loosely based on a first iteration of the design spiral (Section "Stepping Through Design Spiral"). The part "Mission and Owner Requirements" of this section contains the considerations regarding selecting a suitable vessel for our case study. The next section discusses scope boundary determination and overall design concept feasibility (Section "Discussion"). In conclusion, we provide an overview of the drawn conclusions and future research recommendations (Section "Conclusion and Outlook").

## BASICS OF NUCLEAR FUSION

Nuclear fusion of deuterium and tritium atoms does not readily take place. Under normal situations, the Coulomb force between the two nuclei – which are both positively charged – keeps them far apart. The nuclear force becomes dominant only when they get very close together. Then fusion can occur. Very high temperatures, on the order of several million Kelvins, are required for nuclei to brave the Coulomb barrier and for fusion to occur at all. At these temperatures, deuterium and tritium form a plasma: free electrons, deuterium ions, and tritium ions coexist in a gaseous state. Besides the temperature of the plasma, the number density is also important: if more deuterium and tritium are present, more reactions will occur. Finally, if we want to use fusion for net power generation, the plasma should be well enough insulated that the fusion power production offsets the thermal losses. A figure of merit that is often quoted in this context is the triple product  $n\tau_e T$ , where  $n$  is the number density,  $\tau_e$  is the energy confinement time – which is a measure of the insulation – and  $T$  is the temperature. Only when this triple product is larger than some value can a fusion reactor produce net power (Freidberg, 2007).

The main difficulty in achieving fusion on Earth is the energy confinement time  $\tau_e$ . The materials of the wall limit the temperature at the wall of a fusion reactor, while the inside of the plasma has to be in the order of 150 million Kelvins. This large temperature difference results in extremely steep temperature gradients. Such gradients drive thermal transport, which turns the question of insulating the plasma into a huge problem. Several methods have been proposed to tackle this issue, but magnetic confinement fusion (MCF) is the most conventionally accepted method. MCF uses the Lorentz force to constrict charged particles within specially designed magnetic fields, limiting the heat transfer from the plasma to the reactor wall by several orders of magnitude. The large magnetic fields required for MCF can only be achieved using superconducting magnets, which operate at very low temperatures (Freidberg, 2007).

MCF-based designs are toroidally shaped. The best-known torus is a doughnut. The size of a doughnut is determined by its minor radius  $a$ , i.e. the radius of the uncurved cylinder, and its major radius  $R_0$ , i.e. the distance from the doughnut's central hole to the middle of the curved cylinder. They come in two flavours, tokamaks and stellarators, but the details of what sets them apart do not factor into the present study. Most reactors, including ITER, are tokamaks. Figure 1 visually represents a tokamak. This part houses the plasma, the layer around it, and its main auxiliary components. It is called the vacuum vessel. A near vacuum inside the vessel exists because of the low density. The magnets are placed outside the vacuum vessel. Nowadays, tokamaks are closer to curved elliptic cylinders, meaning that  $a$  can be larger in the vertical direction than in the horizontal, which is referred to as elongation and denoted by  $\kappa$ . For more information on the basics of nuclear fusion, we refer to Freidberg (2007).

**Figure 1:** Representation of tokamak

Important for this study is that there exists a limit to how small toroidal reactors can become. This is caused by the choice of the D–T reaction on the one hand and the fact that MCF designs require superconducting magnets on the other. The D–T reaction produces a neutron with extremely high energy that, if it arrives at the superconducting magnet with sufficient en-

ergy, would quench the magnet, rendering the fusion reactor inoperable. These magnets are placed both on the inboard-side as well as on the outboard-side of the torus. To prevent quenching, the magnets are shielded by the blanket. The thickness of this shielding depends only on the shielding material and the energy of the neutron that it is meant to stop. The energy of the neutron is imposed by the D–T reaction (14.1 MeV, cf. equation 1) while other functions of the blanket impose constraints on the materials it can contain. As a result, the blanket will always have to be about a meter thick regardless of the reactor size (Freidberg, 2007), resulting in a minimal major radius and, thus, a minimal size of the torus.

More detailed 0D modelling based on plasma-physical considerations yields results that are largely in line with back-of-the-envelope reasoning. There is a strong coupling between the geometry of the reactor and the plasma performance, which means that not all parts of the design space are available. One cannot simply choose reactor size and power output. Using current-day superconducting magnet technologies (NbTi and Nb<sub>3</sub>Sn) and available plasma physics regimes, economically viable reactors would need a major radius  $R_0 = 8\text{--}9$  meters. Advanced superconducting magnet technologies like Rare-Earth Barium Copper Oxide (REBCO) might reduce  $R_0$  to 5 meters. Such reactors generate power well over the level that can be utilised by a single ship. To make economically viable tokamaks that are smaller still, like the Affordable, Robust, Compact (ARC) reactor (Sorbom et al., 2015), one would need more optimistic assumptions on the physics performance (Zohm, 2019).

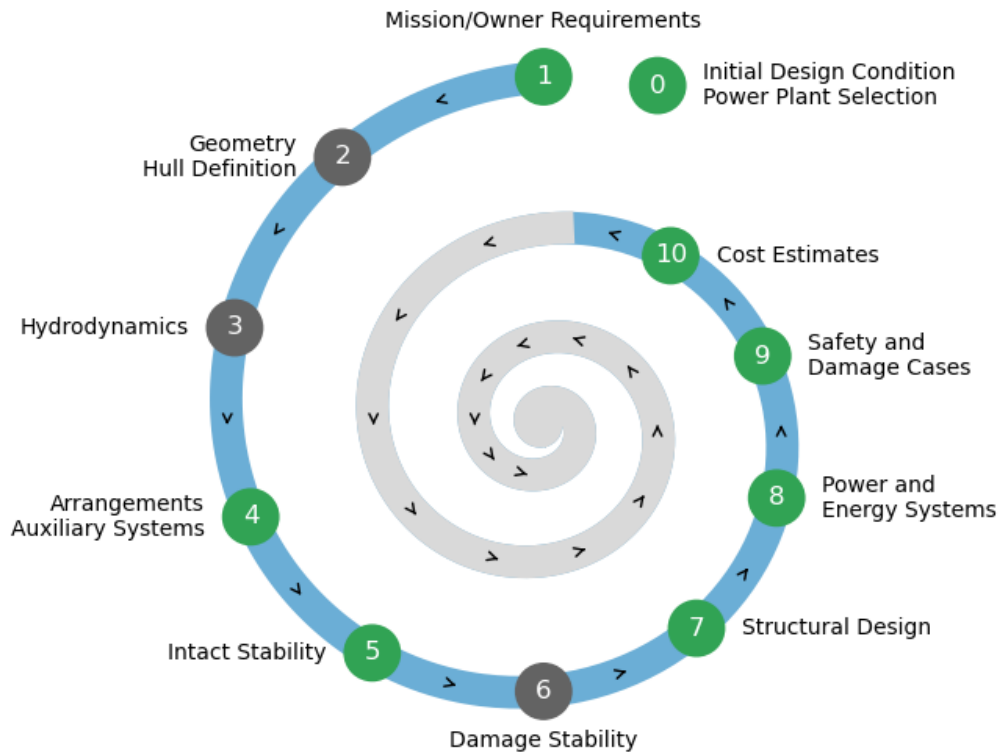

The concept of MCF could be disregarded completely, and alternative fusion concepts could be looked into. One that sometimes makes the news is inertial confinement fusion (ICF) using high-intensity lasers. While headway is being made (Betti & Hurricane, 2016) and ignition (a self-sustained fusion reaction) was even recently achieved (Osolin et al., 2023), it is unclear what an ICF-based power plant would look like. Then there is a host of more and less exotic designs that are championed by private industry. They often promise much shorter road maps to commercial reactors than presented in, e.g., the European road map (EUROfusion, 2018), but they usually rely on large technological breakthroughs. While such developments cannot be ruled out, they are far from certain. Although not much is known about the compact fusion concept for ship propulsion (Lockheed Martin, n.d.), we may assume that it will sit somewhere in this category. Alternatively, it might be a tokamak after all in which case all of considerations with regard to MCF apply to it.

In our opinion, ARC strikes a balance between being innovative enough to allow potential application on a ship – conventional fusion technology results in far too bulky machines – while being conservative enough – requiring limited technological development in some domains – to be deemed likely based on today’s available technology. It also aids the present work that a rather detailed design study is already available (Sorbom et al., 2015). The ARC reactor produces 525 MW of fusion power and has a total thermal power of 708 MWth. After considering thermal efficiency and recirculating power in the auxiliary systems, 190 MW net electric power is left. The vacuum vessel has a major radius  $R_0 = 3.1$  m, minor radius  $a = 1.1$  m and elongation  $\kappa = 1.84$ . The on-axis magnetic field, i.e. the field at  $r = 0$  where  $r$  runs from 0 to  $a$ , is 9.2 T while the peak on-coil magnetic field is 23 T. The entire reactor, excluding the balance of plant equipment, fits in as little as 1320 m<sup>3</sup>, weighs 7190 tonnes and would cost 5.5 billion dollars. In this study, we will work with rounded numbers for convenience and install a reactor that has dimensions  $10 \times 10 \times 10$  m<sup>3</sup>, a weight of 7000 metric tonnes and that produces 200 MWe net power.

## STEPPING THROUGH DESIGN SPIRAL

This study aims to provide a preliminary overview of the adjustments required and the feasibility of installing a fusion reactor as part of the ship power train. Therefore, all relevant aspects within the ship design process need to be addressed, as if the refit will take place in the near future. Several approaches to the ship design process exist, such as concurrent design (Sohlenius, 1992), set-based design (Doerry et al., 2014) or design-space exploration (de Vos, 2018). Since this study is not focused on design methodologies, one of the more basic design approaches is followed: an iterative design process following the design spiral as defined by Evans (1959). Since this study is, to our knowledge, the first paper on installing nuclear fission onboard a ship, developing a complete detailed design is considered unfeasible and premature at this moment. Therefore, following the six design stages as defined by Lamb (2003): (1) Concept Design, (2) Preliminary Design, (3) Contract Design, (4) Functional Design, (5) Transition Design, (6) Workstation/Zone Information Preparation, this study remains in the domain of concept or early-stage design.

**Figure 2:** Ship Design Spiral (Evans, 1959) adjusted showing the first (blue) iteration of the ship design process: the concept design phase. The green design aspects are considered within the scope of this study, and the grey design aspects are either considered to be more fitting in later design stages or considered less relevant within a retrofit design process. All aspects are reconsidered in secondary and tertiary iterations.

## Design spiral

In the design spiral representation of a design process (Figure 2), only a single iteration addressing the different design aspects is completed. Note that the power plant concept selection is considered "design aspect 0" for it is an initial requirement in the design process within this study.

### *Disregarded Ship Design Aspects*

Several of the design aspects are considered less relevant within this specific study. Some of these should be considered for later design phases, whereas others are generally less relevant for a retrofit. The hull form and by extension the hydrodynamics, for example, is assumed to remain rather constant. Therefore, this study does not consider the design aspects concerning hull lines, body plan, and Bonjean curves. The floodable length and freeboard calculations are considered unchanged as well. Thus, steps 2 and 3 from Figure 2 are left out in this study.

Damage stability refers to the case in which one or more watertight compartments have been damaged or breached, often caused by grounding (Costa Concordia) or collision (RMS Titanic). Stability considerations in these cases are a vital concept in guaranteeing the ship's overall safety. However, current knowledge on the Queen Mary 2 with a nuclear fusion power plant retrofit does not permit a thorough damage stability analysis.

# Mission and Owner Requirements

In this first step of the design spiral, the selection of a suitable case study is addressed. In the Theory Section, we described a lower limit to the power that can be generated by a fusion reactor of approximately 200 MWe. This is over the upper limit of the generators that drive the world’s biggest commercial ships and is only surpassed by the newest naval fission power plants (Sea Forces, n.d.). As a result, only very few use ships are potentially compatible with a fusion reactor based on power requirements. We decided to reverse-engineer the mission/owner requirements from existing vessels. To this end, we looked at various extremely large or powerful ships.

Table 2 gives an overview of very powerful ships. The most powerful ships are aircraft carriers. However, aircraft carriers are naval vessels that play a vital role in national defence. Information on these ships is thus minimal, which is why they are disregarded as reference ships for this study. Icebreakers demand high power and significant autonomy, making nuclear propulsion an interesting option. The most powerful icebreakers are propelled by nuclear power (Brigham, 2022.; Manaranche, 2021.). However, information about these Russian nuclear icebreakers is extremely limited. Thus, they are disregarded as reference ships for this study.

Current cruise ships are all optimized for high energy efficiency and comfortable travel. Their speed is less important, and they have a low power demand compared to their size (Thakkar, 2023). Ocean liners, however, are generally sailing faster. The fastest ocean liner, the SS United States, required 185MWe to set the record for the fastest crossing of the Atlantic Ocean in 1952. Due to the ship’s retirement, however, this ship is not considered. On the other hand, the second fastest ship was built more recently. The Queen Mary 2 is another ocean liner, with 117MWe installed power and top speeds of 30 knots. This ship was also featured in significant ships of 2003, the year she was delivered (Chanev, 2022.). Thus, the general arrangement and the power and propulsion layout of the Queen Mary 2 is known. Consequently, Queen Mary 2 was chosen as the reference ship for this study.

**Table 2:** Overview of powerful ships

Ship name	Ship type	Installed power	Power generation type	Source
Gerald R Ford	Aircraft carrier	600 MWe	Two nuclear reactors	(Sea Forces, n.d.)
Admiral Kuznetsov	Aircraft Carrier	150 MWe	Eight boilers, four steam turbines	(Naval Technology, 2021)
Charles de Gaulle	Aircraft Carrier	122 MWe	Two nuclear reactors	(Naval Technology, 2018)
Project 10510	Icebreaker	120 MWe	Nuclear reactor, planned	(Manaranche, 2021.)
Arktika	Icebreaker	60 MW shaft power	Nuclear reactor	(Brigham, 2022.)
Icon of the Seas (Largest cruise ship as of 2023)	Cruise ship	67.5MW	Six multi-fuel engines	(Thakkar, 2023)
SS United States	Ocean liner	185 MWe	Eight boilers, four steam turbines, ship retired	(Gibbs, 2021.)
Queen Mary 2	Ocean Liner	118 MWe	Diesel generators and gas turbines	(GE, 2017.; Chanev, 2022.)

The Queen Mary 2, visible in Figure 3, is the largest ocean liner ever built (Chanev, 2022.). It has a Combined Diesel Electric and Gas Turbine (CODEG) power plant layout, with four Wärtsilä diesel engines and two General Electric gas turbines (GE, 2017.; Chanev, 2022.). The diesel engines provide 16.8 MWe each, while the turbines provide 25 MWe each. The turbine sets, designed by GE, are about 35 tons lighter than similar turbines, resulting in more design freedom (GE, 2017.). The Queen Mary 2 has split engine rooms. The diesel engines are in one room, and the two gas turbines are in a different room (Cruise Industry News, 2004.). The power delivered by the power plant is used for propulsion, hotel, platform and auxiliary systems. The Queen Mary 2 has a small hospital with 11 beds. Its desalination plant can produce 2000 tons of fresh water daily. The garbage system requires heat of up to 1000 °C to burn trash (Chanev, 2022.). All these additional systems require energy, next to the energy needed for systems to keep the guests entertained. The ship currently takes up to 6 hours to fully bunker its fuel tanks (Chanev, 2022.). The Queen Mary 2 is 345m long, with a beam of 41m at the waterline (Chanev, 2022.). She is 72m high (including the funnel) and has a draft of 10m. The gross tonnage of the Queen Mary 2 is about 150000 GT. The block coefficient of the Queen Mary is 0.61 (Cruise Industry News, 2004.).

## Arrangements & Auxiliary Systems

The main consideration is adapting a standard diesel generator power plant with its related auxiliary systems into a fusion reactor power plant. Whereas the current systems of the selected vessel can be found in the ship's general arrangement (GA), such a list is less standardized for nuclear fusion plants. Therefore, land-based plants are assumed to provide sufficient information to estimate the required auxiliary systems' main dimensions on the concept design level.

The Queen Mary 2 has an integrated electric propulsion set-up featuring a CODEG plant layout, consisting of four diesel engines and two gas turbines (Chanev, 2022.). These engines, including their fuel, will not be required anymore when installing a fusion reactor. As a fusion reactor forms a single point of failure, an emergency generator set is advised that can generate sufficient power for emergency board systems such as fire fighting, communication and basic lighting. It is outside the scope of this paper to define the exact power required for these emergency systems. Next to removing three diesel engines and two gas turbines, the fuel tanks are not required anymore either. These fuel tanks can hold 3000 tonnes of fuel and are thus of significant size. As the ship is already operating on electric propulsion, this does not need to be changed; a fusion reactor produces electricity, too. The hotel systems are not expected nor required to change significantly. Therefore, the HVAC System, water desalination and distribution systems, and low-voltage electricity distribution systems remain intact.

Several additional auxiliary systems are required to keep a fusion reactor running. Some of these systems, such as the blanket and plasma diagnostics, are embedded inside the fusion reactor (Sorbom et al., 2015). Other fusion-specific auxiliary systems are not embedded into the system. Federici et al. (2017) estimates that the DEMO fusion power plant will need a tritium recovery plant, heating and current drive (H&CD) systems, control systems, a cryoplant and a vacuum system. Other auxiliary systems will be similar to those of fission power plants, such as the requirement of a secondary cooling system (Garcia et al., 2012; Lee et al., 2023). Table 3 gives an overview of the auxiliary systems and their estimated relative locations, while the estimated influence of removing the current engine room with ARC is visualised in figure 4 (Chanev, 2022.).

Auxiliary system	Location	Size
Cryoplant	Relatively close to power plant	Large
Tritium recovery plant	Relatively close to power plant	Small/medium
Heating and Current Drive	Next to reactor	Small
Control systems	Irrelevant	Medium
Vacuum system	Next to reactor	Small
Secondary cooling system	Close to reactor	Large
Turbines	Close to reactor	Medium

**Table 3:** Overview of auxiliary equipment and approximate locations of equipment

The cryoplant is significantly sized, as the cryoplant used in ITER will be approximately 6000m<sup>2</sup> with a maximum height of the buildings of 19m, excluding the storage required for storing the gaseous helium and liquid nitrogen (Fauve et al., 2017). In ITER, this cryoplant will require approximately 35 MW of electrical power to run. In contrast, the electrical power to run the cooling systems of ARC is estimated to be only 5.1 MW (Fauve et al., 2017; Sorbom et al., 2015). Despite this large difference, it is still assumed that the cryoplant will be the most significant auxiliary system. The cryopumps themselves will likely be small as the ITER exhaust pumping system will consist of 8 cryopumps (Day & Murdoch, 2008). A full-scale prototype torus cryopump has been developed by Day and Murdoch, which was 1.8m long and 1.6m in diameter. Next to the cryopumps, ITER also makes use of roughing pumps. These pumps themselves do not have to be located close to the reactor. In ITER, the vacuum systems are connected to a roughing pump in a vacuum pump room located 40m away from the torus (Day et al., 2004). Additionally, as there are only 8 pumps, the size they take up is considered to be relatively small. The tritium recovery plant is estimated to be small, especially if direct internal recycling is used (Day & Giegerich, 2013). The heating and current drive systems must be close to the main reactor. The size of these systems depends on their power and the choice of the system. For example, an ion cyclotron resonance heater capable of delivering 20 MW of power is approximately 14m<sup>3</sup> and weighs between 45 and 50 tonnes (Brans, 2020). As the external heating power for ARC is estimated to be approximately 25 MW, the size of this auxiliary system will be moderate. The control system is not fusion-specific, as fission reactors also need control systems. These systems do not have to be close to the reactor and can be distributed throughout the ship. They are also not expected to be extremely large. Comparison with the control system space in ITER is not likely useful, as this building in ITER will also be used as a visitor space next to ITER being a testing facility. The main control room of ITER will be able to house 60 to 80 people (ITER, 2023). The turbines are not specific to fusion-driven ships and are expected to be of medium size, similar to current turbines (No, Kim, & KIM, 2007; Houtkoop et al., 2022).

## Intact stability

In this subsection, we consider the static stability effects of putting a nuclear fusion power plant onboard a ship. We study the effect of adding the reactor on the ship's draft and analyse the freedom in placing the reactor in terms of trim. We use the ship's length  $L_{OA} = 345\text{m}$ , width  $B = 41\text{m}$ , height  $H = 62\text{m}$  (including funnel  $H_{total} = 72\text{m}$ ), draft  $D = 10\text{m}$ , displacement  $\Delta = 79287\text{tonnes}$  and block coefficient  $C_B = 0.61[-]$ , combined with the sea water density  $\rho_{sw} = 1025\text{kg/m}^3$  and gravitational constant  $g = 9.81\text{m/s}^2$ . Figure 4 gives an overview of the main dimensions of the Queen Mary 2. The length at the waterline  $L_{WL}$  is calculated based on the given displacement and block coefficient:

$$L_{WL} = \frac{\Delta}{B \cdot D \cdot C_B \cdot \rho_{sw}} = 309[\text{m}] \quad (2)$$

**Figure 4:** Schematic side view showing the main dimensions of Queen Mary 2 as well as the current location of the engine room approximately to scale. The tokamak building of the fusion reactor has been drawn, again to scale, inside this engine room to indicate that it would fit.

The fusion plant has a mass  $m$  of 7000 tonnes and is regarded as a point mass, due to its relatively small volume  $V_m = 10 \times 10 \times 10 = 1000 \text{ m}^3$ . In our calculations, we use dimensions as shown in Figure 4 and use the following notation:

$$\begin{array}{lll}
 K_z & 0 & [\text{m}] \\
 K_{0,y} = B_{0,y} = G_{0,y} & 0 & [\text{m}] \\
 G_{0,z}, G_{1,z} & \frac{KG_0, KG_1}{G_{1,y} - G_{0,y}} & [\text{m}] \\
 y & \frac{G_{1,y} - G_{0,y}}{KG_1 - KG_0} & [\text{m}] \\
 z & \frac{KG_1 - KG_0}{\Delta_m} & [\text{m}] \\
 M & \Delta_m & [\text{kg}]
 \end{array} \quad (3)$$

### Draft

The change in draft is a relative simple calculation once the waterline area is known. We assume that the waterline area is

$$A_{WL} = L_{WL} \cdot B \cdot C_B^{2/3} [\text{m}^2]. \quad (4)$$

Where the block coefficient is adjusted to not take the draft into consideration. This gives us the difference in draft  $\delta D$  and the new draft  $D_m$ , which are

$$\begin{aligned}
 \nabla_m &= \frac{m}{\rho_{sw}} \quad [\text{m}^3], \\
 \delta D &= \frac{\nabla_m}{A_{WL}} \quad [\text{m}], \\
 D_m &= D + \delta D = 10.75 \quad [\text{m}].
 \end{aligned} \quad (5)$$

This draft does not take the reduced mass by removing the fuels of the ship into consideration. If we address this reduced mass,  $m_{fuel}$  of 3000 tonnes, the new draft  $D_1$  becomes 10.43m. Based on visual inspection of the ship's hull shape, this change in draft is not expected to change the waterline area markedly. It has, therefore, limited effects on the ship's stability.

### Center of Gravity Height

The ship's current centre of gravity (CoG) has not been explicitly mentioned in the studied literature. Therefore, we calculate its location based on the three assumptions. First, we assume that the spaces below the waterline are mainly technical spaces. Second, that technical spaces have double the density of the hotel spaces. Third, that the block coefficient and main dimensions determine the volume below the waterline, while the volume above the waterline consists of two blocks that

represent the part of the hull above water and the superstructure (see Figure 4). Therefore, we find

$$\begin{aligned}
M_{AWL} &= V_{AWL} \cdot \rho_{AWL} & [\text{tonnes}], \\
M_{BWL} &= V_{BWL} \cdot \rho_{BWL} = V_{BWL} \cdot 2\rho_{BWL} & [\text{tonnes}], \\
\overline{KG}_{tot} &= \frac{M_{AWL} \cdot \overline{KG}_{AWL} + M_{BWL} \cdot \overline{KG}_{BWL}}{M} = 21 & [\text{m}].
\end{aligned} \tag{6}$$

Here, subscript  $_{AWL}$  refers to the volume  $V$  and mass  $M$  above waterline and  $_{BWL}$  the submerged mass and volume. This gives the original CoG  $\overline{KG}$  as 21m. It is known amongst ship designers that adding mass above the CoG leads to less stability, whilst adding mass below CoG increases the ship's stability. If, however,  $\overline{KG}$  is too large, the ship's overall level of comfort reduces due to its movement. Therefore, placing the plant in the lower part of the hull but not in a fully submerged area is recommended.

### Trim

The trim caused by placing the reactor at any other place than the CoG requires additional ballast (water) to be present at all times. Since this would lead to a certain increase in draft, it also causes an increased resistance. Therefore, this design aspect is chosen so that the maximum angle caused by the presence of the reactor is 5° degree. This degree can still be considered a "small angle" and is sometimes described as the angle of comfort: a larger angle would reduce comfort levels for the cruise passengers. All calculations regarding trim follow from (Moore, 2010), where  $GM$  is the difference between the center of gravity and the metacentric height. First, we calculate the maximum deviation in transverse direction ( $y$ -axis), which yields

$$\begin{aligned}
\overline{GM} &= \overline{KB} + \overline{BM} - \overline{KG} \simeq \frac{D}{2} + \frac{I_T}{\nabla} - \overline{KG} = 6.72 & [\text{m}], \\
\frac{y_{max} \cdot m}{M + m} &= \overline{GM} \sin(\phi_{max}) & [\text{m}], \\
|y_{max}| &= \overline{GM} \sin(\phi_{max}) \left(1 + \frac{M}{m}\right) = 7.22 & [\text{m}].
\end{aligned} \tag{7}$$

Next, we calculate the maximum deviation in the longitudinal direction ( $x$ -axis), which yields

$$\begin{aligned}
\overline{GM}_L &= \overline{KB} + \overline{BM}_L - \overline{KG} \simeq \frac{D}{2} + \frac{I_L}{\nabla} - \overline{KG} = 1291 & [\text{m}], \\
|x_{max}| &= \overline{GM}_L \sin(\phi_{max}) \left(1 + \frac{M}{m}\right) = 1386 & [\text{m}].
\end{aligned} \tag{8}$$

Both values do not instantly constrain the placement of a reactor onboard the Queen Mary 2. It is self-explanatory that the location is more limited than the location of fuels onboard, but we consider the available positions to be within acceptable limits. In line with Payne et al. (2005), having a maximum longitudinal location of  $|x_{max}| = 1386\text{m}$  off-centre suggests that longitudinal stability, also in the case of head waves, is not a major issue for this ship.

### Structural Design

Nuclear fusion reactors are known for their high density, with ARC weighing over 7000 tonnes with a volume of  $V_{reactor} = 10 \times 10 \times 10\text{m}^3$ . This gives the entire reactor a density  $\rho_{reactor}$  of  $7000 \frac{\text{kg}}{\text{m}^3}$  and is equivalent to adding a solid block of lead of over  $600\text{m}^3$  near the heart of the ship. Structurally, we do not consider this mass to be a critical point within the design considerations.

A second consideration are the mechanical vibrations. Power spectra on a ship might differ considerably from those observed on land. In a first-order approximation, let us only consider the one-way couplings: ship-to-reactor vibrations and reactor-to-ship vibrations. Ship-to-reactor vibrations may come either from the ship itself or the interaction between the ship and its environment. Regarding the former, Van Dokkum (2005) identifies the two most common onboard sources of vibrations as the propellers and the engine. In the QM2 case, only the propellers survive the retrofit. Regarding the latter, wave-induced resonance-based vibrations like springing and whipping must be accounted for, as well as the potentially exacerbating effects of heavy weather. A perusal of the literature did not, in fact, yield a starting point for assessing the consequences of such ship-to-reactor vibrations outside of one. Land-based reactor designs consider the effect of seismic activity (also discussed in the ITER Preliminary Safety Report (Taylor et al., 2009)) on the structure of and components in the tokamak building (Ushigusa et al., 2000; Sorin, Barabaschi, & Sannazzaro, 2003), and ways of mitigating these via seismic pads (Syed et al., 2014). However, these studies do not seem principally interested in the reactor operation under vibrations but rather whether the structure would survive. This indicates that external vibrations do not seem top-of-mind in the operation of a fusion reactor. For the plasma itself, this makes sense in that it needs to be actively controlled for a large range of frequencies anyway.

Moving to reactor-to-ship vibrations, the story is quite different. While there are no large moving parts in a fusion reactor (hence no large vibrations during routine operation) and the thermal content of the plasma is negligible, there are large currents and magnetic forces at play. Failure modes that tap into these represent a serious risk. Plasma disruptions, Edge-Localised Modes (ELMs) and Vertical Displacement Events (VDEs) are to be avoided for various reasons (Hassanein, Sizyuk, & Ulrickson, 2008), but the mechanical stresses that they cause are certainly among them. In terms of mechanical stresses, the worst-case scenario is a VDE. For ITER, symmetric VDEs are expected to result in vertical forces on the reactor structure up to around 100 MN, while asymmetric VDEs result in horizontal forces up to 50 MN. While the vibrations that these cause in the ship will depend on the power spectra of these events – which are beyond the scope of this work – such vibrations are perhaps subordinate to the instantaneous mechanical stresses that VDEs cause in the ship's structure. Making a back-of-the-envelope estimation, a vertical force of 100 MN is equal to a weight of 10,000 tonnes. As a reactor weighs about 7000 tonnes, this amounts to a weight increase of +150%. While it is not clear how VDE forces in ITER translate to ARC (although they are similar in terms of fusion power) and the ship's structural material response to transient forces is not necessarily the same as to constant forces, this does indicate that the structural requirements need to take such failure modes into account.

Assuming that we design the ship to withstand these transient loads, it would seem that one-way coupled effects, both ship-to-reactor and from reactor-to-ship, are not showstoppers per se. It remains the case, however, that both fusion reactors and ships have eigenmodes that are best avoided. For example, the coil system of ITER has an eigenfrequency at around 1.5 Hz (Ushigusa et al., 2000). Designing ships such that they do not resonate at certain frequencies is already a complex issue (Kianejad et al., 2020) and adding a tokamak on board introduces a host of extra eigen frequencies that need to be taken into consideration. Two-way-coupled effects will start playing a role here: we want to prevent characteristic frequencies of the ship from exciting those of the tokamak and vice versa. Tackling such resonances would seem to be a challenge in the ship design. Further research in this area would be recommended.

Finally, damage stability is already considered outside the scope of this study. However, preventing the case where damage stability is required can be considered. Queen Mary 2 currently has a double hull for strength and collision protection, having a second function as storage space for fluids like ballast water and fuel. If the retrofit permits changing this structure, the "Y-Scheldehuid" could be considered as an alternative (Roller, 2012). This hull type, based on Y-shaped stiffeners, reduces the chance of crack formation in case of a collision. This hull type cannot prevent damage to the reactor resulting from the impact but might improve ecological preservation.

## Powering and Energy Systems

The Queen Mary 2 has an installed power of 118 MWe, but it does not often use its full power. Payne et al. (2005) investigated several scenarios, ranging from constant power and accepting delays to using more power to recover delays. In all of these scenarios, the engines were mostly run at 60% or less. Engine usage of 60 to 80% was used in three of the four sce-

narios, and engine usages above 80% were very limited (Payne et al., 2005).

ARC, on the other hand, produces approximately 200 MW of electrical power available for the ship (Sorborn et al., 2015). Fusion and fission reactors are similar because they provide a large amount of high-quality heat. On fission-powered ships, a direct drive from the gas turbine to the shaft can be used to minimize conversion power losses (Houtkoop et al., 2022). Thus, a fusion reactor could also be coupled with a direct drive. It is estimated that this results in a system which is approximately 5% more efficient than using electrical power only. However, direct drive is disregarded here for several reasons. First of all, the Queen Mary 2 currently operates a full electric system and four azimuth thrusters for propulsion (Chanev, 2022.). Installing direct drive would result in significant changes in the propulsion system.

Secondly, a direct drive from the fusion reactor to the shaft results in more unnecessary power sources on board. When looking at the general arrangements, two turbines are required to transfer energy from the fusion reactor to electricity or the shaft. One or two backup engines are also required depending on the arrangement (Houtkoop et al., 2022). If an all-electric backup is chosen, only one backup engine is needed; otherwise, an additional one is necessary. Without direct drive, only one turbine is needed, and with an all-electric system, only one backup engine is required, resulting in two power sources instead of three or four. So the system becomes more complicated when using direct drive.

Finally, the Queen Mary 2 only requires 118 MWe at peak moments but usually requires around 75 MWe. It is not straightforward to reduce the power output of a fusion reactor, because of complex interplay of plasma parameters, which was also discussed in the context of reactor size (cf. Section "Basics of nuclear fusion") ("The resilience of an operating point for a fusion power plant", 2015)<sup>1</sup>. A system optimized for energy efficiency is thus not necessary. However, in port lower power requirements are often in place. A useful approach to overcome this challenge would be ship-to-shore-power, which is feasible in case of an ocean liner only visiting a limited number of ports. On the other hand, a reliable electrical system is needed regardless for the hotel load. If the power surplus is to be used to charge batteries, create conventional fuels using the Fischer–Tropsch process or create hydrogen, an electrical system is needed. Thus, an electrical system results in more desirable flexibility of the system.

## Safety and Damage Cases

Novel damage cases occurring on ships are hard to qualify or quantify exactly. Consequently, we will explore a non-exhaustive list of situations unique to ships that may influence fusion reactors and assess their potential impact on a fusion reactor. While crucial in the design of a ship, a traditional damaged stability analysis is far beyond the scope of this conference paper. However, a crude conceptual analysis is possible assuming the fusion reactor does not affect the rest of the ship in terms of safety and damage cases. Under that assumption, the only novel damage cases are those inherent to the fusion reactor design and those arising from putting that reactor on board a ship.

To understand the specific risks associated with a fusion reactor, we looked at a summary of the Preliminary Safety Analysis Report for ITER (Taylor et al., 2009). In this summary, it is described that the two main fusion-specific safety functions of ITER relate to the confinement of radioactive material and the limitation of exposure to ionising radiation. While ITER is an experiment and will not be used to generate electricity, at 500 MW of fusion power, it is in the same ballpark as ARC. Two risks that are not present in fusion reactors, as opposed to fission reactors, are runaway thermal reactions (meltdown) and proliferation. Other safety concerns exist, of course, but those are of the conventional types associated with large industrial facilities.

### *Worst-case: Confinement of Radioactive Waste in Case of Sinking*

The current design phase does not consider the detailed effects of a ship sinking due to the complexity of predicting the outcome. Several factors significantly influence the consequences, including the specific design of watertight compartments

---

<sup>1</sup>This would clearly pose a challenge for vessel types with times of low or even no propulsion whilst at sea.

and bulkheads, the fusion reactor's location, and its compartment's size and contents. Additionally, the specific location of the sinking event itself can further impact the situation. It's important to note that while fission is considered a viable option for some ships, the potential consequences of a sinking event involving a fusion reactor are not necessarily deemed significantly worse. However, further research is necessary to fully understand the impact due to the numerous and unpredictable factors involved.

In this research, we only look at what could happen to the radioactive materials in case of a sinking. The confinement of radioactive material is probably the most pressing question in this case. Perfect safety cannot be guaranteed, and it stands to reason that incidents will happen. In 2001, IAEA released a tech doc listing the release rates due to wrecks that resulted from past marine accidents (*Inventory of Accidents and Losses at Sea Involving Radioactive Material*, 2001). Fusion reactors do not produce much long-lived radioactive waste compared to fission reactors, and much of that waste is locked into the structure – the vacuum vessel and components behind it are neutron-activated – so that the radioactivity cannot escape all at once. Besides activated structures, there is operational waste, the coolant may be activated and part of the fuel (tritium) is radioactive.

The operational waste for ITER is estimated at, at some 200 tonnes/year (Taylor et al., 2009). Only 5% of this is expected to be non-short-lived waste. It stands to reason that this waste can be stored such that it will not be released all at once in the case of an accident. For ARC, there is the additional consideration of FLiBe, which is used as coolant (as opposed to ITER, which uses water). However, FLiBe solidifies below 732 K (Sorbom et al., 2015), so we assume that it will be solid on the sea bed. Moreover, activity in FLiBe dies out rather quickly (Bocci et al., 2020). If it can be contained for a year, it does not pose a radiological risk afterwards (but it might still pose a chemical risk).

Finally, there is the question of the fuel. While deuterium is stable and naturally present in the sea, tritium is radioactive. The total amount of tritium in the plasma is negligible. For a fusion reactor of the size of ARC (with a plasma density of  $n_e = 1.3 \times 10^{20} \text{ m}^{-3}$  and a plasma volume of  $141 \text{ m}^3$ ), the weight of the plasma is approximately 0.07 grams as can be seen from the simple calculation

$$m = n_e V m_a = 1.3E20[\text{m}^{-3}] \cdot 141[\text{m}^3] \cdot \frac{2+3}{2} \cdot 1.66E-24\text{g} = 0.07[\text{g}] \quad (9)$$

with  $m$  in kg,  $n_e$  in  $\text{m}^{-3}$ ,  $V$  in  $\text{m}^3$ ,  $m_a$  in u. However, there are orders of magnitude more tritium in the rest of the fusion system, mainly in the tritium recovery. The exact amount depends on, amongst others, the burn-up fraction and the throughput time. Our previous research showed for a burn-up fraction of 5%, a total tritium inventory of approximately 1 to 2kg per GW of fusion power, including an emergency inventory (Van Rheen, 2021). The overall inventory can be as low as 500 grams per GW of fusion power without the emergency inventory. As ARC has a fusion power of 500 MW, the expected total tritium inventory is approximately 1 kg. At a specific activity of  $358 \text{ TBq g}^{-1}$ , this means that a total source term of  $358 \text{ PBq}$  radioactivity is present. This is on the order of the total amount of tritium that has been released by the Le Hague reprocessing plant over the last thirty years (Bailly du Bois et al., 2020).

Whether this tritium source term is problematic depends strongly on how it is released, but that it is significant can be seen using a back-of-the-envelope approach. Regulatory recommendations for tritium in drinking water range from 30 kBq/L to 100 Bq/L (Dingwall et al., 2011). Taking these recommendations, we can calculate the equivalent bodies of water in which 358 PBq needs to be homogeneously dissolved to be compliant. For 30 kBq/L that would be  $12 \text{ km}^3$ , and for 100 Bq/L  $3580 \text{ km}^3$ . Of course, much depends on the mixing properties of the ocean. A surface release will disperse very differently than a release at depth. When the ship would sink in shallow water, and assuming a mixing depth of 100 m (D'Asaro, 2014), the tritium would have to spread over  $2000 \text{ km}$  by  $2000 \text{ km}$  to stay under 100 Bq/L or  $10 \text{ km}$  by  $10 \text{ km}$  to stay under 30 kBq/L. A very crude estimate of how far the effects range can be made using an analogy from atmospheric dispersion physics (Stockie, 2011). Assuming a Gaussian puff (a conservative approach, which assumes that the entire inventory is released as a single puff) and a horizontal eddy diffusivity on the order of  $5\text{--}20 \text{ m}^2\text{s}^{-1}$  (Döös & Engqvist, 2007), the distance that the puff needs to travel from the release point ranges between  $500 \text{ km}$  to  $2000 \text{ km}$  to go under the 30 kBq/L limit, and much further to go under 100 Bq/L. This tritium inventory thus poses a potential hazard to the environment, and suitable measures must be taken to ensure that it is not released to the environment in case the worst happens.

What the sinking of a fusion-driven ship would ultimately do to local and regional marine life and to human activities in

the area is too complex to answer in this conference paper. Taking a broader perspective, we feel that recommendations would need to be put into place, preferably at an international level by the IAEA, regarding the licensing of fusion reactors on ships. However, such policies at the moment appear insufficient even for conventional nuclear reactors on board ships (Wang et al., 2023).

### ***Reactor Safety Risks caused by Motions of Vessels in Waves***

A major difference between a fusion reactor based on a ship, contrary to on land, is the movements of a ship. As a ship moves in waves, the fusion reactor will also experience these movements. As the plasma has a very low density and is contained by magnets, we believe that the influence of the movement on the plasma itself may be negligible. These magnets, however, are suspended in concrete and may be influenced by ship motions. All auxiliary components, too, must be designed to withstand ship motions and movements. Placing the reactor at a height such that  $\overline{GM}$  is positive but relatively small diminishes the ship's accelerations, possibly reducing the motions' influence on the reactor.

### **Cost Estimate**

Capital expenditure (CAPEX) and operational expenditure (OPEX) costs of a fusion reactor are expected to change over time. The first fusion reactors will likely be significantly more expensive than later generations, the difference is estimated to be over a factor of 2 for small reactors (Lopes Cardozo, 2019; Lindley et al., 2023). Additionally, small, ARC-like reactors are estimated to be approximately 2.11 to 2.31 times relatively more expensive than larger, conventional fusion reactors (Lindley et al., 2023). Sorbom et al. have made an estimate for the CAPEX costs of ARC, which would lie at 428M USD for the materials, and a total fabrication cost of 5.56B USD. A nuclear fission reactor of a similar size would cost approximately 1.2B USD. The costs of building the Queen Mary 2 were approximately 780 million USD, in 2002 (Keck, 2003.). Thus, a fusion reactor of the size of ARC is approximately 7 times more expensive than the Queen Mary 2, while a fission reactor is only 1.5 times more expensive.

The operational costs are more difficult to estimate. Fuel costs are only a small part of the operational costs, estimated for a demonstration fusion reactor (DEMO2) to be 0.44 USD/MWh, only 1% of the total electricity cost (Entler et al., 2018). The total cost of electricity is estimated to be around 60 USD/MWh. The main part of the cost of electricity consists of the depreciation costs (57%), replaceable components (23%) and operation and maintenance (17%). The first of these costs, the depreciation costs, are likely to become much lower over time, as these are related to the CAPEX costs (Entler et al., 2018). To compare this with fission costs, the energy cost for a fission reactor is approximately 136 USD/MWh and is estimated to be around 99 USD/MWh in the future (Lindley et al., 2023). Thus, no overall cost estimate can be made due to the uncertainty of the operational costs. However, a nuclear fusion reactor's investment costs will be extremely high, both compared to fission reactors and to the overall cost of the ship in general.

## **DISCUSSION**

Table 4 summarizes various aspects, data availability, and impacts of using fusion for ship propulsion from this research's design spiral. Drawing definitive conclusions based on the table is hindered by insufficient data for several aspects. Nevertheless, the available information highlights potential challenges with utilizing fusion as a ship's power source.

Two of the aspects were estimated to have a problematic influence on adding a fusion reactor as a power source on a ship. These aspects are matching the power supply and demand for the mission and owner requirements and the cost estimates. A fusion reactor will likely be too powerful and expensive for commercial ships. The influence on the arrangements and auxiliary systems, structural design and safety and damage cases all require additional data to estimate the influence of these aspects. Our first results show that the arrangements and auxiliary systems may not be problematic. Nothing can be said about the structural design and safety and damage cases with any certainty, as these aspects are too complex to estimate

Aspect	Availability Data	Estimated influence
Mission/Owner requirements	Sufficient	Problematic due to mismatch output power fusion reactor and required power ship
Arrangements/ Auxiliary systems	Insufficient	Not enough data, but does not seem to be problematic
Intact stability	Sufficient	Not a problem
Structural design	Insufficient	Adding a fusion reactor is likely to influence this Exact influence unclear
Powering	Sufficient	Additional power problematic, rest of system not a problem
Safety and damage cases	Insufficient	General safety too complex, more information required
Cost estimate	Sufficient	Likely too expensive for commercial application
Nuclear fusion power plant	Sufficient	Technology Readiness Level still too low for commercial application

**Table 4:** Summarizing table

their influence. The powering itself will, except for the large surplus of power, probably not form any large problems. Additionally, the fusion reactor can be placed in the ship without compromising the intact stability.

While this single iteration of the adjusted design spiral provided valuable insights, its scope is limited, and additional considerations are crucial. We highlight two such issues, acknowledging there are likely others to explore.

Constructing a vessel to meet specific power needs does not resolve the surplus power problem. An additional problem with fusion reactors is their constant power output, whereas conventional engines and fission reactors can adjust based on demand. Complex control systems with batteries or storage solutions are necessary to bridge this gap.

Additionally, current fusion reactor designs anticipate the need for regular significant maintenance activities. A component called the diverter, amongst others, has to be replaced every 2 years. As the diverter is in the centre of the reactor, this replacement process is believed to take 3 months. Maintenance will thus significantly influence the ship's operational time. This poses a major challenge for sectors that prioritize high availability, such as cruise ships and ocean liners.

## CONCLUSION AND OUTLOOK

While nuclear fusion holds the potential to offer ships a virtually limitless energy source, its practical application remains distant. Despite this, this paper aims to identify specific challenges of implementing fusion technology on ships by exploring the influence of placing the fusion reactor ARC on the most powerful, commercial, available ship, the Queen Mary 2. Several factors have the potential to become critical roadblocks.

The minimum power output of an MCF fusion reactor, around 200 MWe, poses a challenge for its application in commercial shipping. While naval vessels may require such high power levels, current commercial ships operate at most with a maximum required power of about 120 MWe. This mismatch necessitates a significant increase in commercial shipping's power demands or the exploration of alternative applications for the surplus energy such as green fuel production. Additionally, a fusion reactor will likely require significant maintenance every two years, which poses a major challenge for

commercial ships focusing on high availabilities. Next to the power mismatch, deploying a fusion reactor on a ship introduces additional complexities. The influence of the ship's motions and vibrations on a fusion reactor is not trivial and could significantly influence the design and the working mechanisms of the fusion reactor. Researching these influences is crucial to determine potential mitigation strategies and the feasibility of a fusion reactor on a ship. Besides, placing a fusion reactor onboard a ship, a floating platform in the middle of the ocean, will result in safety and damage cases that have never been considered before. Because of the risks associated with nuclear materials, these safety and damage cases must be thoroughly addressed. The financial feasibility of a fusion reactor on a ship is a significant concern. A fusion reactor will be significantly more expensive than a fission reactor and additionally more expensive than the ship itself, as the estimated costs are 7 times more expensive than the Queen Mary 2.

Therefore, addressing these factors is crucial for fusion deployment onboard ships. Each of these factors may prove to be prohibitive to the use of fusion power on ships. While the idea of fusion on ships is captivating, its realization in the near (before 2100) future or with current technologies, appears unlikely. At least, these conclusions are true for 'conventional' fusion technology, i.e., those concepts based on magnetic confinement fusion (MCF). While more exotic, future fusion technologies might turn out to be the holy grail of ship propulsion, we believe it for the best that the nuclear fusion community should first vet such concepts.

With the current status of the technology behind nuclear fusion, using it as a power source on ships seems far-fetched. However, this research failed to present a single point of failure regarding the application of nuclear fusion onboard ships. Thus, only time will tell whether fusion will in the far future be used on ships.

# Ship system design changes for the transition to hydrogen carriers

E.S. van Rheenen<sup>1,\*</sup>, J.T. Padding<sup>2</sup>, A.A. Kana<sup>1</sup> and K. Visser<sup>1</sup>

## ABSTRACT

*Reducing the use of fossil fuels in shipping requires new, alternative maritime fuels. Hydrogen carriers offer a safe and energy-dense solution for storing hydrogen, a zero-emission alternative fuel. This research focuses on ammonia borane,  $\text{NaBH}_4$ , *n*-ethylcarbazole and dibenzyltoluene. Applying hydrogen carriers influences ship design significantly, as they require additional specialised equipment to remove hydrogen from the hydrogen carrier. This research estimates the size of the equipment. As this equipment will need to be stored and maintained on the ship, the exact sizing and sequence of the additional equipment will likely influence ship design. Results show that the reactor size is significant for all hydrogen carriers. The mixing tank is considerably sized for  $\text{NaBH}_4$  and ammonia borane, while the heat exchangers are large for dibenzyltoluene and *n*-ethylcarbazole.*

## KEY WORDS

Hydrogen carriers; Heat exchangers; Dehydrogenation; Solid hydrogen carrier; LOHC

## INTRODUCTION

Reducing fossil fuels in shipping requires new, alternative maritime fuels. However, applying alternative power sources can have significant implications for ship design and is thus extensively researched, mainly focusing on using ammonia or methanol as alternative fuel (Pawling et al., 2022; Souflis-Rigas et al., 2023; de Vos et al., 2022). Hydrogen is another of these alternative fuels, but it has a low volumetric energy density. Hydrogen carriers offer a safe and energy-dense solution for storing hydrogen, a zero-emission alternative fuel (van Rheenen, Padding, Slootweg, & Visser, 2023). Using hydrogen carriers will significantly influence the ship's power plant and, consequently, ship design, as additional components such as hydrogen release reactors are required. Additionally, these reactors cannot be placed everywhere on the ship, as they produce pure hydrogen and thus need to be in regulated and well-ventilated spaces. Besides the reactor, more components, such as heat exchangers, may be necessary. All these additional components that are required to release hydrogen from hydrogen carriers are components that are not necessary without hydrogen carriers. So, using hydrogen carriers may result in more components and, thus, more complexity.

As these additional components are of unknown size, it is unclear whether they are significantly sized to influence ship design. For other alternative fuels, such as methanol or LNG, it is clear that the additional components will influence ship design (Souflis-Rigas et al., 2023; de Vos et al., 2022). Research focuses on resulting required design changes because of the space other components take up (Souflis-Rigas et al., 2023; de Vos et al., 2022). However, the number of components

explicitly needed for hydrogen carriers as power sources, and the size of these specific components are unknown. The sequence, size, and number of this specialised hydrogen carrier equipment are required to see how they influence and perhaps limit ship design.

Our previous research identified a promising set of hydrogen carriers for use as alternative fuels on ships (van Rheenen, Padding, Sloodweg, & Visser, 2023). The most promising ones were sodium borohydride ( $\text{NaBH}_4$ ), potassium borohydride ( $\text{KBH}_4$ ), ammonia borane ( $\text{NH}_3\text{BH}_3$ ), n-ethylcarbazole (NEC), and dibenzyltoluene (DBT). Next, we developed a 0D thermodynamic model to evaluate the effective energy density of these hydrogen carriers in combination with various energy converters (van Rheenen, Padding, & Visser, 2023). The energy converters were a proton exchange fuel cell (PEMFC), solid oxide fuel cell (SOFC), hydrogen-powered internal combustion engine (ICE) and gas turbine (GT). Integration of the carrier with the energy converter is crucial to calculate the overall energy density. Heat integration can minimise losses, particularly for DBT and NEC, which require heat during the hydrogen release process. Findings from the model suggest that these hydrogen carriers hold significant promise as alternative fuels. However, the 0D model does not account for geometrical parameters or the ship's sizing restrictions.

Thus, this paper aims to identify and size the relevant components when using the hydrogen carriers mentioned earlier as power sources onboard ships. First, all the required components for each hydrogen carrier must be known. Only the specifically relevant components for hydrogen carriers are considered; general equipment for hydrogen-fueled ships is not regarded. Each of these components will then be sized. This will form a first step in designing hydrogen carrier-powered ships.

## BACKGROUND

Sodiumborohydride, ammonia borane, N-ethylcarbazole and dibenzyltoluene are considered in this research. Table 1 gives an overview of the relevant parameters of these hydrogen carriers. As energy converters, same as in the previous model, the ICE, GT, PEMFC and SOFC are considered (van Rheenen, Padding, & Visser, 2023).

## Hydrogen carriers

The hydrogen carriers will be divided into endothermic and exothermic release hydrogen carriers. Within these groups, the processes and, thus, the required equipment are very similar. The phase, energy density and energy requirements are also similar. All processes occur at relatively low pressures, around 1 to 10 bars; thus, specialised high-pressure equipment is unnecessary.

### *Endothermic release*

The endothermic release hydrogen carriers are NEC and DBT. Both are liquid organic hydrogen carriers (LOHCs). The release mechanism for the LOHCs is very similar and is as follows:

The significant difference is the temperatures at which they react and the heat required for dehydrogenation. DBT's dehydrogenation temperature lies between 553 and 593K; temperatures above 573K are required to reach full dehydrogenation, while DBT will start dissociating at temperatures above 563K. A temperature of 573K is chosen in the model, as this temperature is often used in experiments, and full dehydrogenation can be achieved without compromising the fluid too much (Asif et al., 2021). The dehydrogenation process requires 558 kJ/mol of full LOHC (Niermann et al., 2019). The dehydrogenation temperature for NEC lies between 453 and 523K. The dehydrogenation process is much slower at lower temperatures. The model uses a temperature of 503K. The dehydrogenation process is fast at this temperature, without having

**Table 1:** Parameters of hydrogen carriers

Parameter	DBT	NEC	NaBH <sub>4</sub>	Ammonia borane
Theoretical energy density [MJ/kg]	7.44	6.98	25.56	23.52
Theoretical energy density [MJ/L]	7.0	6.63	27.34	14.4
Hydrogen yield per molecule of hydrogen carrier [mol/mol]	9	6	4	3
Molecular weight [g/mol]	290.54	207	37.8	30.8
Heat capacity fuel (incl. water if necessary) [kJ/kgK]	1.96	2.04	4.54*	4.54*
Heat capacity spent fuel [kJ/kgK]	1.82	1.56	N.R.	N.R.
Dehydrogenation temperature [K]	573	503	353	353*
Dehydrogenation energy [kJ/mol Fuel]	558	318	-210	-156
Sources	(Lee et al., 2021) (Kwak et al., 2021)	(Stark et al., 2015) (Müller et al., 2015) (Teichmann et al., 2012)	(Zhang et al., 2006) (Kojima, 2019) (Ye et al., 2020)	(Sanyal et al., 2003) (Chandra & Xu, 2007)

Values denoted with \* are estimated by the authors combined with data from Aspen as no precise information was available.

N.R. stands for 'Not required' as these values are not required in this calculation. When a solution is mixed, the heat capacity of the sol

high heating loads (Brückner et al., 2014). The hydrogenation process requires 318 kJ/mol of full LOHC (Niermann et al., 2019). van Rheenen, Padding, and Visser (2023) showed that, with an essential integration, a large part of the required heat could be supplied by the energy converter and heat available in the spent fuel, with similar results found by Preuster et al. (2018), who looked at a specific hydrogen carrier and energy converter. Figure 1 gives an overview of the specific components required for the hydrogen carrier to release hydrogen. After the carrier is transported from the tank, heat exchangers are used to preheat the carrier up to the dehydrogenation temperature. Part of this heat exchange already has to occur in the tank, as DBT is highly viscous; thus, preheating is required to get it out of the tank.

**Figure 1:** Simplified flow diagram with required components and main heat and mass flows for endothermic release hydrogen carriers

## Exothermic release

Ammonia borane and  $\text{NaBH}_4$  release hydrogen exothermically upon reacting with water, according to the following equations:

These reactions are similar, requiring water and releasing equally or more hydrogen than initially stored in the molecule, as the process also releases hydrogen within the water molecules. The boron-based spent fuel is also very similar. Regeneration of this spent fuel to the original molecule is possible but energy intensive due to the strong B-O bonds (Stephens et al., 2007). The exact composition of the spent fuel of  $\text{NaBH}_4$  (equation 2) depends on the temperature of the reaction. At the optimal reaction temperatures of 333 to 353K, the composition is  $\text{NaBO}_2 \cdot 2\text{H}_2\text{O}$ .

Equation 3 shows the release mechanism of ammonia borane, which produces hydrogen and ammonia. Ammonia gas can be burned in a heat engine, for example, in a dual-fuel ammonia-hydrogen internal combustion engine. Additionally, it can be decomposed into  $\text{N}_2$  and  $\text{H}_2$ , after which the  $\text{H}_2$  can be used in a fuel cell. Finally, ammonia gas can be stored on board. Storage is not considered feasible because of the required safety regulations and additional space. The decomposition process is also disregarded, as this process is highly energy-intensive. Thus, in this study, similar to in van Rheenen, Padding, and Visser (2023), only dual-fuel options of ammonia and hydrogen gas are considered. Only the PEMFC cannot run on the ammonia-hydrogen dual-fuel of the four investigated energy converters.

**Figure 2:** Simplified flow diagram with required components and main heat and mass flows for exothermic release hydrogen carriers

## Energy converter

Energy converters convert the chemical energy inside hydrogen to electrical or mechanical energy. The model will simulate four different energy converters, namely a hydrogen spark ignition (SI) ICE, a PEMFC, SOFC and GT, as these are all considered possible alternatives within the shipping sector. At the moment, a compression ignition running on pure hydrogen is not feasible without a way to ignite the hydrogen and is thus not regarded (Dimitriou & Tsujimura, 2017). Additionally, SI ICEs are more researched, and more data is available for these heat engines (Wang et al., 2019). The output of both the SI ICE and GT is regarded as mechanical. Both are assumed to be able to run on pure hydrogen and a hydrogen-ammonia mixture (Gohary & Seddiek, 2013; Rosado et al., 2019; Wang et al., 2019).

**Table 2:** Parameters of energy converters, including sources.

Parameter	SI-ICE	PEMFC	SOFC	GT
T coolant [K]	363	348	-	-
P coolant [%]	30	44.8	0	0
P effective [%]	35	42.9	48	37.5
T flue gas [K]	623*	-	1023	790
P flue gas [%]	25	0	42.1	53
P losses [%]	10	12.3	9.9	9.5
Sources	(Wang et al., 2019)	(Zhao et al., 2017)	(van Veldhuizen et al., 2023)	(Gohary & Seddiek, 2013) (Rosado et al., 2019)

P is the percentage of overall power distribution, mainly based on Sankey diagrams. \* Flue gas temperature of SI-ICE largely fluctuates depending on operating conditions and can range from 423 to 773K

## METHOD

Using hydrogen carriers on ships results in additional components needed on board compared to using pure hydrogen or conventional fuels. Some of these components are specific to hydrogen carriers, whereas other components, such as the energy converter, may be different for hydrogen-based fuels in general. This research only covers the hydrogen carrier-specific components, not the hydrogen-specific components. These components are visible in figure 3, where the components that will be looked at in detail in this research are coloured green. The required input parameters, such as mass flows, compositions and temperatures, are calculated using the 0D model we previously created (van Rheenen, Padding, & Visser, 2023). Figure 4 shows a simplified model outline based on van Rheenen, Padding, and Visser (2023). The model is built so that each energy converter, regardless of the hydrogen carrier, will always have an output power of 2 MW, which is relevant for medium-sized vessels such as ferries and small cargo ships.

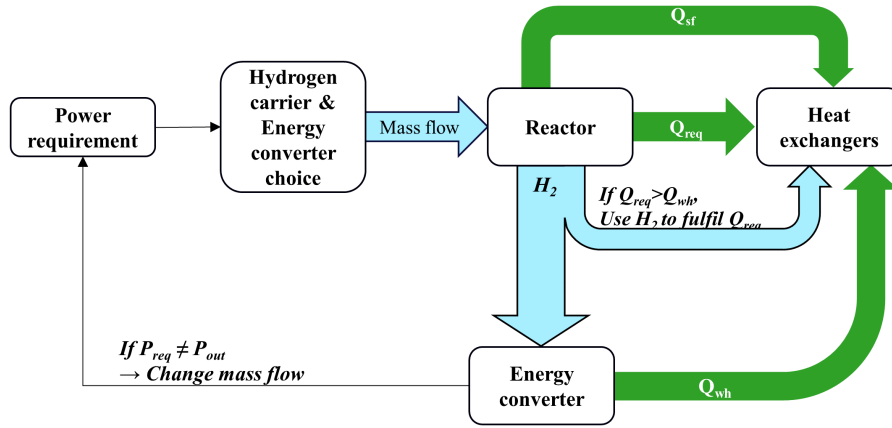

**Figure 3:** Overview of all components required on a ship when using hydrogen carriers as a power source. The components denoted in green are hydrogen carrier specific components and, thus, the main focus of this research

This section describes the necessary steps to upgrade them to get an overview of the sizing. A different approach is used for each component due to their significant difference in functionality. The parameters required for upgrading the components, such as mass flows and temperatures, are given by the 0D model. The following subsections will describe each critical component in detail and how they can be upgraded.

## 0D Model

Figure 4 gives an overview of the 0D thermodynamic model's layout, as implemented in Matlab Simulink. The power requirement, the hydrogen carrier and the energy converter can be chosen. These three parameters then define the mass flow of the hydrogen carrier. This mass flow, in its turn, defines the required energy for preheating and, if applicable, dehydrogenation. The model runs a complete iteration, including an energy balance check, and adjusts the mass flow accordingly if the required power and the output power do not match.

**Figure 4:** Simplified overview model. Flows that are used as a heat source can be turned on and turned off when necessary.  $Q_{wh}$  stands for waste heat,  $Q_{req}$  is the heat required for preheating and, if applicable, dehydrogenation and  $Q_{sf}$  stands for the heat inside the spent fuel

Tables 1 and 2 give an overview of the used parameters and the resources from which they were derived. The thermodynamic model provides estimates and a simplified representation of reality. For example, the model does not consider the preheating of air for a SOFC. In reality, this preheating, which is required, is a major, high-temperature heat sink (van Veldhuizen et al., 2023). When the heat needed for the dehydrogenation of the hydrogen carrier cannot be covered with waste heat from the energy converter, hydrogen will have to be burnt to cover the heat requirement. The heat required for preheating and dehydrogenation,  $Q_{req}$ , and the heat available inside the spent fuel,  $Q_{sf}$ , are calculated according to the following equation:

$$\dot{Q} = \dot{m} \cdot c_p \cdot \Delta T \quad (4)$$

With  $\dot{Q}$  the heat in kW,  $\dot{m}$  the mass flow in kg/s,  $c_p$  the heat capacity, in kJ/kgK and  $\Delta T$  the temperature difference in Kelvin. In the Matlab model,  $c_p$  is considered constant, not temperature-dependent.  $Q_{wh}$  is defined by the percentage of heat going from the reactor to heat losses (denoted by P coolant and P flue gas in table 2). A fixed temperature difference is set for flue gasses and coolant, which is used to calculate the flue gas's or coolant's mass flow, using equation 4. The required mass flow of the flue gas or coolant to go into the heat exchanger is similarly calculated. However, if the heat (denoted by Q) is larger than required to heat the hydrogen carrier in that temperature window, the mass flow is adjusted, as equation 4 is always true (Cengel & Ghajar, 2014).

### Pretreatment: mixing tank

The boron-based hydrogen carriers are mixed with water in the mixing tank. This mixture is then further heated in heat exchangers before entering the reactor. The mixing tank uses a stirrer. The size of the mixing chamber depends on the required power and the selection of spent fuel. The hydrolysis reaction of the boron-based carriers is visible in equation 2 and 3. The hydrolysis requires a surplus of water. The amount of water, defined by the  $(2+x)$  term, is the minimum amount

needed for the reaction to happen. Additionally, it defines the composition of the spent fuel. The  $(2+x)$  term depends on the temperature if enough water is available (Andrieux et al., 2012). More important, however, is the solubility of the fuel and spent fuel in water. The amount of water should be sufficient to avoid spontaneous crystallisation, which may result in clogging. For both ammonia borane and sodium borohydride, the spent fuel is less soluble in water than the fuel. As both the fuel and spent fuel are present in the reactor, the limiting substance defines the amount of water. For ammonia borane and its spent fuel product, boric acid, the limit at temperatures of 353K is about 19 wt% of ammonia borane in water (Crapse & Kyser, 2011). For sodium borohydride, this limit lies at around 44 wt% sodium borohydride in water (Andrieux et al., 2012). These limits thus define the minimum amount of water required in the mixing tank.

The size of the mixing tank is determined as follows. The amount of water required for the boron-based hydrogen carrier spent fuel to completely dissolve at 353K (the operating temperature of the reactor) is calculated. This amount of water is compared to the stoichiometric amount of water required for the reactions (as depicted in equations 2 and 3). The largest amount of water is taken. This amount should always be compared to the amount of boron-based hydrogen carrier that can be dissolved at room temperature (293K) without crystallisation (Demirci, 2020; Haynes, 2011). The spent fuel is the limiting factor for sodium borohydride and ammonia borane. The largest amount of water (stoichiometric or dissolvent value) must be held in the mixing tank. As the boron-based hydrogen carriers will completely dissolve, their volume is negligible.

## Pretreatment: heat exchangers

All hydrogen carriers need to be heated before entering the reactor. The amount and type of heat exchangers depend on the energy converter chosen and the hydrogen carrier.

A heat exchanger with a large heat transfer surface per unit volume is a compact heat exchanger. The ratio of heat transfer surface area to the volume of the heat exchanger is called the area density, denoted with  $\beta$  (Cengel & Ghajar, 2014). Generally speaking, heat exchangers with a  $\beta$  in excess of  $700 \text{ m}^2/\text{m}^3$  are classified as compact, with heat exchangers in microreactors reaching area densities of over  $15000 \text{ m}^2/\text{m}^3$  (Cengel & Ghajar, 2014; Reay, Ramshaw, & Harvey, 2008). However, these high-area density heat exchangers, which also include printed circuit heat exchangers, have high pressure drops, making them less suitable for the specific applications addressed in this paper due to the high viscosity of some of the fluids, such as LOHCs (Cengel & Ghajar, 2014). To have an efficient heat exchanger, the thermal conductance of both fluids should be similar (Shah & Sekulić, 2003). This is more likely the case for liquids than for liquid-gas heat exchangers. Thus, liquid-liquid heat exchangers generally require different heat exchangers compared to liquid-gas heat exchangers (Shah & Sekulić, 2003).

The type of heat exchanger is defined by the fluids flowing through it. Generally, heat exchangers can differ depending on the fluid (gas or liquid), viscosity, fouling, pressure and temperature of the fluid (Cengel & Ghajar, 2014; Shah & Sekulić, 2003). As the pressures are similar for all four hydrogen carriers (1-10bars), different heat exchangers are unlikely to be required based on pressures. Fluid types differ, and both liquid-liquid and gas-liquid heat exchangers are required. Similarly, the temperature ranges of the hydrogen carriers vary significantly, as dehydrogenation temperatures range from 353K to 573K. Finally, the viscosity of the different hydrogen carriers differs. The boron-based hydrogen carriers are mixed with water, and these mixtures have viscosities that are relatively similar to water. Dibenzyltoluene is highly viscous at low temperatures, with viscosities of up to 4000 mPas (Müller et al., 2015).

Additionally, several other parameters must be known to evaluate the sizing of heat exchangers, namely, the mass flows, and in- and outlet temperatures of both the hot and cold sides. Thus, the 0D model should provide these mass flows. However, the 0D model uses a fixed heat capacity to calculate the mass flows of the hot side, which may result in small errors. The heat exchangers will all be designed in Aspen Exchanger Design & Rating (EDR), which will adjust the mass flow of the hot fluid when necessary. Aspen EDR can calculate the exact size and mass of heat exchangers and is widely used in industry and heat exchanger design research (K. Hooman, personal communication, November 27 2023). As a basis, the material properties from Aspen are incorporated. When a disagreement occurs between data obtained from any of the Aspen databases and experimental values from the literature, the data from the literature is taken. As the 0D model only incorporates a fixed, heat capacity value, the heat exchanged within a heat exchanger might differ between Aspen and the 0D

model. In these cases, the mass flow of the heat source is adjusted accordingly while checking if the mass flow does not exceed the maximum mass flow according to equation 4.

### ***Expected amount and sequence of heat exchangers***

Because we used the 0D model before, we can estimate the amount and sequence of the heat exchangers (van Rheenen, Padding, & Visser, 2023). The boron-based hydrogen carriers are mixed with water before entering the release reactor. This mixture has to be heated as well, and considering the difficulty of heating solid powders, the boron-based hydrogen carriers will be heated as a mixture. Heating the mixture will occur in a heat exchanger and requires only one heat exchanger, as they need to be heated to only 353K. No heat exchangers with spent fuel are used to avoid crystallisation inside heat exchangers. So, either flue gasses or coolant is used to preheat the exothermic-release hydrogen carriers, which are believed to contain enough heat to fulfil the requirements.

The endothermic-release hydrogen carriers, the LOHCs, will likely need more heat exchangers. When applicable, the LOHC will be heated in the first heat exchanger using the coolant from the energy converter. The second heat exchanger uses the spent fuel to heat the LOHC to almost the dehydrogenation temperature. A drawback for NEC here is that its spent fuel turns into a solid at temperatures lower than 343K. Thus, the fuel must be heated to at least 343K before entering the second heat exchanger. Finally, using flue gasses, a third heat exchanger will heat the LOHC until it reaches the dehydrogenation temperature.

### **After treatment: separator and crystallizer**

If the conversion rate of the LOHC is below 100%, a separator may be advantageous. The threshold below which a separator becomes worthwhile depends on the energy density, desired ship range, and volumetric fuel tank requirements. However, if a separator is larger than the additional fuel required to compensate for the lower conversion efficiency, it would not be worth using.

Next to the separator, a crystalliser can crystallise the spent fuel from the water to avoid storing large amounts of spent fuel. This water prevents the spent fuel from crystallising and thus clogging the system. The water required depends on the spent fuel, as the solubility of the spent fuel is lower than that of the fuel itself (Andrieux et al., 2012; Sanyal et al., 2003; Crapse & Kyser, 2011). However, the water also adds a large amount of weight and volume to the spent fuel, reducing the energy density of the whole system. Thus, crystallising the spent fuel is essential, and a crystalliser has to be added to the system. For hydrogen carriers that exothermically release hydrogen, such as sodium borohydride and ammonia borane, the crystalliser's size must be at least as big as the reactor's. In an emergency, the content of the reactor can then be dumped in the cooled crystalliser to stop or at least significantly slow down the hydrogen release reaction. This is unnecessary for hydrogen carriers that release endothermically as withholding heat will stop the reaction.

The sizing of the crystalliser and the separator highly depends on the conversion rate inside the reactor. In turn, this depends on the choice of catalyst, the amount of catalyst, the temperature, the throughput time of the reactor and, for boron-based carriers, the amount of additional water. Especially the catalyst choice is of significant influence and is thus well-researched (Abdelhamid, 2021). Because of the depth of the studies on this subject, it was decided not to incorporate this.

### **Release reactor**

The hydrogen release reactor is where the hydrogen is released from the hydrogen carrier. In this reactor, the hydrogen carrier passes by the catalysts, upon which it reacts and releases hydrogen. Many researchers are studying this process. We refer to Fogler (2016) for more detailed information on release reactors. In this work, however, the release reactor will be modelled as a plug flow reactor, with a jacket around it to provide the necessary heat or cold. The plug flow reactor is as-

sumed to have a membrane to remove the hydrogen. The hydrogen gas will expand vastly and thus significantly influence the reactor's working if not removed immediately.

The dehydrogenation of endothermic-release hydrogen carriers requires heat. A buffer fluid will be used when the heat has to be supplied to the reactor, and the heat source is not considered constant (such as flue gasses). This buffer fluid reduces the system's efficiency but controls the heating system. Using a buffer fluid can prevent overheating of the reactor, which can result in the decomposition of the hydrogen carrier and has to be avoided.

## RESULTS AND DISCUSSION

This section discusses the main results. The model is first validated using pinch diagrams and a sensitivity analysis. The sizing of the mixing tank and reactor, as well as the type and sizing of the heat exchangers, is discussed next. It is important to realise that only the components from figure 3 are considered. The storage tanks, engines or fuel cells, and potential hydrogen burners are not considered, despite taking up significant amounts of space. The PEMFC is not considered in the case of ammonia borane. Ammonia borane releases both hydrogen and ammonia. Cracking or storage of ammonia is not deemed feasible and the ammonia will be used as fuel, together with hydrogen (van Rheenen, Padding, & Visser, 2023). This rules out a PEMFC, as ammonia is toxic to PEMFCs and strongly reduces the performance of the PEMFC (Halseid, Vie, & Tunold, 2006). Thus, the figures of ammonia borane will have only three results and the PEMFC is left out.

### Validation

The model is validated in multiple ways. Pinch diagrams are used to check whether the heat flows from the 0D model are thermodynamically possible. A sensitivity analysis provides information on the influence of the viscosity on the size of a heat exchanger.

#### *Pinch diagrams*

Pinch diagrams are used to validate the results. Pinch diagrams show whether heat exchangers comply with the second law of thermodynamics and also where the design is most constrained. Heat exchangers will correctly transfer heat if the lines representing the hot fluid stay above the lines representing the cold fluid at all times; crossing lines means that the exchanger does not comply with the second law. The design is most constrained at the location where the hot and cold lines are closest, the 'pinch' (Kemp & Shiun Lim, 2020).

Figure 5 gives an overview of four of the pinch diagrams generated by the 0D model. As there are no crossing lines, the required heat exchangers all comply with the second law of thermodynamics. The figures, however, do show interesting differences. Figure 5a is an example of what all pinch diagrams look like for both  $\text{NaBH}_4$  and ammonia borane: two straight lines, with a sufficiently significant temperature difference (at least 10 K or more). The lines are straight because the mass flow of the flue gas is calculated following the temperature and heat demand: it is less than the total mass flow of the flue gas. Mass flows are more straightforward to regulate than temperatures and lower mass flows require smaller heat exchangers.

Figure 5b gives an overview of an endothermic-release hydrogen carrier, DBT, combined with an ICE. The flue gas of the ICE does not contain sufficient heat to cover the heating demand of the dehydrogenation reactor. Hence, additional heat by burning hydrogen is required. Similarly, figure 5c shows that combining a PEMFC and DBT will result in hydrogen burning necessary for heating and dehydrogenation. The hydrogen used for burning is a loss, as it is first released from DBT but cannot be used for power. This combination is thus unfavourable. Finally, figure 5d shows the combination of NEC and a gas turbine. No additional heat is required as the flue gas (HT) line covers the whole dehydrogenation. Thus, no hydrogen has to be burned. As the spent fuel of NEC is solid at temperatures lower than approximately 343K, the preheating of the

fuel is done using low-temperature flue gas. This flue gas is not cooled below 373K to avoid condensation in the heat exchanger.

### Validation: Influence of viscosity

The viscosity of ammonia borane mixed with water is unknown. Thus, we made an estimation. The level of ammonia borane in the water (3mol/L, (Crapse & Kyser, 2011)) is much lower than the solubility limit. Therefore, low viscosity (1-2 mPas) is assumed. A sensitivity analysis was used to control the influence of small changes in the viscosity on the output of Aspen EDR. The viscosity was changed with a factor of 1.5 and 2, without any changes in the heat exchanger. Thus, such small changes in viscosity are insignificant.

## Mixing tank

To estimate the size of the mixing tank, the residence time and the mass flow of the mixture must be known. The residence time is defined by the dissolution time of the crystals, and is strongly influenced by the mixing equipment. The residence time should be sufficient to ensure sufficient mixing to avoid crystallisation. The residence time in mixing vessels for sodium borohydride and ammonia borane is estimated to be relatively short (about 3 minutes), resulting in small mixing tanks. The mixing time is based on data from Aspen for  $\text{NaBH}_4$ . The same mixing time for ammonia borane is taken, as no additional data is available for ammonia borane. Experiments should be performed on the mixing time to estimate the mixing tank size better. Figure 6 gives an overview of the mixing tank size without considering a safety factor.

Figure 6: Size of mixing tanks, without safety factor

## Heat Exchangers

This section will describe the choice and consequent size of heat exchangers. Table 3 gives an overview of the types of heat exchangers required for the different hydrogen carrier and energy converter combinations.

### Choice of heat exchangers

Two main types of liquid-liquid heat exchangers exist: the shell-and-tube heat exchanger and the plate heat exchanger. The shell-and-tube heat exchanger is very common in industrial heat exchangers but is less suitable for the specific applications onboard ships, as they are relatively large and heavy (Cengel & Ghajar, 2014; Shah & Sekulić, 2003). This thus leaves plate

Cold medium	Hot medium	Mediums	Heat exchanger type	Sizing (Order of magnitude)
NaBH <sub>4</sub> and NH <sub>3</sub> BH <sub>3</sub>	Coolant	Liquid-Liquid	Plate	$8 \cdot 10^{-3} \text{ m}^3$
NaBH <sub>4</sub> and NH <sub>3</sub> BH <sub>3</sub>	Spent fuel	Liquid-Liquid	Avoided due to crystallisation resulting in possible clogging	N.A.
NaBH <sub>4</sub> and NH <sub>3</sub> BH <sub>3</sub>	Flue gas	Liquid-gas	Plate with fins	$5 \cdot 10^{-3} \text{ m}^3$
LOHCs	Coolant	Liquid-Liquid	Plate	$5 \cdot 10^{-3} \text{ m}^3$
LOHCs	Spent fuel	Liquid-Liquid	Plate	$8 \cdot 10^{-3} \text{ m}^3$
LOHCs	Flue gas (Preheat)	Liquid-gas	Plate with fins	$1 \cdot 10^{-3} \text{ m}^3$
Heat transfer fluid	Flue gas	Liquid-gas	Plate with fins	$1 \text{ m}^3$
LOHC (dehydrogenation)	Heat transfer fluid	Liquid-Liquid	Jacketed reactor	$4 \text{ m}^3$

**Table 3:** Summary heat exchangers and reactor types and sizes

heat exchangers, which are well suited for liquid-to-liquid heat exchange applications. The main limitation of plate heat exchangers is their unsuitability when large pressure or temperature differences between the hot and cold fluids occur (Cengel & Ghajar, 2014; Shah & Sekulić, 2003). Neither occurs in any of the heat exchangers. Plate heat exchangers are generally cheaper, have less fouling and have shorter residence times than shell and tube heat exchangers (Shah & Sekulić, 2003). As the dehydrogenation processes for all of the mentioned hydrogen carriers occur at only a few bars, and coolants are generally in a similar pressure range, this does not seem to be an issue. Thus, plate heat exchangers are the only type of heat exchangers considered in this research for liquid-to-liquid use.

The only exception to the plate heat exchangers is dehydrogenation reactors' heating (and cooling). The reactor design focuses on the reactor itself and less on the heating or cooling. For simplicity, a jacketed reactor is chosen. The jacket around the reactor can provide necessary heating or cooling. The reactors will be considered plug flow reactors, and the hydrogen is assumed to be immediately removed from the reactor. This latter is required as hydrogen is a gas and takes up a lot of volume. Removing hydrogen gas as soon as possible is essential for the reactor to keep working properly.

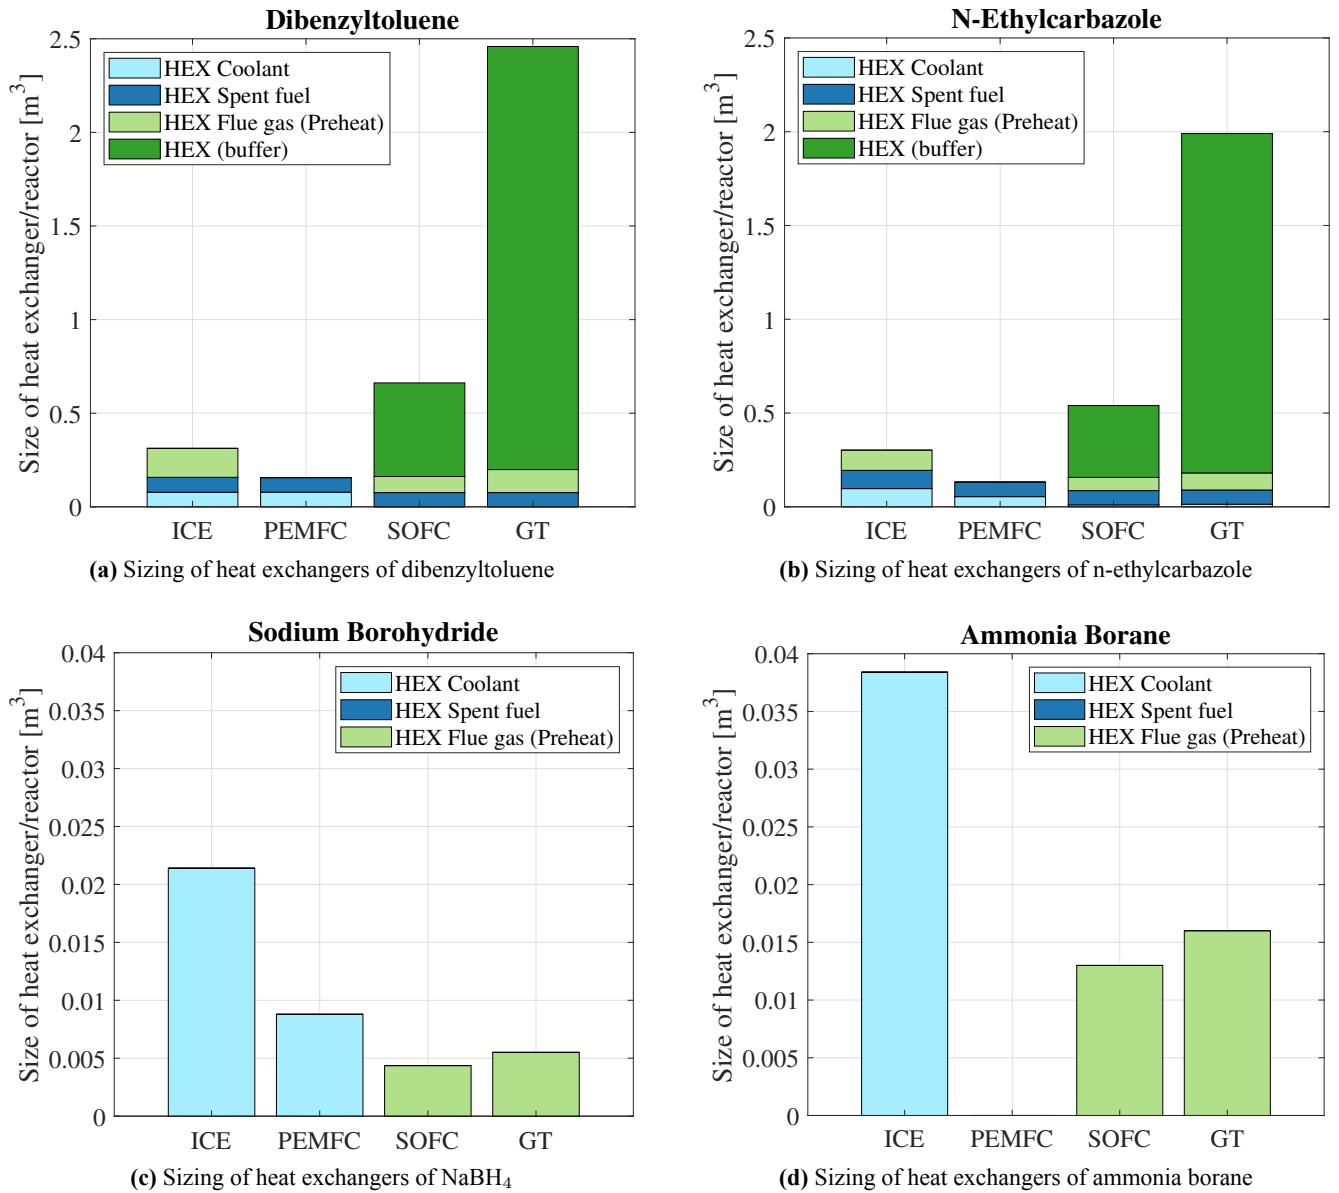

For liquid-gas use, plates with fins heat exchangers are used. A sensitivity analysis showed that plate heat exchangers would be significantly larger than plate-with-fins heat exchangers. Plate with fin heat exchangers are often used for liquid-gas heat exchangers, as they can have different surface areas for the gas and the liquid. Gasses usually require larger surface areas due to their lower heat capacities.

Table 3 gives an overview of the types of heat exchangers chosen for each combination of cold and hot fluids, including the type of fluid and the resulting order of magnitude.

### *Sizing of heat exchangers*

Figure 7 gives a more in-depth overview of the sizes of the different heat exchangers. Clear differences between the boron-based hydrogen carriers and the LOHCs can be seen. The LOHCs require several heat exchangers, which are significantly sized, while the boron-based hydrogen carriers require a single, small heat exchanger with a size of several litres. Between the boron-based carriers, the heat exchangers required for heating sodium borohydride (represented in figure 7c) are smaller than those for ammonia borane (figure 7d). This difference is explained by the different amounts of water required for these carriers. Due to the higher solubility limits of the spent fuel of sodium borohydride, less water is required in the process. More water is required in the process for ammonia borane, resulting in a larger overall mass flow, greater heat demand and thus, a larger heat exchanger. These figures also show that heat exchangers that use hot gasses as heat sources can be smaller than liquid-liquid heat exchangers. The internal area of the plate with fins heat exchanger is larger than that of the plate heat exchangers.

The results of the heat exchanger geometry for liquid organic hydrogen carriers differ greatly. The heat exchangers are generally tenfold larger than those of the boron-based hydrogen carriers. From figures 7a and 7b, it appears that the heat ex-

**Figure 7:** Sizing of heat exchangers for different hydrogen carriers, additional possible hydrogen heaters are not taken into account

changers, when integrating with an ICE or PEMFC, are significantly smaller than those with a SOFC or GT. However, it should be noted here that the ICE and the PEMFC cannot cover the complete heat requirement of the preheating and dehydrogenation process of the LOHCs. An additional heat source, most likely hydrogen burning, is thus required. This reduces the energy density and efficiency of the system and requires an additional heater. This additional heater also needs to be sized. However, as this is a burner and not a heat exchanger, it is not considered here.

On the other hand, the complete system of heat exchangers required for the SOFC or GT integration can be simulated. Figure 7a shows that heating the buffer fluid results in an extremely large heat exchanger for this system. The large heat demand of the dehydrogenation process can explain this. The complete flue gas flow is required to heat the buffer fluid sufficiently. For both N-ethylcarbazole and dibenzytoluene, the differences between the gas turbine and the SOFC buffer-fluid heat exchanger are significant. These differences occur due to the mass flow of the flue gas of a gas turbine and SOFC. The mass flows are calculated using equation 4. As the SOFC has a larger temperature difference, the mass flow is consequently less than for the GT, with a smaller temperature difference. Additionally, the SOFC has a higher efficiency and, as visible

in table 2, the overall component of the total available power going to heat is less for an SOFC than for a GT. Thus, combined, the mass flow of an SOFC is much lower than that of a GT, resulting in a smaller heat exchanger. However, figure 7a shows much larger heat exchangers in general, especially visible in the buffer, but also the other heat exchangers (for all energy converters) are larger. This difference occurs because dbt generally requires more heat, both for preheating and dehydrogenating. In figure 7b, a very small, additional heat exchanger is visible, which is required as the spent fuel of NEC should not be used to preheat the fuel at low temperatures. The spent fuel freezes at around 343K and should thus not be cooled down strongly. Thus, a heat exchanger must be added to do the first flue gas cooling step. These heat exchangers are generally very small, approximately 10L.

Knowing the size of the heat exchangers is not the only result of this study. The sequence and amount of heat exchangers is also an important input for ship design. As all the heat exchangers have to be connected to each other and different heat sources, they introduce limitations to the ship's design (Souflis-Rigas et al., 2023). These limitations occur less when using fewer and smaller heat exchangers; the design freedom when incorporating boron-based hydrogen carriers is thus much higher compared to LOHCs.

## Reactor

**Figure 8:** Estimated reactor sizes of different hydrogen carriers for different energy converters

Figure 8 gives an overview of the reactor sizes. The reactor size depends largely on the throughput time. In this case, a throughput time which results in a high conversion rate (>95%) is chosen. The throughput time can be shorter for lower conversion rates. The conversion rate depends on the temperature, catalyst, reaction rate, type of reactor, and more (Brückner et al., 2014; Abdelhamid, 2021). Additionally, catalyst packing influences the volume size. In all of the cases, a packing factor of 0.5 is considered. The throughput time and conversion rate do not depend on the energy converter. The differences for each energy converter, as visible in figure 8, occur due to different mass flows. Higher mass flows with the same throughput time result in a larger reactor size.

Experiments are generally required to calculate conversion rates and throughput times. These conversion rates and throughput times strongly influence the reactor size and the hydrogen release rate. Literature shows this as well. NaBH<sub>4</sub>, for example, was reported to have throughput times of 1 to 2 hours (Li & Kim, 2012), whereas more recently, throughput times in the order of 20 minutes have been reported (Erat, Bozkurt, & Özer, 2022). Thus, they form an area of very active research, as the hydrogen release rate influences the suitability and usability of a hydrogen carrier. As this area of research is very specialised, we only considered known throughput times with a high conversion rate (Brückner et al., 2014; Qiu, Wu, Wu, Liu, & Huang, 2016; Erat et al., 2022). Figure 8 clearly demonstrates the requirement for low throughput times, as the difference in reactor size is large.

## Overview of total required components

Figure 9 gives an overview of the total sum of the size of the required components. Each of the specific components is influenced by several factors, each with its own levels of reliability. Thus, the resulting sum of the sizes is an indication. The reactor size is the main influence of the components' total sizing. This figure clearly shows that the equipment's total size does not differ too much if the throughput time of the reactor is low enough. The relatively large heat exchangers required for NEC and DBT are only relevant if the reactor size is similar to that of  $\text{NaBH}_4$  and ammonia borane. Even then, the overall sizing of the equipment is similar. The size of the mixing tank required for  $\text{NaBH}_4$  and ammonia borane is similar to the heat exchangers required for DBT and NEC (except when combining these with a GT, in which case the heat exchangers are significantly larger).

**Figure 9:** Overview of sizing of all components

## CONCLUSION AND RECOMMENDATIONS

The sizing of all relevant components must be known to estimate the possible ship design changes required for incorporating hydrogen carriers as the power source. This research aims to give an overview of all the relevant components and their sizes.

The size of the release reactor is most significant for all hydrogen carriers. Further research on catalysts will hopefully result in shorter throughput times. This research clearly shows the benefit of shorter throughput times, as these strongly influence the reactor sizing. As this reactor has to be placed in a specialised room (due to the release of hydrogen), having an exact size is important. The reactors required for ammonia borane appear slightly larger than those for sodium borohydride reactors. This size largely depends on the throughput time and dehydrogenation rate. The other components, such as heat exchangers and a mixing tank, are significantly smaller than the reactor. The heat exchangers are of such small size that it is unlikely they will influence ship design.

The sizing of heat exchangers is of importance only for LOHCs. The heat exchangers required to heat the buffer fluid are especially large. When no buffer fluid is required, and the main part of heating has to be done using hydrogen, no estimates on equipment size have been made. In general, the heat exchangers required to preheat and, when possible, provide enough heat for the dehydrogenation process of LOHCs are large and numerous. As these heat exchangers need to be in a fixed sequence and use waste heat, they create limitations on the ship design. Additionally, all of the equipment for DBT is larger than that for NEC.

All in all, the boron-based carriers pose fewer limitations to ship design. The required equipment is smaller and less numerous, even though it is still in a fixed sequence. In all cases except for the PEMFC, only three components are necessary: a mixing tank, a single heat exchanger and a reactor vessel. When a PEMFC is used, a small hydrogen burner is also required. For LOHCs, more and larger components are needed. The only setups in which no hydrogen burner is required need at least 3 (for DBT) or 4 (for NEC) heat exchangers. Besides these, a reactor is also required.

To design ships using hydrogen carriers, knowing the amount of components and their sizing is imperative. This research has given an overview of all required components and estimated the sizing of each of these components. This is the first step in designing zero-emission ships powered by hydrogen carriers.

# Simulation of LNG-Battery Hybrid Tugboat Under the Influence of Environmental Loads and Manoeuvre

Sharul Baggio Roslan<sup>1</sup>, Dimitrios Konovessis<sup>2</sup>, Joo Hock Ang<sup>3</sup>, Nirmal Vineeth<sup>3</sup> and Zhi Yung Tay<sup>1,\*</sup>

## ABSTRACT

*This paper presents a system modelling approach aimed at designing and simulating real-time conditions, with a specific focus on extreme scenarios to assess the impact on the annual CO<sub>2</sub> emissions and the consumption of LNG and batteries in a hybrid tugboat. Environmental variables such as wave period, wave height, current speed, and wind speed are considered. The tugboat system model is validated using manually logged historical operational data from a similar tugboat profile using both AMESIM and MATLAB\Simulink to simulate diverse environmental conditions and estimate annual fuel operational costs and emissions. A comparative analysis of the different system configurations is then conducted between traditional diesel, LNG and several control configurations of LNG-battery hybrid. Results demonstrate a significant reduction of 96.5% in CO<sub>2</sub> emissions and a 95.3% decrease in annual fuel operational costs with the adoption of LNG-battery hybrid propulsion with the rule-based control system. The study notes a slight increase in vessel operational time by 10.8% due to higher wave heights and a 0.97% rise in added resistance from increased wind speed. Insignificant differences are observed in variations of wave period and current speed. Additionally, the CII ratings of the different system configurations were then compared and concluded with the LNG-battery hybrid with a rule-based control system being the most environmentally and economically sustainable.*

## 1. INTRODUCTION

Given Singapore's standing as home to one of the world's busiest ports, addressing greenhouse gas (GHG) emissions has become a top priority. The Marine Port Authority (MPA) targets ensuring that by 2030, all newly commissioned harbor vessels operating within Singapore's port waters will either be entirely electric, have the capacity to utilise B100 biofuel or be compatible with net-zero fuels like hydrogen. Vessel owners are mandated to collaborate with MPA on these designs by 2027 (Maritime & Port Authority Of Singapore, 2023). The MPA's initiative serves as a strategy to ready operational vessels for compliance with the MARPOL Annex VI, established by the International Maritime Organization (IMO) in 2016, aiming to halve annual GHG emissions by 2050 (International Maritime Organization, 2016), with an intermediate target of a 40% reduction by 2030 and an even more substantial 70% reduction by 2050. Additionally, stringent emissions limits, such as the 0.5% m/m marine sulfur content limit in emission-controlled areas (ECA) implemented in January 2020 (International Maritime Organisation, 2019), have necessitated vessel owners to explore diverse methods to curtail CO<sub>2</sub> emissions (Tadros *et al.*, 2023). This includes the adoption of scrubbers/exhaust gas clearing systems, carbon capture and storage, or net-zero fuel sources like

hydrogen, ammonia, or LNG (Mallouppas & Yfantis, 2021). With the various results from reducing emissions, the results are then assessed based on two new indexes introduced by the 76<sup>th</sup> Marine Environment Protection Committee (MEPC) (The Marine Environment Protection Committee, 2021). The Efficient Existing Ship Index (EEXI), the annual carbon intensity indicator (CII) operation report and the CII rating that was implemented in 2023. The EEXI applies to existing ships and requires these ships to fulfil the minimum energy efficiency standards, otherwise, the ship may need to implement technical and operational measures to improve its energy efficiency (ClassNK, 2021). CII ratings and annual CII operational reports are required for vessels of more than 5,000. CII ratings are based on the ship's CO<sub>2</sub> emissions during an operation, achieving a grade "A" CII rating signifies a highly efficient ship in reducing carbon emissions during operation. Ships with a rating of "D" or "E" for three consecutive years are required to develop a corrective action plan. A past study by Ejder and Arslanoğlu (2022) on CII explored using ammonia fuel engines, identifying potential savings of 12,660.07 tonnes of CO<sub>2</sub> and achieving an 'A' CII rating. However, the \$5 million retrofitting cost makes building a new ship more economically viable. Another study by Gianni *et al.* (2022) assessed various power configurations for a cruise ship not meeting CII regulations. Only marine gas oil (MGO) failed to comply with the 2024 CII regulations, while LNG power was the sole option capable of securing an 'A' CII rating until 2026.

Given the urgent need to decrease GHG emissions, it is important to explore alternative solutions. Notably, there has been a surge in technological advancement and the widespread commercial adoption of electrical or hybrid propulsion in recent years. The earliest application of electrical propulsion in vessels existed since the 1990s, primarily used in military and cruise ships (Moreno, 2007) and the world's first electric-powered car ferry, the Ampere, was built later in 2015 (Ship Technology, 2015). The electrical propulsion system provides higher efficiency lower carbon emission or zero emission in low loading conditions (Tay & Konovessis, 2023), and overall reduces operational cost. Since LNG shrinks by a factor of 1/600 during liquification, it becomes easier to be transported around making it more accessible when compared to other alternative fuels, hybrid propulsion using natural gas-powered engines or batteries has also recently seen an increase in popularity (Roslan *et al.*, 2022). A few noteworthy research studies, including Vadset (2018) thesis which delved into LNG-powered systems. Vadset's research specifically explored LNG–battery hybrid systems, comparing those with variable speeds to full-LNG systems. The study revealed that a variable-speed LNG-battery system could achieve a 20% reduction in fuel costs compared to a fixed-speed fully LNG system. Another significant research from Lebedevas *et al.* (2021) conducted notable past research on the utilisation of LNG dual-fuel engines for tugboats. Their work achieved reductions of 10%, 91%, and 65% in CO<sub>2</sub>, SO<sub>2</sub>, and NO<sub>x</sub> emissions, respectively. Compared to utilising diesel, using a hybrid diesel-LNG propulsion system saves 33% on fuel costs. Moreover, LNG serves as a cost-efficient fuel with the potential to cut down CO<sub>2</sub> emissions by 26%, and it is sulphur-free, although the presence of methane slip may diminish its environmental advantages (Karaçay & Özsoysal, 2021). The authors are not aware of many studies focusing on the LNG–battery hybrid system, especially in the context of tugboats. This gap in research serves as the motivation for exploring this subject in the current paper.

In addition to enhancing emissions through the incorporation of renewable energy, it is important to explore ways to boost ship energy efficiency. This involves investigating the most optimised environmental conditions for optimal operation to achieve further reduction in emissions. Some noteworthy research on the impact of environmental factors on energy consumption has been conducted. A study done by Lindstad *et al.* (2013) revealed that a 4m head wave could increase energy consumption by up to 35%, while an 8m wave height might lead to a doubling of energy consumption for a bulk carrier. A study which explored different conditions of wind speed, wind direction and wave height conducted by Wang *et al.* (2023), managed to reduce fuel consumption by 3.38%. Currently, there is limited research employing system modelling on the impact of environmental loads on the performance and manoeuvrability of an LNG-battery hybrid system. This led to incorporating the topic into the current. While the selection of a route significantly influences a ship's efficiency, this paper specifically focuses on a fixed operational route. Future research is encouraged to explore route optimisation-based solutions based on the most efficient conditions discovered in this paper.

This study aims to evaluate the environmental and economic effects of adopting a LNG–battery hybrid propulsion system in a 65-ton tugboat in comparison to utilising diesel or LNG as the sole propulsion system. By utilizing data obtained from a comparable diesel-powered tugboat, the study profiles the loading operations of the modelled tugboat. The hybrid LNG–battery tugboat system is created in MATLAB/Simulink<sup>®</sup> and a diesel-powered tugboat is created in AMESIM, the full system breakdown is described in Section 2. The case study adopted for this study was obtained based on the design operational profile. Several different environmental conditions are tested to analyse the effects of varying environmental conditions on the engine load, annual fuel operation cost and annual CO<sub>2</sub> emissions emitted. Finally, an assessment was conducted to compare the CII rating of an LNG-battery hybrid system, employing rule-based control and various load distribution strategies, against conventional diesel and LNG systems. The goal was to identify the system with the best rating and economically and environmentally beneficial. Although CII ratings are not required for vessels below 5,000GT, this paper will neglect the weight requirements and categorise the tugboat as a cruise passenger ship for comparison purposes. The rule-based control and load distribution strategies adopted from this study are based on a past study conducted by the author (Roslan, Konovessis, *et al.*, 2023; Roslan, Tay, *et al.*, 2023). Further development of the system modelling could be conducted with the advancement of digital twins that incorporates machine learning (Abebe *et al.*, 2020; Cheliotis *et al.*, 2020; Fam *et al.*, 2022; Hadi *et al.*, 2022a; Tay, Z.Y.; Hadi, J; Konovessis, D.; Loh, D.J.; Tan, D.K.H; Chen, 2021; Tay *et al.*, 2021) and big data analytics (Hadi *et al.*, 2022b; Mirović *et al.*, 2018).

The paper is structured as follows: Section 2 provides an overview of the tugboat, details of the methodology for obtaining the vessel loading profile, and a brief description of both the diesel-powered tugboat system modelled on AMESIM and the hybrid LNG–battery power system modelled on Simulink. In Section 3, a mathematical overview is presented for the comparison study. Section 4 compares the annual operation cost and annual CO<sub>2</sub> emissions across different cases and configurations. Finally, Section 5 concludes with a summary of the work and provides recommendations for future research.

## 2. SYSTEM OVERVIEW

The diagrams of both the diesel and LNG-battery hybrid tugboats are shown in Figure 1 and Figure 2, respectively. Figure 1 shows the system diagram of a diesel tugboat. Operational data from JMS Kappa was acquired due to its resemblance in operational requirements and vessel architecture. The diesel tugboat is equipped with two diesel engine generators as a primary source, with a rated output of 1,471kW, and rated speed of 750rpm and a low output nominal voltage of 400V generator with a capacity of 1,390kWe for the auxiliary load (IHL, 2022). The auxiliary load includes service and hotel loads, heating, ventilation and air-conditioning (HVAC), lighting and pumps. The two diesel engines are then directly connected to a gearbox, to reduce engine speed and reversing shaft rotation. Subsequently, connected to an azimuth thruster individually. The diesel power system is modelled in Simcenter AMESIM to replicate the dynamic response of the system.

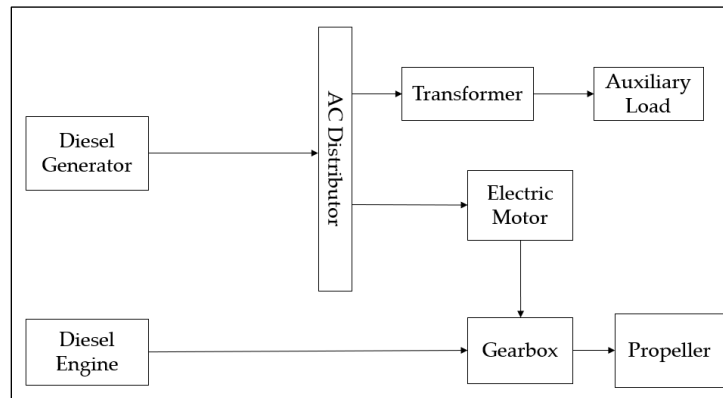

Figure 1. Simplified diagram of a diesel-electric vessel power system.

The tugboat's hybrid power system, shown in Figure 2, utilises two LNG generator sets (Gensets) with a maximum output of 1,492 kW, 1,600 rpm speed, and 545 V voltage for primary power generation. Additionally, two lithium-ion batteries, each with a 452 kWh capacity, provide energy storage. The vessel loads include the two azimuth thrusters with ducted propellers, service and hotel load, HVAC, lighting and pumps. A 1,000 V modern direct current (DC) distribution system is used in the present system due to its simplicity and fuel efficiency (Zahedi *et al.*, 2014). To streamline the system, AC power from the Gensets flows through a rectifier to become DC, while the battery directly feeds the DC distribution. This reduces equipment and boosts round-trip efficiency. The hybrid power system is modelled in MATLAB/Simulink® to simulate the dynamic response of the system.

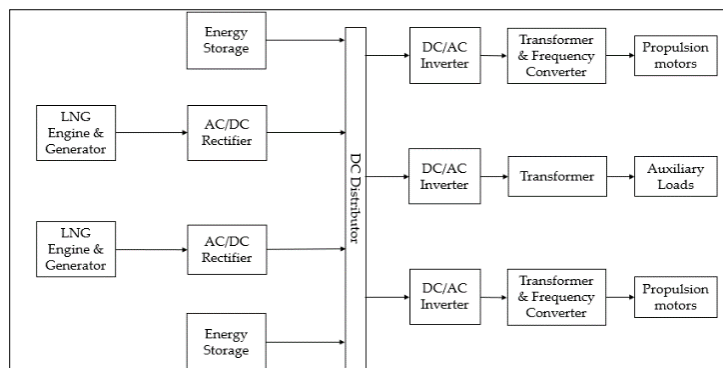

Figure 2. Diagram of LNG–battery hybrid vessel power system

### 2.1 Loading Profile

This study focuses on a 65-tonne tugboat equipped with two Gensets and batteries. The three primary operational modes categorised in this study are (i) idle or standby: in this mode, the vessel load ranges below 520kW and is either stationary or travelling along with the current. (ii) Transit: During transit, the speed and vessel load range between 6 - 12 knots 550kW and

1,100kW, respectively. (iii) Tugging: When performing tugging operations, the vessel load ranges up to a maximum load of 1,492kW, however, it averages 540kW with varying travelling speeds. The tugboat's operational time-domain load profile was created based on past studies done by the authors (Roslan, Konovessis, *et al.*, 2023; Roslan, Tay, *et al.*, 2023), utilising a combination of data manually recorded during an operational on the diesel tugboat, JMS Kappa, and the designed operational profile of the LNG-hybrid tugboat provided by the industrial collaborators.

## 2.2 Modelling of Diesel Propulsion System on Simcenter AMESIM

The Simcenter AMESIM model of the diesel propulsion tugboat consists of two major parts, i.e., the diesel generator set (genset) and vessel resistance shown in Figure 3. The system model shown is based on combinations of examples found in the Simcenter AMESIM library, with the values reconfigured to suit the parameters of JMS Kappa.

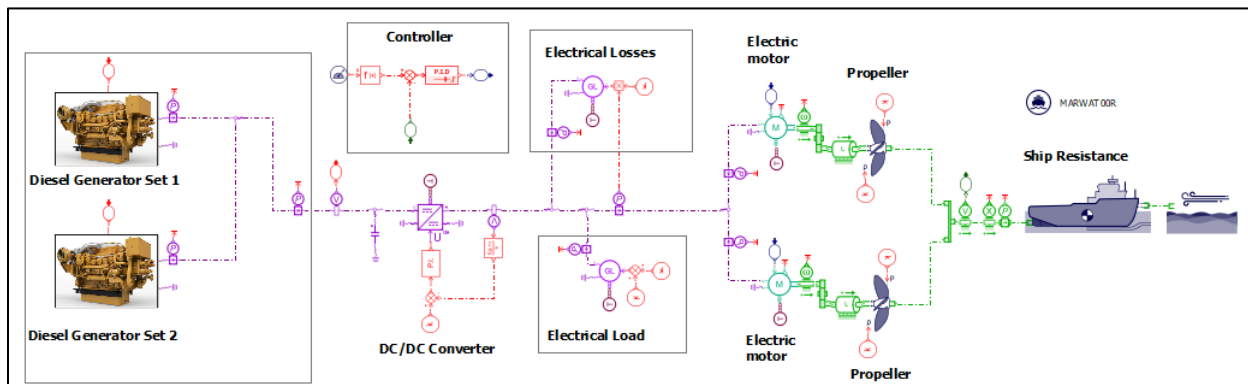

Figure 3. Model of the diesel power system in Simcenter AMESIM

### 2.2.1 Diesel Genset

The diesel engines are the main energy source for the diesel-powered tugboat. The generators are made up of diesel engines – DRVCE01H connected to electrical machines – DRVEMO3. The electrical generators then provide power through the DC/DC converter to two electrical motors that are connected to the propellers – MARPROP00, with a gear reduction system. The model also factors estimated auxiliary electrical load and electrical losses of 500kW and 0.5%, respectively. The parameters of the diesel genset – Niigata 6L26HLX, are based on the performance curves provided by the engine provider which are then replicated to the diesel engine model using the DRVCE table creator.

### 2.2.2 Vessel Resistance

The vessel resistance was based on CFD results shown in Figure 4, done on ANSYS Fluent and Finemarine with similar hull parameters to JMS Kappa. The results are then exploited and input into the vessel model, MARSHIP00, vessel resistance as a function of ship velocity. Speed ranging outside of the results provided are extrapolated linearly.

Figure 4. Vessel speed against resistance CFD results

The complete vessel route used in the study is shown in Figure 5, generated from the AMESIM Simcenter system simulation results and overlayed with Google Maps for easier visualisation. The operation observed in this study is based on data manually logged by the author during an operation. The route comprises segments of the tugboat cruising at high speed, tugging a vessel to an area near the shipyard and cruising back to the tugboat's original dock. The return trip of the tugboat in the example used

emissions associated with LNG-hybrid propulsion. The AMESIM model is then employed to examine how different environmental conditions impact vessel loading in Section 4 Case II.

### 2.3 Modelling of Hybrid LNG-Battery Propulsion System on MATLAB Simulink

The Simulink model for the hybrid system discussed in this paper follows a similar approach to that presented in (Roslan, Tay, *et al.*, 2023). However, this paper advances upon previous findings by incorporating operational condition results obtained from the AMESIM model. For a detailed explanation and parameters of the hybrid LNG-battery power system modelling using MATLAB/Simulink, readers are referred to (Roslan, Konovessis, *et al.*, 2023; Roslan, Tay, *et al.*, 2023). The LNG-hybrid model consists of three primary components: the Genset, the Gas Turbine (GAST), and the Battery, as illustrated in Figure 6. It is worth pointing out that the efficiency of the system components in both AMESIM and Simulink was assumed to be a constant of 90% and assumed that 10% is wasted due to heat. This assumption was made due to the lack of the component's efficiency curves. A system model that accounts for the efficiency curves of its components will be closer to real-world behaviour, important for digital twinning.

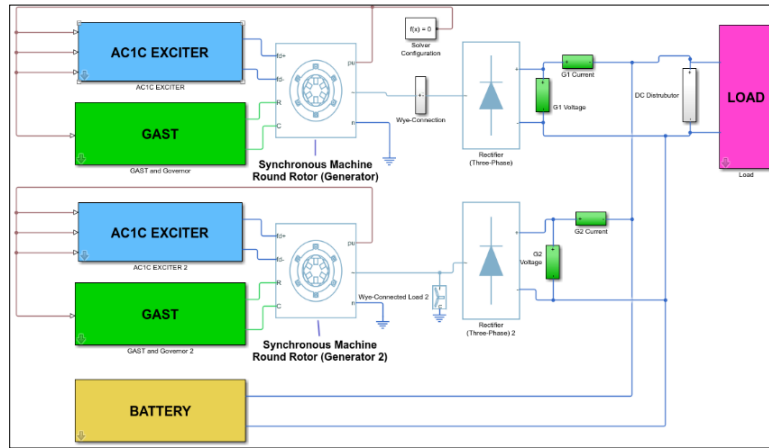

Figure 6. Model of Hybrid LNG–battery power system in Simulink.

### 2.4 Energy Management System

The energy management system (EMS) controls the different types of energy sources on board and fluctuating operational requirements. The optimal power distribution between the engine and energy storage system differs in the vessel fuel cost and emission emitted. To control and maintain the stability and distribution of the load required, a basic rule-based (RB) control strategy is added to the system model. The RB method is ideal with known loading conditions and past data of the system (Chua, 2019), where the past data are used as a benchmark for the RB control. This will then improve the power management of the hybrid system by allocating the different power sources efficiently to reduce operational costs and improve system longevity. The load-dependent RB control will be implemented in each case study similar to the one used in Roslan *et al.* (2023). The two types of RB strategy used in this paper are (1) LNG-RB: The Genset will be switched on/off to regulate the power switch to the fully battery-operated mode when the required load is consuming more than 200 g/kWh LNG or when each engine load of 300kW and below. (2) LNG/BAT: Based on the flexibility of the load sharing within the hybrid propulsions, different percentages of LNG and battery power in increments of 10% were investigated. A simple overview of the energy management framework is shown in Figure 7 below.

## 3. MATHEMATICAL OVERVIEW

### 3.1 Diesel Fuel Consumption

The calculation for diesel consumption is based on the method proposed by Hansen (2000) with some variations to accommodate the different systems. The mean specific fuel oil consumption ( $\overline{SFOC}$ ) could be obtained from the specific fuel oil consumption ( $SFOC$ ) for each Genset given in the diesel engine fuel consumption graph as follows,

$$\overline{SFOC} = \frac{1}{2t} \int_0^t [SFOC_{Gen\ 1}(t) + SFOC_{Gen\ 2}(t)] dt \quad (1)$$

where  $t$  is the total duration and the subscript in (1) denotes the  $SFOC$  for the respective Genset.

The  $\overline{SFOC}$  is then used to calculate the mean diesel consumption using the average generator power ( $P_{Avg}$ ). The mean diesel consumption  $\overline{C}_{diesel}$  calculation is shown in Equation (2).

$$\bar{C}_{diesel} [kg/h] = \overline{SFOC} [g/kWh] \times P_{Avg} [kW] \times 1000 \quad (2)$$

Note that the brackets in the equations represent the units for the variables and all the cost is in USD.

The annual operation cost  $Cost_{annual}$  given in (3) is then calculated by taking the assumed diesel price  $P_{diesel}$ . As of writing, the average price of marine diesel oil is set to be USD 1.023/kg (Ship&Bunker, 2023).

$$Cost_{annual} [USD] = \bar{C}_{diesel} [kg/h] \times P_{diesel} [USD/kg] \times 24h \times 365 \quad (3)$$

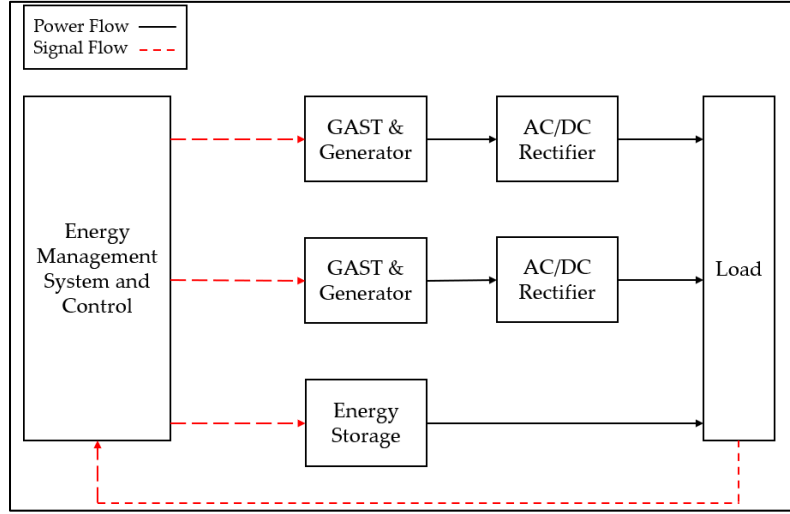

Figure 7. Simplified energy management framework (Roslan *et al.*, 2022)

### 3.2 LNG Consumption

For the LNG calculations, a similar concept to the diesel fuel counterpart is implemented. The mean LNG consumption  $\bar{C}_{LNG}$  is directly calculated from the summation of the  $SGC$  at the active load obtained from the engine limit curve in Figure 4.

$$\bar{C}_{LNG} \left[ \frac{Kg}{h} \right] = P_{Avg} [kW] \times \frac{1}{1000(2t)} \times \int_0^t \{SGC_{Gen1}(t) + SGC_{Gen2}(t)\} dt \left[ \frac{g}{kWh} \right] \quad (4)$$

The annual operation cost of the LNG is given in (5). The price of LNG  $P_{LNG}$ , as of writing, is set to be USD 0.40/kg (IndexMundi, 2022).

$$Cost_{annual} [USD] = \bar{C}_{LNG} [kg/h] \times P_{LNG} [USD/kg] \times 24h \times 365 \quad (5)$$

### 3.3 Battery Consumption

The battery consumption for the example will be calculated based on the difference in the battery state of charge (SOC). Using the Coulomb counting method (Vadset, 2018) given in (6),

$$SOC(t) = SOC(t-1) + \int_0^t \frac{P [kW]}{E_{bat} [kWh]} dt \quad (6)$$

where  $SOC(t)$  is the battery  $SOC$  at time  $t$  in %,  $SOC(t-1)$  the battery's initial  $SOC$  in %,  $t$  the time in hour,  $P$  the charge/discharge power and  $E_{bat}$  is the battery capacity.

Charging the battery with 1800 kW for 130 s makes it possible to add USD 1.95 as claimed by Vadset (2018) with a rate of USD 0.03/kWh. A separate study from Kersey *et al.* (2022) used the price of electricity of USD 0.035/kWh. This paper, however, will utilise the average value of USD 0.033/kWh. The cost to charge the battery fully after every trip will be based on the formula in equation (7),

$$Battery\ Charging_{Cost} [USD] = (SOC - SOC(t)) \times E_{bat} [kWh] \times Charging\ Cost [USD/kWh] \quad (7)$$

where  $SOC - SOC(t)$  is the percentage of battery to be fully charged,  $E_{bat}$  is the battery capacity and Charging Cost will be USD 0.033/kWh at 1800 kW. To obtain the annual operation cost with battery charging for configurations with a battery, the  $Battery\ Charging_{cost}$  is multiplied by the total number of trips completed in a year and added with  $Cost_{annual}$  in (5), not factoring downtime and inactivity periods such as system breakdown or lunch. Charging duration will progressively improve as the technology matures, evidenced by successful cases in the automobile industry where the chargers are capable of charging one vehicle at 1 MW or three vehicles simultaneously at 360 kW (Heliox, 2022).

### 3.4 CO2 Emissions

The CO<sub>2</sub> emissions  $Emission_{CO_2}$  calculation is based on MEPC.245 (66) (The Marine Environment Protection Committee, 2014). The total CO<sub>2</sub> emissions can be calculated using the following formula based on the total fuel oil consumption  $C_{fuel}$ .

$$Emission_{CO_2} (ton) = C_{fuel} (ton) \times C_F \quad (8)$$

where  $C_F$  represents the CO<sub>2</sub> emission coefficient based on the type of fuel oil consumed. The coefficients are based on MEPC.245 (66) Committee 2014. The diesel used in this paper is diesel oil and has a  $C_F$  value of 3.206, whereas the LNG has a  $C_F$  value of 2.75.

### 3.5 CII Ratings

Lastly, the  $EEOI$  or  $CII$  attained will be calculated from (9), whereas the required annual operational  $CII$  is obtained from (10).

$$EEOI \text{ or } CII \text{ attained } \left[ \frac{g}{tonne - nm} \right] = \frac{Emission_{CO_2}}{DWT \text{ or } GT [tonne] \times Distance \text{ Sailed } [nm]} \quad (9)$$

$$CII_R = aCapacity^{-c} \quad (10)$$

$$\text{Required Annual Operational } CII = \left( 1 - \frac{Z}{100} \right) \times CII_R \quad (11)$$

where  $Z$  refers to the reduction factor, starting from 5% in 2023 and afterwards increasing by 2% each year. The  $CII$  reference value  $CII_R$  (10) is based on the respective ship type and capacity from the table found in MEPC.353 (78) (The Marine Environment Protection Committee, 2022a). The values of  $a$  and  $-c$  are 930 and 0.383 respectively. The distance sailed in this study is the average distance travelled by the diesel operational tugboat of 10.4 nm. The calculated values will have a  $CII$  rating based on Table 3. The rating is based on the ratio of  $EEOI$  or  $CII$  attained (9) to the required  $CII$  (11), where a higher ratio indicates a worse rating, and vice versa. Any values lower than column B in Table 3 are rated as A (Gianni *et al.*, 2022). As tugboats are not categorised under the list of vessel types in MEPC.354 (78) (The Marine Environment Protection Committee, 2022a), this study adopts the cruise passenger ship values for  $EEOI$  calculations and  $CII$  ratings.

**Table 2 CII rating for the different types of ships** (The Marine Environment Protection Committee, 2022b)

Ship Type	Ship Size	B	C	D	E
Bulk Carrier		0.86	0.94	1.06	1.18
Gas Carrier	DWT ≥ 65,000	0.81	0.91	1.12	1.44
	DWT < 65,000	0.85	0.95	1.06	1.25
Tanker		0.82	0.93	1.08	1.28
Container Ship		0.83	0.94	1.07	1.19
General Cargo Ship		0.83	0.94	1.06	1.19
Refrigerated Cargo Carrier		0.78	0.91	1.07	1.20
Combination Carrier		0.87	0.96	1.06	1.14
LNG Carrier	DWT ≥ 100,000	0.89	0.98	1.06	1.13
	DWT < 100,000	0.78	0.92	1.10	1.37
Ro-ro Cargo Ship (VC)		0.86	0.94	1.06	1.16
Ro-ro Cargo Ship		0.76	0.89	1.08	1.27
Ro-ro Passenger Ship		0.76	0.92	1.14	1.30
Cruise Passenger Ship		0.87	0.95	1.06	1.16

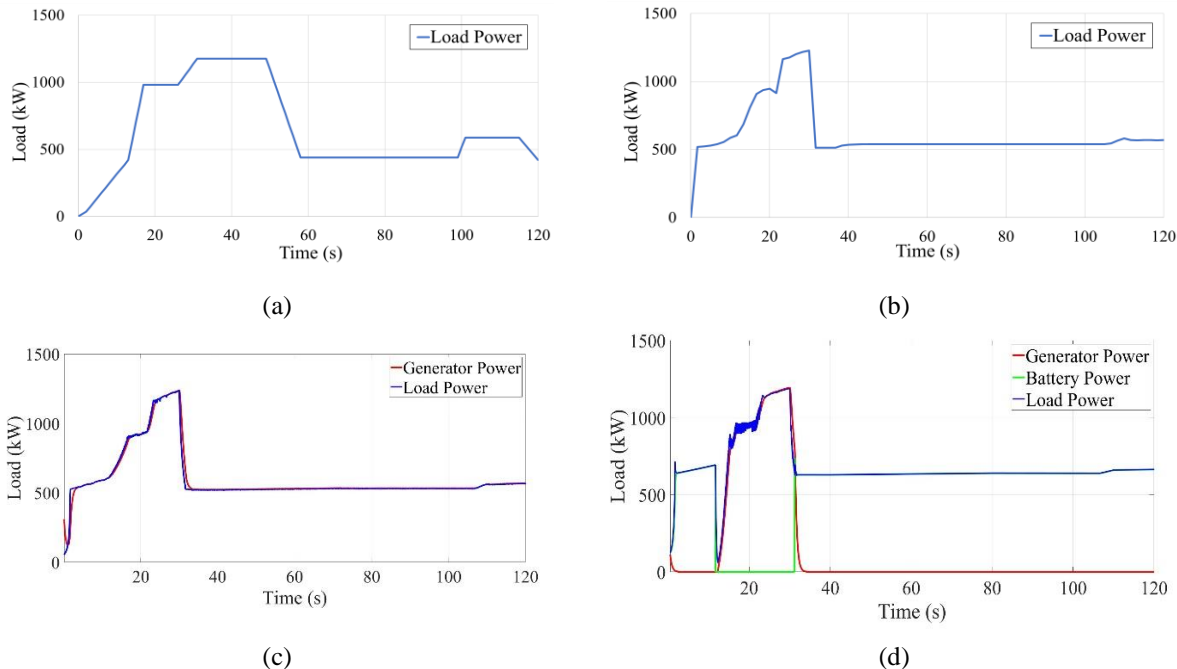

## 4. RESULTS AND DISCUSSION

The results and discussion in this section are of the following cases: (I) System validation and (II) Varying environmental conditions. The types of system of configuration considered in this paper include diesel, LNG with variable engine speed and two variations of LNG-battery hybrid with control strategies. The target of the study is to first provide validity of the system model based on past operational results in Case I. This is followed by studying the different effects on the vessel load, annual operational cost and CO<sub>2</sub> emissions when different environmental conditions are encountered in Case II. The study is then concluded with a comparison of the different system configurations and highlighting the most economically friendly based on the different results and design sustainability based on CII ratings. The load profile presented in this section represents a single tugboat operation based on the system models mentioned in the System Overview.

### 4.1 Case I: System Validation with Past Operational Data

The purpose of system validation of the system modelled is to showcase the reliability and accuracy of the profiles simulated when compared to real-time operations. The load profiles used in this study are based on a combination of manually logged engine load data from past operations conducted by JMS Kappa and the designed operation load profile distribution of the LNG-battery hybrid tugboat provided by the industry collaborator. The ideal distribution of the load profile used in this study is shown in Figure 8(a). Figure 8(a), however, does not factor in the distance of the operation including the environmental conditions, as shown in Figure 5, which will affect the duration during the specified operation.

On the other hand, Table 3 breaks down the load profile given in Figure 8(a) by the operational profile by using both the manual data obtained and the duration of the stated operation provided by the industrial collaborator. Figure 8(b) however shows the results of the same input from Figure 8(a), with the consideration of the distance, environmental conditions and added resistance in AMESIM. Results show that travelling at a higher speed of 10-12 knots in Figure 8(b) requires a shorter time when compared to Figure 8(a). The breakdown of the operational profile in Figure 8(b) by its distributed duration and simulated load, is given in Table 3 where a majority of the operation is spent on tugging. The average load for Figure 8(a) is 630kW. Compared to the average load of 606kW of Figure 8(b), that factors the added resistance throughout the trip. A lower average load since more than 50% of the operation was spent tugging and requiring a load less than 550kW, reducing the overall average load. As compared to Figure 8(a) which spent 35% of the operation tugging and spent a longer duration transiting at 10-12 knots, hence the higher average load. The following study in this paper references Case I results shown in Figure 8(b) as the controlled load profile.

**Figure 8: (a) Load profile based on past data (b) load profile based on operational conditions (c) Load profile simulated without battery (d) Load profile simulated with battery**

Several types of system configurations such as diesel, LNG and LNG-battery hybrid with control strategies are then simulated to compare the annual cost and CO<sub>2</sub> emissions emitted based on the calculations in Section 3. Table 4 summarises the annual fuel cost and annual CO<sub>2</sub> emissions from the different system configurations. To simplify the annual calculations, no day off or downtime of the vessel throughout the year was assumed. Figure 8(c) and Figure 8(d) display the results of LNG

propulsion and LNG-battery hybrid systems on Simulink respectively. LNG-RB configuration displays the best results when compared to the other system configurations. The LNG-RB control strategy can reduce annual CO<sub>2</sub> emissions by up to 96.5% and save annual fuel operation costs of up to 95.3%. This is an improvement as compared to the results found in Roslan *et al.* (2023) because of the difference in the distribution of operation duration shown in Table 3 and the lower average load. It is worth mentioning that RB strategies will differ from study to study, it is not a one rule fits all solution. A separate RB study conducted by Diniz *et al.* (2023) controls the operational performance of the generators of an escort tug to perform at optimal efficiency and to have bi-directional battery control, which reduced CO<sub>2</sub> emissions by 10.7% for a single load profile.

Although LNG-RB results in having the best results concerning cost and emission, the number of daily trips is lesser than the conventional diesel system. This is due to the high battery usage per trip of 73.2% when compared to the other hybrid control configurations as shown in Table 4. The total number of trips completed daily is calculated based on the total duration of a day divided by the total time to complete an operation and the time to charge the battery fully. Therefore, with a higher SOC used, it will require the ship to return to port to charge after every trip. Without a bi-directional converter the battery will not be able to charge offshore, hence limiting the number of trips daily. With the current battery system configuration, the only means of charging is by connecting to shore power or swapping batteries. Therefore, with the current battery system configuration the LNG/BAT at 80% LNG and 20% battery load distribution configuration is ideal, since it consumes 16.2% SOC. A more operational-orientated configuration where a fully charged battery is capable of a single operation of up to 10 hours or five 120-minute operations, with varying loading conditions between idle, transiting and tugging up to an average of 3150kWh power consumption. While still having a reduction of annual fuel cost and CO<sub>2</sub> emissions by 65.9% and 27.7% respectively.

**Table 3 Operation Profiles**

Operation	Logged Load (kW)	Designed Duration (%)	Simulated Load (kW)	Simulated Duration (%)
Idle	420	10	521	6.9
6-knot Transit	588	25	549	26.4
10-knot Transit	980	10	927	5.6
12-knot Transit	1176	20	1083	8.3
Tugging	440	35	538	52.8

**Table 4: Case I results in comparison using different system configurations.**

Fuel Type	Annual Fuel Cost (\$USD)	Annual CO <sub>2</sub> Emission (tonne)	Battery SOC used per trip (%)	Number of trips Daily	% Reduction*	
					in Cost	in CO <sub>2</sub> Emissions
Diesel	2,571,224	8,050.1	-	12	-	-
LNG	917,906	6,245.5	-	12	64.3	22.4
LNG-RB	121,678	278.2	73.2	10	95.3	96.5

## 4.2 Case II: Varying Environmental Conditions (Extreme and Operational Cases)

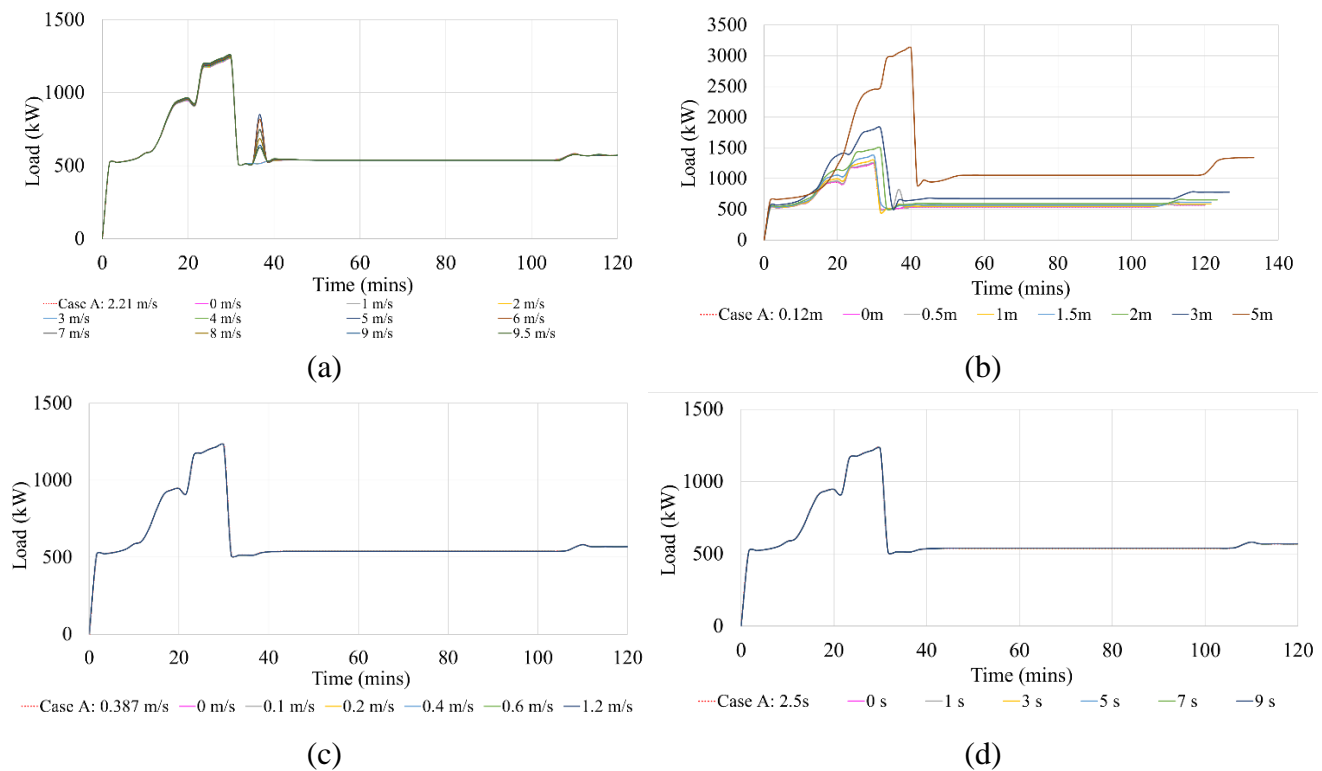

### 4.2.1 Loading and Energy Consumption of Battery

The four environmental conditions that investigated in this paper are based on the capabilities of the Simcenter/AMESIM module MARWAT00R, i.e., wind speed, wave height, current speed and wave period. The data are based on the data mentioned in Section 2.2 The required vessel loads of the varying extreme environmental conditions are then simulated between the minimum and maximum values based on past data experienced along the vessel route shown in Figure 5. Figure 10(a) compares the vessel load with varying wind speeds ranging between 0 m/s and 9.5m/s. An increase in the load is observed when a

variation of vessel speed is required. Significant observation can be seen at 30 – 40 minutes where a change of speed is required to accelerate back up. A surge of load is observed to increase incrementally with the wind speed. However, the average vessel load only increased by 0.93% when the wind speed increased to 9.5m/s from 0 m/s as observed from the AMESIM simulation. Table 5 summarises the comparison of the extreme results between the minimum and maximum environmental conditions. Aside from the vessel load, the vessel's added resistance and specific fuel consumption (SFOC) are also compared using the Simcenter/AMESIM software. A decrease of 0.24% and an increase of 0.97% were observed for the average SFOC and vessel's added resistance respectively.

A major difference could be observed when comparing the results of varying wind speeds against varying wave heights. In Figure 10(b), the vessel load of varying wave heights is shown, ranging from 0m to 5m. Notably, two key variances emerge in terms of the total time required to complete the operation and the maximum load. The total duration for completing the same operation extended from 120 minutes to 133.3 minutes, while the maximum load surged from 1228kW to 3121kW. Comparing between 0m and 5m wave heights, the average load doubled. This increase in the average vessel load led to a rise in the average vessel's added resistance by 50.3kN, nearly seven times higher than the results obtained without considering any wave height. From past studies found in Roslan *et al.* (2023), the higher the vessel load required the lower the SFOC. A decrease of 9.6% in the average SFOC was observed due to the higher average load in general.

However, simulating extreme conditions of current speeds and wave periods produced minimal to negligible effects on the vessel load, SFOC, and added resistance. Figure 10(c) illustrates the absence of effects on the vessel when varying current speeds within the range of 0 m/s to 1.2 m/s. Additionally, Figure 10(d) depicts the variation in wave periods between 0 seconds and 9 seconds, resulting in a mere 0.06% increase in average load and a 0.80% increase in the average vessel's added resistance observed in the AMESIM simulation (see Table 5). A summary of the findings from the varying environmental conditions is shown in Table 5, concerning the difference in percentages between the minimum and maximum results. Based on the summary Table 5, the environmental conditions that govern the loading and energy consumption of the vessel are the varying wind speeds and wave heights.

**Figure 9: Load profiles of (a) varying wind speeds (b) varying wave heights (c) varying current speeds (d) varying wave periods**

**Table 5: Results comparisons between the minimum and maximum results from varying environmental conditions**

	Wave Period	Current Speed	Wind Speed	Wave Height
<b>Load</b>	0.06%	0.00%	0.93%	104.03%
<b>SFOC</b>	-0.02%	0.00%	-0.24%	-9.62%
<b>Added Resistance</b>	0.80%	0.00%	0.97%	681.96%

#### 4.2.2 Annual Costs and CO<sub>2</sub> Emissions

Next, the study focuses on studying the average load, annual fuel operational cost and CO<sub>2</sub> emissions for the different system configurations under varying environmental conditions of the specified route. The range of values of wave heights is based on the average values obtained from past data (Windfinder, 2020) where the typical wave height along the route and around Singapore typically averages between 0.5 m and 1.0 m (Bricheno *et al.*, 2015).

The annual fuel operation cost and annual CO<sub>2</sub> emissions for the varying operational conditions under different wave heights are shown in Table 6 and Table 7, respectively. A small difference in the average load is observed between 1.0m and 0.5m wave height at 608.14kW and 608.20kW respectively. The change in speed from high speed to low speed causes the vessel's average load to be higher at 0.5m wave height. The 1.0m wave height, however, takes more time (1.67 minutes more in the simulation) to complete the operation. The results for the annual cost and annual CO<sub>2</sub> emissions are found to correlate with the increase in average load where the cost and emission increase with the increase in average load. The highest increase in the annual fuel operation cost and CO<sub>2</sub> emissions along the route due to wave heights is by 4.8% and 16.3% respectively, at 0.5m wave height using LNG-RB system configuration. This is likely due to the increase in the average load from 604.45kW to 608.20kW, although a higher load typically leads to having lower SGC. The period where the increase in load for this configuration occurred was less than 800kW, therefore 200g/kWh SGC was consumed instead of 195g/kWh resulting in a higher cost and emission.

\* concerning respective Case I results

The operational wind speed experienced by the vessel along the route changes from 0 m/s to 9.5 m/s, as indicated by data collected from sensors on a vessel navigating the same route. Table 8 and Table 9 present the differences in annual cost and annual CO<sub>2</sub> emissions, respectively. The average load is 602.16kW at 0m/s and 606.55kW at 9.5m/s wind speed. This load is lower when compared to the impact of wave height. The increase in average wind speed along the route results in a 2.8% rise in annual fuel operation cost and a 9.4% increase in annual CO<sub>2</sub> emissions at a wind speed of 9.5m/s using the LNG-RB system configuration. The results with 0m/s wind speed are expected to be lesser in cost and emissions because Case I was simulated with an average wind speed of 2.25m/s.

\* concerning respective Case I results

In summary, the results summarised in Table 5 show the extreme results for load, SFOC and added resistance between the minimum and maximum environmental conditions. Varying wave heights are found to have the highest effect on the results followed by varying wind speed. The results from varying operational wave heights show an increase of up to 4.8% and 16.4% in the annual fuel operation cost and annual CO<sub>2</sub> emissions, respectively. As for the varying operational wind speeds, an increase of up to 2.8% and 9.4% in the annual fuel operation cost and annual CO<sub>2</sub> emissions, respectively. Additionally, different system configurations were tested. Similar to Case I, the LNG-RB configuration demonstrated the most significant reduction in cost and emissions when compared to the diesel configuration. The capabilities of the system model used in this study to simulate the effects of environmental loads to the system performance will be beneficial for vessel operator or machine learning algorithms. Algorithms such as route optimisation-based solutions based on the most efficient conditions discovered in this paper. Having knowledge of which environmental conditions to avoid will save valuable operational cost and emissions.

### 4.3 Economical and Sustainability System Comparison

With the results of the different system configurations in Case I and Case II, the CII ratings of the respective system are then calculated using the equations (9) – (11) expressed in Section 3. Table 10 summarises the results of the CII ratings for the following years based on the results simulated. Achieving a grade “A” CII rating signifies a highly efficient ship in reducing carbon emissions during operation. With future readiness for a more environmentally friendly maritime industry. Vessel designs with a score of “D” or “E” for three consecutive years are required to develop a corrective action plan. Based on the CII ratings of the configuration tested, it is highly recommended that the vessels operate with at least 30% of the load with battery and 70% on LNG. Operating on diesel and LNG is not recommended since it is the least efficient with a grade “E” CII rating.

**Table 10: CII Ratings of the respective configurations through the years**

Configuration \ Year	2024	2025	2026	2027
<b>Diesel</b>	E	E	E	E
<b>LNG</b>	E	E	E	E
<b>LNG-RB</b>	A	A	A	A
<b>LNG/BAT (10/90)</b>	A	A	A	A
<b>LNG/BAT (20/80)</b>	A	A	A	A
<b>LNG/BAT (30/70)</b>	A	A	A	A
<b>LNG/BAT (40/60)</b>	A	A	A	A
<b>LNG/BAT (50/50)</b>	A	A	A	B
<b>LNG/BAT (60/40)</b>	A	B	C	D
<b>LNG/BAT (70/30)</b>	B	C	D	E
<b>LNG/BAT (80/20)</b>	D	E	E	E
<b>LNG/BAT (90/10)</b>	E	E	E	E

Although the CII ratings play a big part in selecting a system configuration with efficient carbon emission and sustainability, the reality in operation is to have a system design capable of providing both efficiency in completing more operations and in reducing emissions. LNG-RB demonstrated the best in performance with the biggest reduction in annual fuel operation cost and annual CO<sub>2</sub> emission and obtained a grade “A” CII rating. However, the total number of trips capable of completing within a day is limited to 10 trips as compared to the 11 trips using a 30% LNG and 70% battery load distributed system. The single increase in operation leads to an increase in the annual fuel operation cost and CO<sub>2</sub> emissions by \$USD 305,663 and 2,202 tons, respectively. It is imperative, therefore, to refrain from increasing the trip count to 11, and instead allocate the extra time for battery charging due to the significant surge in costs and emissions. With the cost saved, an enhancement to the configuration could involve incorporating a bi-directional converter due to their electrical isolation capabilities and high reliability in renewable energy sources (Dung *et al.*, 2017), and also enabling the battery to be charged by the LNG generators onboard.

The annual fuel operation cost and CO<sub>2</sub> emissions results from this paper could be used for a further study on the life cycle assessment (LCA) and life cycle cost assessment (LCCA) of the LNG-battery hybrid system model. A similar study done by Fan *et al.* (2021) where the economic and environmental impact of the lifetime of a LNG-battery hybrid river ship was assessed and compared to a diesel propulsion. The annual emissions reduced by 33.44% and fuel cost reduced by 39.15%, including carbon emission tax, when compared between the LNG-battery hybrid to diesel system. For future LCA assessment on CO<sub>2</sub> emissions, factors to consider include but not limited to the following: emission during equipment manufacturing stage, energy production stage and energy transportation. For LCCA on the other hand considers the total cost including investment cost,

operation cost (maintenance cost, fuel cost and carbon credit cost) and decommission cost. The results from Fan's LCCA concluded with LNG-battery hybrid system costing less than the diesel-powered system. Future works alternative tugboats propulsion systems should consider comparing different renewable energies such as methanol and hydrogen. A similar work had been done by Perčić *et al.* (2021), where he investigated on the LCA and LCCA of various ships using alternative fuels. The study concluded with fully electric ships being the most environmentally and cost-effective solution, followed closely by methane and LNG. A similar study could be conducted in the near future for tugboats with the results obtained from the current study which will benefit potential vessel owners before converting current diesel systems to an alternative renewable energy propulsion system.

## 5. CONCLUSIONS

The paper presented the influence of environmental loads and manoeuvre on the vessel load in several different system configurations. The configurations include a full diesel system, LNG system, LNG-battery hybrid system with rule-based control and LNG-battery hybrid system with flexible load sharing. The annual fuel operation cost, annual CO<sub>2</sub> emissions and CII ratings for each system configuration at the varying environmental load were calculated and discussed in the paper. The cases covered in this paper are as follows: Case I: System Validation and Case II: Varying environmental conditions. Case I validates the system modelled with past results manually captured from similar tugboats. The model was created on Siemen/AMESIM for the diesel system configuration and MATLAB/Simulink for the LNG and LNG-battery hybrid systems. The LNG-RB system showcased its capabilities with the lowest annual fuel operation cost and annual CO<sub>2</sub> emissions when compared to the conventional diesel system with a reduction of 95.3% and 96.5% respectively.

The results in Case I were set as a benchmark when compared to results from Case II with the varying environmental conditions. The conditions included in the study are wind speed, wave height, current speed and wave periods. Each environmental condition was tested between zero and the extreme condition experienced through the route. The results concluded that wave height had the biggest impact on the vessel load performance, with an average increase of 104.03% and 681.96% in load and added resistance respectively. The varying wind speed displayed a slight increase in the load and added resistance, unlike the varying current speed and wave periods that had no impact on the vessel's performance. The wave height and wind speed are then simulated using operational conditions to calculate the respective annual fuel operational cost and annual CO<sub>2</sub> emissions. The operational wave height along the route ranges between 0.5m and 1m. An increase of up to 4.8% and 16.3% to the annual fuel operational cost and CO<sub>2</sub> emissions when compared to Case I results. The operational wind speed experience along the route simulated ranges between 0 m/s to 9.5m/s. An increase of up to 2.8% and 9.4% in annual fuel operational cost and CO<sub>2</sub> emissions can be obtained between extreme wind speed and average wind speed at 2.25 m/s.

The paper concludes with the CII ratings of each system configuration to find the most efficient system for reducing emissions. LNG-RB and LNG/RB load sharing with more than 40% battery load had the best CII rating of grade "A". However, based on the number of daily trips capable of completing with a fully charged battery, LNG-RB was limited to 10 trips whereas LNG/RB with 30% LNG and 70% battery load sharing was able to complete 11 trips. The annual increase in cost and emission for the additional trip increased by \$USD 305,663 and 2,202 tons, respectively. Therefore, it is more economical and efficient to maintain 10 trips using LNG-RB system configuration. Using the allowance of time to travel back to shore for charging or battery swap. Moreover, the funds designated for this purpose could be redirected to enhance the vessel system by integrating a bi-directional converter. This converter facilitates better control over the battery's voltage and current, crucially enabling offshore charging by the LNG generators. To enhance the credibility of the modelled system, future investigations should encompass a broader range of case studies, including diverse routes and varying operational vessel loads. Subsequent studies could involve integrating live sensor data into the model to create a digital twin capable of producing route optimisation and load predictions.

# An optimisation-based approach to reduce fuel consumption and emissions from shipping navigation

Ribeiro e Silva, S.<sup>1,\*</sup> and Bento Moreira, M.<sup>2</sup>

## ABSTRACT

*This study presents an optimisation-based approach to reduce fuel consumption and emissions from shipping navigation. The main objective is to improve energy efficiency and simultaneously turn a case-study vessel compliant with Carbon Intensity Indicator (CII) proposed by IMO. This optimisation module has been devised as part of a new robust integrated real-time digital solution that will involve a significant number of both technical and operational measures in practice aiming to optimise operational efficiency (during navigation and port calls). Namely, the tool will be capable of situational awareness and decision support to reduce fuel consumption and Green House Gas (GHG) emissions from shipping and must be combined with intrinsic vessel systems to improve vessel hydrodynamic performance, resulting also in improved vessel safety and widening of the operational weather window.*

## KEY WORDS

Ship energy efficiency; Real-time fuel consumption estimation; Hydrodynamic optimisation; Weather routing; Vectorized simulated annealing.

## INTRODUCTION

As the most energy efficient mode of transportation, the maritime transport sector is one of the major sectors of cargo shipping of goods around the world, but is also responsible for 681 [t] of CO<sub>2</sub> every year (see Hieminga and Luman (2023)). Hence, IMO is targeting a drastic reduction of Green House Gas (GHG) and CO<sub>2</sub> for shipping (see IMO (2023)). These ambitious targets involve major changes in the way ship owners, in general, and the maritime industry sector operates, bringing the need to adopt new technologies, investing in greener alternative fuels and adopting practical measures to improve current energy efficiency of the means of transportation.

In addition to this most challenging context of the maritime industry sector, many weather routing service providers claim the ability to save fuel and increase safety and schedule reliability. However, many seaman lives are frequently put at risk since more than 3,000 containers are lost overboard every year. According to the most recent report issued by the World Shipping Council ((see Larsson (2023)), the average annual loss for the two-year period 2020-2021 saw an increase to 3,113 from the 779 of the previous period, driven by major incidents. In 2020 the ONE Opus lost more than 1,800 containers in severe weather. The Maersk Essen also experienced severe weather in 2021 that resulted in the loss of some 750 containers. Also a study conducted by Gershanik (2011) revealed that weather routing helped to reduce ship rough weather damages by 73% and costs of maintenance and cargo damage law suits by 29% and 87%, respectively. At the same time the length of ship delays due to unfavourable weather reduced by 80% and fuel savings amounted to about 6%. With exaggerated capabilities and unsubstantiated benefits being advertised by weather routing companies, port authorities, ship owners,

operators or charterers often face the difficult task of selecting the right service provider and level of technology suitable for their operations.

Anticipating that fuel prices in years to come will remain high due to war in Ukraine (see International Energy Association (2023)) and the conflict in the Middle-East plus the recent emphasis on reducing GHG emission in Europe, have resulted in renewed interest in further optimising ship performance. A recent DnV study (see DNV (2022)) indicated that while hydrodynamic performance (hull coating, hull form and trim optimisation and regular propeller cleaning) can achieve 5 to 15% reduction in fuel consumption and associated GHG emissions, more than 20% improvement can be achieved through technical and operational measures such as speed management, fleet planning and weather routing (the so-called logistics and digitalisation). Moreover, an experimental campaign conducted by HSVA with scaled models of a containership have demonstrated that hydrodynamic performance can be further improved in case an anti-rolling tank is installed to reduce ship motion waves (see HSVA (2020)).

To tackle the problem above, firstly, a numerical program has been developed at University of Lisbon, IST to evaluate added resistance in waves using output data of a standard strip theory seakeeping program developed by Ribeiro e Silva (2008). In this case, the strip theory code is based on Frank's Close-Fit method and the added resistance in waves is evaluated using the formulation originally proposed by Salvesen (1978). The program has provided good results against experimental data available in literature, especially for slender ship forms (see Ribeiro e Silva et al. (2011)). The numerical predictions presented in here have been compared against experimental data relative to ship's models with the same  $L/B$  ratio. Additionally, another Computational Fluid Dynamics (CFD) solver of the Navier-Stokes (N-S) type has been utilised to provide additional numerical predictions of the ship's total resistance in calm water and more detailed information on the flow characteristics around the ship's hull for distinct trim angles (see further details in Ribeiro e Silva and Eça (2024)). More recently progressive increase in memory and speed of computers favours the utilisation of CFD N-S solvers, for current voyage planning purposes (i.e., simulations close to real-time for variable meteorological conditions) in conjunction with Salvesen method to predict added resistance in waves seems to be the most suitable decision support tool. Where a multi-dimensional (velocity and heading), multi-disciplinary constrained (rms ship motions and eventually with prevention of dynamic instabilities in waves), single objective (fuel consumption) optimisation algorithm has been proposed in order to take into account not only the pertinent fuel savings, but also the safety aspects of the voyage. Efforts have been focused so far on key technical-economic challenges that can demonstrate cost effectiveness and applicability of the concept. In particular, use of CFD simulations have been conducted with the aim of obtaining reliable predictions of calm water resistance, which combined with corrections for current, wind and wave effects lead to the development of this optimisation-based approach to reduce fuel consumption and emissions from shipping navigation.

Furthermore, development of a voyage planning module based on weather routing to save fuel and increase safety and schedule reliability (in terms of Just in Time arrival to port) has been envisaged. Hence, prior to integration of voyage planning module with the other Ship Operation Optimisation System (SOOS) modules and their full-scale demonstration during sea trials, all these modules must be extensively tested in a virtual environment to properly de-risk this new technology.

Firstly, the methodology used in this paper is presented in the Theoretical Background section, where an optimisation-based approach for enhanced fuel efficiency and safety aboard is described.

Secondly, in the Numerical Results section, some preliminary figures on the performance of the newly developed voyage planner are shown for a synthetic environment to demonstrate the capabilities of the tool. Namely, the range of surface currents, wind loading conditions and sea states which a typical containership usually operates in the Atlantic West coast of Portugal were simulated in order to set a numerical model that could be utilised to calculate the optimised fuel consumption for a desired average speed between two ports.

As mentioned in Conclusions, it is believed that calculation of specific hydrodynamic responses such as added resistance in waves for a real-time loading condition of the vessel, represents a major advantage in comparison with other commercial available tools, allowing as well the designer to define the most suitable hullform and superstructure area for the most energy efficient mode of operation of the vessel.

## THEORETICAL BACKGROUND

In general, the hydrodynamic performance of a ship is influenced by the surrounding environmental conditions. In this context the existing space and time realizations of wind, waves and ocean current conditions can be defined as the environmental factors in any voyage. These factors will affect the fuel consumption by changing the power requirements for the propul-

sion of the vessel. Hence, this section attempts to presents a summary of the basic concepts in the realm of power estimates for the ship propulsion.

## Power Curve Estimation

Ship's resistance is particularly influenced by the ship's hullform, speed, displacement and trim. In addition to these calm water parameters, added-resistance in waves or even wave-induced roll motion can also have a significant impact in the power delivered by the propeller. The total resistance  $R_T$  consists of several resistance components acting on the ship, which will be briefly describe in this section, while also referring to some relevant works that provide a more thorough and analytical presentation of methodologies to estimate those components of ship's resistance.

Hydrodynamic analysis for a specific hullform and ship loading condition can be used to calculate the components resistances acting on the ship by means of dimensionless resistance coefficients (see for example Harvald (1983)). This analysis may consist of using towing tank tests with scaled models, developing CFD models to simulate the flow around the ship, quasi-experimental methods using results of experiments and calculations. In case, calm water resistance is obtained, then seakeeping models can be utilised to estimate ship motions in irregular waves. In terms of CFD applications there are open source or commercial software that can be used in modelling ship resistance. In this study, CFD Simerics MP software considering a marine template to calculate ship resistance is used to determine calm water effective hull resistance at a given loading condition and range of ship speeds, i.e., the so-called power curve in calm water.

Calm water resistance is what a vessel would face in the event of total calm weather conditions, with an absolute lack of waves excluding the waves created by the ship moving in otherwise calm deep water condition. Calm water is very seldom encountered in real world conditions, particularly in ocean going voyages. For example, in the North Atlantic the probability of encountering calm water conditions is only 26 days in a year, i.e., 0.7%.

According to Scheekluth and Bertram (1998), calm water total resistance of a ship is made up of a number of different components, which are caused by a variety of hydrodynamic factors, and interact one with each other in a extremely complex way. Adopting a reductionist approach, calm water resistance consists of a viscous resistance plus the resistance due to the Kelvin waves generated by the hull. Viscous resistance is due to the viscosity of the water, which creates friction with the hull of the ship and depends, among other things such as the hull surface curvature, on the hull roughness and cleanliness of the hull. With regard to the second component of calm water resistance component, wavemaking resistance,  $R_W$ , is closely associated with Kelvin wave system (i.e., waves generated from a moving pressure field with divergent and transverse systems). As it can be seen in Fig. 1, the wave system of a ship is composed of different Kelvin wave systems. Note that waves are generated by every point of the containership, where larger waves (more visible) are generated at the bow and stern.

**Figure 1:** Different Kelvin wave systems of a typical containership, where: a) divergent bow wave; b) divergent stern wave; c) transverse wave; d) turbulent wake; e) quarter wave.

Ship calm water resistance,  $R_T$ , can be calculated as a function of the total resistance coefficient,  $C_T = C_V(Rn) + C_R(Fn)$ , the density of seawater,  $\rho_{sw}$ , the ship's speed over water,  $V_s$ , and the total wetted area of the hull,  $S_w$ , given by Eqn. (1).

$$R_T = \frac{1}{2} \rho_{sw} S_w V_s^2 C_T = \frac{1}{2} \rho_{sw} S_w V_s^2 (C_V + C_R) \quad (1)$$

Note that equation above is a simplified formulation of the complex nature of ship resistance in calm water, where viscous resistance coefficient,  $C_V$ , is assumed to be only dependent of Reynolds number ( $Rn$ ), whereas the coefficient of residuary resistance,  $C_R$ , mainly composed by wavemaking resistance,  $C_W$ , is assumed to be dependent on Froude number ( $Fn$ ). Once the main resistances have been estimated, it is possible to calculate the required effective power with appendages,  $P_{EA}$ , to move the ship through the water at the required sailing speed. Note that the effective power is simply the product of the total resistance times the speed over water,  $V_S$ . Based on that, the required nominal power at the main engine shaft ( $P_S$ ) can be calculated using the shaft-line efficiencies, given by Eqn. (2).

$$P_S = \frac{P_{EA}}{PC} = \frac{R_{EA}V_S}{QPC\eta_S} = \frac{(R_T + R_{APP})V_S}{\eta_H\eta_O\eta_R\eta_S} \quad (2)$$

Hull efficiency,  $\eta_H = \frac{P_{EA}}{P_T}$ , is the ratio between the effective power with appendages and the power thrust, which depending on hydrodynamic pressure distribution around the hull, may attain values larger than 1.0. Open water propeller efficiency,  $\eta_O = \frac{P_T}{P_{D_o}}$ , ranges approx. 0.60-0.75, whereas relative rotative efficiency,  $\eta_D = \frac{P_{D_o}}{P_D}$ , of a conventional propeller ranges approx. 0.95-1.02. Note that power thrust ( $P_T$ ) of the propeller is the power output that can be measured at thrust block bearing, whereas the open water delivered power or propeller power in open water ( $P_{D_o}$ ) is the power input measured during scaled model test of the propeller in open water, i.e., either towing tests or cavitation tunnel tests to measure thrust and torque developed by the rotating propeller without the presence of the ship's hull. Hence, propulsive coefficient ( $PC$ ) can be calculated from quasi-propulsive coefficient ( $QPC$ ) once shaft transmission efficiency is known, which is given by the ratio between delivered power with the propeller installed behind the hull (power measured at propeller flange) by power at the main engine shaft, i.e.,  $\eta_S = \frac{P_D}{P_S}$ . Shaft transmission efficiency in conventional propulsion systems ranges 0.97-0.99 depending whether a simple or reversible reduction gearbox is intercalated in the shaft line or not (cases where 2-stroke low-speed diesel engine is installed).

**Figure 2:** Different power and efficiencies along the shaft-line of a propulsion system, and locations where: a) effective power with appendages; b) shaft power; c) delivered power; d) thrust power can be measured.

As illustrated in Figs. 1 and 2, the behaviour of the flow around the hull determines the ship resistance and the wake at the propeller, which are interrelated. While the magnitude of the resistance directly determines the power requirements, the magnitude of the wake and its distribution at the propeller plane also affects the power requirements as well as the performance characteristics. When the wake distribution is highly non-uniform at the propeller plane, this is a major source of poor propulsive efficiency ( $\eta_R$ ), cavitation, vibration and noise. Assuming some simplifications, the main engine that satisfies the propeller's demands, and allows the ship to sail at its nominal speed during voyage, can be selected. Note that this main engine rated power should cover the propulsion demands considering as well an appropriate power margin that will depend on certain cost elements (acquiring, operating and maintenance), reliability and adaptability to different operating patterns of the vessel.

## Wind Resistance

In first place, it is recalled that wind is the cause to the creation of waves so that their incoming direction is sometimes practically the same, and simultaneously wind acts as a force on the vessel known as wind resistance. Wind resistance will affect all surfaces of the ship above the sea-surface as well as cargo when the latter is above the hull, as it is the case of most containerships. According to Bernoulli's equation, wind resistance either in the  $x$  or  $y$  direction is directly proportional to the projected transverse cross-sectional ( $A_T$ ) or lateral ( $A_L$ ) areas of the ship above the waterline, the density of the air,

$\rho_{air}$ , and the square of the wind speed. These two projected areas are defined by the above-water part of the main hull and any superstructures (e.g., cargo, bridge, funnel, and equipment). Normally wind represents around 2% of the total resistance, with the notable exception of container ships where due to both large projected transverse cross-sectional and lateral areas of the vessel (due to 60% of containers on-board are piled-up above main deck) the contribution can reach up to 10%.

**Figure 3:** The non-inertial body-fixed tri-axial coordinate system of the ship, illustrating the six modes of motion and the definition of the true wind vector ( $\alpha$ ) and wave ( $\beta$ ) incoming direction angles.

The wind force is typically divided into two components: the fair wind, which is what the ship is facing during sailing (same speed but opposite direction of the vessel), and the true wind, which is the actual wind speed and direction at the current position at sea. The former can be computed using either a semi-empirical formulation proposed by Gould (1982) or a standard CFD tool Ribeiro e Silva and Eça (2024) and is essentially the wind that the vessel would face due to the fact it is sailing, while the latter would be the wind the vessel would face at the same location if she was anchored. Adding these two vector components, the resulting apparent wind vector can then be used to calculate the total wind resistance. As illustrated in Fig. 3, the true wind induced longitudinal and transverse force components and the yawing moment can be calculated using the following equations originally derived by Isherwood (1972), Gould (1982) and Blendermann (1994):

$$\begin{bmatrix} F_{wx} \\ F_{wy} \\ M_w \end{bmatrix} = \frac{1}{2} \rho_{air} V_w^2 \begin{bmatrix} C_{wx}(\alpha_w) A_T \\ C_{wy}(\alpha_w) A_L \\ C_w(\alpha_w) x_{wc} \end{bmatrix}, \quad (3)$$

where  $x_{wc}$  represents the distance between the center of the lateral area of the ship above waterline and midships and the force components are given by Eqns. (4) and (5):

$$F_{wx}(\alpha_w) = F_w(\alpha_w) \cos(\alpha_w) \quad (4)$$

$$F_{wy}(\alpha_w) = F_w(\alpha_w) \sin(\alpha_w) \quad (5)$$

Assuming that wind force Cartesian components in surge and sway are expressed by  $F_{wx}(0^\circ)$  and  $F_{wy}(0^\circ)$ , respectively, then the resulting true wind induced force at any given incoming angle,  $\alpha_w$ , may be expressed as:

$$F_w(\alpha_w) = F_{wy}(90^\circ) \left\{ \frac{2 \sin^2(\alpha_w)}{1 + \sin^2(\alpha_w)} \right\} + F_{wx}(0^\circ) \left\{ \frac{2 \cos^2(\alpha_w)}{1 + \cos^2(\alpha_w)} \right\} \quad (6)$$

Note that more precise wind load calculations could have been performed to take into account as well a given vertical wind profile. In this case, an effective wind speed and the lateral center of pressure for a gradient wind could be also estimated by

subdividing the frontal and lateral projections into small elements so that after surface integrals have been conducted new non-dimensional wind load coefficients  $C_{wx}(\alpha_w)$ ,  $C_{wy}(\alpha_w)$  and  $C_w(\alpha_w)$  could be obtained.

## Added-Resistance in Waves

Both involuntary and voluntary speed reductions are taken into account to avoid over-predicted ship speed and wrong diversion decisions when facing rough weather, not to mention inaccurate estimates of fuel consumption and time of arrival. To prevent this problem, added-resistance in waves for a specific loading condition and a given hullform will be computed as well using a state-of-the art numerical tool. Note that this additional component of resistance called added-resistance in waves,  $R_{aw}$ , is heavily non-linear. In fact, estimating added resistance is a complex process, as this generally depends on hullform, hydrodynamic characteristics of the ship and the encountered sea spectrum. For the calculation of the added resistance in waves, Salvesen 1978 method using strip theory approximation has been adopted. In this case, the strip theory code is based on Frank's Close-Fit method and the added resistance in waves is evaluated using the formulation originally proposed by Salvesen plus a correction for short waves. Hence, using this strip theory, Salvesen introduce the added-resistance in waves, given by Eqn. (7):

$$R_{aw} = -\frac{1}{2}k \cos \beta \sum_{j=3,5} \zeta_k \left\{ (F_j^I)^* + \hat{F}_j^D \right\} + R_7, \quad (7)$$

where  $(F_j^I)^*$  is the Froude-Krylov force and moment,  $(F_j^D)^*$  is the diffraction force and moment,  $R_7$  is the added-resistance due to diffraction potential,  $\zeta_k$  is the ship's displacement induced by waves in  $k$  direction.

In case head waves scenario is considered, in this study, the equation can be more conveniently expressed as Eqn. (8):

$$R_{aw} = \frac{i}{2}k \left\{ \zeta_3 \hat{F}_3 + \zeta_5 \hat{F}_5 \right\} + R_7, \quad (8)$$

where the incident and diffracted components are given by Eqn. (9):

$$\hat{F}_j = (F_j^I)^* + \hat{F}_j^D \quad (9)$$

The complex amplitude for the incident wave potential for head waves having wave amplitude  $\zeta_w^a$  and angular frequency  $\omega$  can be expressed by Eqn. (10).

$$\phi_0 = \frac{ig\zeta_w^a}{\omega} e^{ikx+kz} \quad (10)$$

Hence, heave components of added-resistance in waves are given by Eqn. (11):

$$\hat{F}_3 = \zeta_w^a \int_L e^{-ikx} e^{-kds} \{ \rho gb - \omega_e (\omega a_{33} - ib_{33}) \} dx, \quad (11)$$

and pitch components of added-resistance in waves are given by Eqn. (12):

$$\hat{F}_5 = -\zeta_w^a \int_L e^{-ikx} e^{-kds} \left\{ \rho gb - \omega_e \left( x + \frac{iV_S}{\omega} \right) (\omega a_{33} - ib_{33}) \right\} dx, \quad (12)$$

where  $d$  = sectional draft,  $s$  = sectional area coefficient,  $b$  = sectional breadth,  $\omega_e = \omega - \frac{\omega^2}{g} V_S \cos \beta$  = encountering wave frequency,  $a_{33}$  = sectional heave added mass coefficient and  $b_{33}$  = sectional heave damping coefficient. Added-resistance due to diffraction potential can be expressed as Eqn. (13) for calculating head sea result:

$$R_7 = \frac{i}{2} (\zeta_w^a)^2 k \frac{\omega_e^2}{\omega} \int_L e^{-2kds} b_{33} dx \quad (13)$$

Note that a non-dimensional added-resistance in waves can then be simply defined by the summation of the three dimensional components  $R_{aw} = \hat{F}_3 + \hat{F}_5 + R_7$  as:

$$R'_{aw} = \frac{\hat{F}_3 + \hat{F}_5 + R_7}{\rho_{sw} g \left( \frac{B^2}{L_{pp}} \right) (\zeta_w^a)^2} \quad (14)$$

Next, a practical simplification can be introduced to estimate added-resistance in waves directly from head sea result, where added-resistance in waves at any angle  $\beta$  relatively to head waves is given by Eqn. (15):

$$R_{aw}(H_S, T_P, \beta) = R_{aw_{180^\circ}}(T_P) \left( \frac{H_S}{2} \right) \cos^2 \beta \quad (15)$$

## Trim Effect on Ship Resistance

CFD with RANS turbulence models can address a wide variety of flows including external flows around bodies of a certain shape, i.e., statistically steady flows that require streamlined shapes aligned with the incoming flow where boundary-layers do not exhibit significant flow separation. However, for trim optimisation these simulations must be supported by relevant background experience in the realm of CFD tools utilisation and must be subjected to a dedicated Verification and Validation (V&V) procedure.

**Figure 4:** Schiffbau Versuchsanstalt Potsdam GmbH: Open-water propeller test diagram of a variable pitch propeller (VP 1124)

CFD simulations of ship performance in waves will be mainly built around an advanced actuator disk model implemented either in or Simerics MP, which reads the open water performance of a real propeller (see Fig. 4). Notice should be given to the fact that being able to remove the actual propeller geometry from the numerical computations considerably simplifies the physics and speeds up the process. Moreover, experimental results from scaled model testing or sea trials having sys-

tematic draught and trim variations are expected to be compared and contrasted against CFD simulation results in the near future.

Firstly, considering the geometry of the hull, accurate ideal trim predictions of the total CFD resistance in calm water must be determined for enhanced stability and fuel consumption optimisation purposes. Secondly, the vessel floatation, and the corresponding flow characteristics at the propeller plane during operation must be optimised to attain the least required power solution for a specific design loading condition by means of altering the vessel's position of centre of gravity of the ship,  $CG(x, y, z)$ . Note that instantaneous location of the center of gravity of the ship,  $CG(x, y, z, t)$  depends on magnitude and location of a large number  $N$  of  $i$  discrete weights aboard, including fuel and ballast water in the aft and peak tanks, is given by:

$$CG(x, y, z, t) = \frac{\sum_{i=1}^N [m_i(t) \times (x_i, y_i, z_i)]}{\sum_{i=1}^N m_i(t)} = \frac{M_i(x, y, z, t)}{\Delta(t)} \quad (16)$$

Next, using one particular hydrostatic parameter called unit moment to change trim ( $M_U$ ), the required instantaneous trim angle variation,  $\delta\theta(t)$ , for enhanced stability and fuel consumption optimisation purposes can be easily calculated by SOOS from the instantaneous variation in the longitudinal inclining moment,  $\delta M_I(x, t)$ , using the Eqn. (17):

$$\delta\theta(t) = \frac{\delta M_I(x, t)}{M_U} \quad (17)$$

Finally, added-resistance in waves component for this particular new loading condition as well as wave induced roll motion component of total ship's resistance will be computed in the near future using SOOS.

## Vectorized Simulated Annealing (VSA)

Fuel consumption  $C$  while sailing from points  $A$  to  $B$ , depends on the route  $L$  chosen and can be computed using the following line integral with respect to the arc length:

$$C = \int_L \frac{\frac{\partial M}{\partial t}}{V} ds, \quad (18)$$

where  $\frac{\partial M}{\partial t}$  and  $V$  stands respectively for fuel consumption time rate and the speed along  $L$ . Note that  $\frac{\partial M}{\partial t}$  and  $V$  depends particularly on environmental conditions such as wind, currents and waves. Therefore, the route that minimizes global fuel consumption, in such conditions, is not the straight (or geodesic) path from  $A$  to  $B$ .

The approach that has been adopted to find the route  $L$  that minimizes the global fuel consumption is the Vectorized Simulated Annealing (VSA) technique which is based on the Simulated Annealing (SA) method, see Press (2007). This method can be roughly described using the analogy with the metallurgical process of annealing to bring a metal from an high energy/temperature state to a crystal lattice state of minimum/temperature energy. At a high temperature, the different elements that characterize the system register significant variations in their respective positions, resulting from their high kinetic energy. As the temperature decreases, the system assumes lower energy and more stable configurations and the changes in position of the system's constituents occur with a smaller amplitude. In case the temperature decrease is not too rapid and if during it the system has the possibility of assuming less probable configurations (of higher energy), the retention of the system in meta-stable configurations will be less likely. A slow and gradual decrease in temperature will allow the system to properly explore the search space and assume the configuration of minimum energy by the end of the annealing process. SA method was developed by Metropolis and co-workers, see Metropolis et al. (1953). A comprehensive description of this method, also known as the Metropolis-Hastings algorithm, can be found in Hitchcock (2003). The VSA method applies components of the SA algorithm in parallel to a population of systems that constitute the components of a vector. This methodology has been successfully applied in previous works such as Maurício and Moreira (2022).

In the application of the VSA method, paths will be modelled by a process of proper concatenating oriented segments. Note that any path between  $A$  and  $B$  can be arbitrarily approximated in the aforementioned manner. So, define  $N$  concatenated oriented segments  $L_i$  (legs) that establish a route  $L$  between points  $A$  and  $B$ . This path is thus defined by  $N - 1$  yaw points  $P_i$ . The global fuel consumption  $C$  in  $L$  is given by:

$$C(L) = \sum_{i=1}^N C(L_i), \quad (19)$$

where  $C(L_i)$  is the fuel consumption in leg  $L_i$ .

Note that Eqn. (19) can be numerically integrated (with respect the arc length) using a standard numerical integration method (e.g., trapezoidal rule) and adopting an appropriate spatial discretization of the leg over the corresponding leg  $L_i$ .

$$C(L_i) = \int_{L_i} \frac{\frac{\partial M}{\partial t}}{V} ds \quad (20)$$

The aim is to determine the positions of the yaw points  $P_i$  thus determining the path  $L$  that minimize the global fuel consumption  $C$ . As previously mentioned, fuel consumption rate  $\frac{\partial M}{\partial t} = \frac{\partial M}{\partial t}(x, y)$  and speed  $V = V(x, y)$  along the routes depend on environmental conditions.

Note that  $(x, y)$  stand for the spatial coordinates. The estimation of the fuel consumption time rate will consider the effect of wind (intensity and direction), the resistance associated with waves (significant height, period, and direction), and the effect of drift produced by currents. Later on consideration of the effects of roll motion in formulating this fuel consumption optimisation problem will be considered.

## VSA NUMERICAL MODELLING

Main details in the implementation of the heuristic to minimize Eqn. (18) comprises five main steps as follows:

- (i) Generate a set  $U$ , of  $2M$  different routes  $L^j$  from  $A$  to  $B$ , each one defined by sequences of  $N - 1$  yaw points in randomly distributed spatial positions;
- (ii) Compute the fuel consumption  $C(L^j)$  on each one of the routes in  $U$  and retain an ordered subset  $V \subset U$  of the routes with the lower global fuel consumption. Typically  $\#V = \frac{\#U}{2}$ . Note that routes  $L^j$ , in

$$V = \{L^1, L^2, \dots, L^j, \dots, L^k, \dots, L^M\},$$

must be ordered such that  $C(L^j) < C(L^k) \Rightarrow j < k$ ;

- (iii) Construct a new set  $U$  concatenating a new set of  $V$  with previous set of best performers  $V$  and apply a randomly uniformly distributed  $2 - D$  spatial perturbation of maximum semi-amplitude  $\varepsilon$  to the positions of each one of the yaw points that define each of the  $2M - 1$  last routes in  $U$ . The first and better route in the current epoch remain undisturbed and survive to integrate the set  $U$  in the next epoch without any perturbation imposed in order to prevent that a top performer candidate prematurely detected could be discarded;
- (iv) Repeat steps (ii) – (iii) using in each repetition a smaller semi-amplitude  $\varepsilon$  of the maximum spatial perturbation;
- (v) Stop when the best route in  $V$  route fails to show significant improvements or, after  $P$  repetitions.

Note that the successive repetition of steps (ii) – (iv) allows us to define a sequence  $U(i)$ ,  $i = 1, \dots, P$  of route sets and a related sequence  $\varepsilon = \varepsilon(i)$ ,  $i = 1, \dots, n, \dots, P$  of maximum semi-amplitude spatial perturbation of the yaw points, where

each  $i$  define an "epoch". Moreover,  $\varepsilon = \varepsilon(i)$ ,  $i = 1, \dots, n, \dots$ , must be a slowly decreasing function in order to ensure an adequate survey of the search space. In particular, the slow decreasing negative exponential function given by the Eqn. (21) can be used:

$$\varepsilon(i) = d \times e^{-\sigma \times i}, \quad (21)$$

where  $d$  stands for a characteristic length, related with the distance from  $A$  to  $B$ , for instance. The decreasing coefficient  $\sigma$  is given by Eqn. (22):

$$\sigma = \frac{\ln\left(\frac{d}{\delta}\right)}{P}, \quad (22)$$

where  $\delta$  is small residual distance and  $P$  is the global number of epochs. Note that when  $i = P$ , the following detection is obtained:

$$\varepsilon(P) = \delta, \quad (23)$$

which means that  $\delta$  and  $P$  must be selected assuring the decrease of  $\varepsilon$  is slow enough and the spatial perturbations of the position of the yaw points of semi-amplitude of  $\delta$  will be irrelevant.

Before real-data is utilised, a synthetic environment has been proposed to obtain preliminary checks on performance of this decision-support tool. After these V&V studies, the newly developed voyage planner must be compared and contrasted with available sea-trials results.

## NUMERICAL RESULTS

In this section the numerical results of a fully integrated voyage planner for enhanced fuel efficiency and safety aboard a 712 TEU geared containership (see Appendix) are presented. Firstly, a synthetic environment is utilised to check consistency of the fuel consumption results under three scenarios: (i) ocean currents, (ii) wind loads and (iii) wave conditions. Moreover, navigation interdiction zones such as traffic corridors or islands have been introduced to check consistency of the optimisation-based approach to reduce fuel consumption and emissions from shipping navigation.

Finally, using a scenario of real-case meteocean conditions for a given geographical area (obtained from the numerical model MOHID) still in a synthetic environment, some preliminary figures on the performance of the newly developed voyage planner in terms of fuel consumption reduction can be obtained. Note that MOHID is a large circulation hydrodynamic model able to provide either hindcast or forecast predictions of wind, waves, and currents for distinct design-points, i.e., either small domestic routes or long hauls (transoceanic crossings).

### Calm Water Power Estimation

As shown in Figs. 5 and 6, the power curve [knots versus kW], can be modelled by means of a 3rd order polynomial fit of the type  $f(x) = a_3x^3 + a_2x^2 + a_1x + a_0$ , where the coefficients of this polynomial obtained by means of linear regression reads  $a_2 = -0.275$ ,  $a_3 = 6.510$ , and  $a_1 = a_0 = 0.0$ . Note that the polynomial function obtained must be equal to zero at the origin so that effective power will be extinct at ship's zero speed ( $a_0 = 0.0$ ). Moreover, a second condition has been imposed to this polynomial fit of the effective power in terms of having also zero resistance at zero speed, so that at the slope of the effective power at the origin must be also zero, i.e.,  $dP_E/dV_s = 0.0$  at  $V_s = 0$  implying additionally that  $a_1 = 0.0$ .

**Figure 5:** CFD resistance coefficients in calm water from Simerics MP of the containership

**Figure 6:** Power curve in calm water of the containership [m/s versus kW]

Finally, to prevent the power curve to take negative values at low speeds (see Fig. 5) a third local condition has been imposed to force the polynomial to move upwards by means of introduction of an extra point located upwards. This extra point that can be interpreted as an outlier point, whose magnitude is large enough to obtain a forced power curve always positive (see forced data curve of Fig. (6) coloured in red).

From the rated power of the CFD effective power curve at an ideal trim of  $\theta = 0.2^\circ$  by the stern, a propulsive coefficient of the containership at top speed of  $PC = 0.656$  has been determined.

## Wind Loads Estimation

Firstly, estimation of forces (and moments) caused by wind resistance have been conducted for the containership facing head and beam winds. Next, as shown in Fig. (7), trigonometric relations given by Eqn. (3) can be used to determine the wind loads coefficients at different incoming angles of direction of the wind relatively to the ship's heading.

**Figure 7:** Wind load coefficients in surge and sway of the containership

Note that instead of using Gould's semi-empirical formulation, a more accurate assessment of the impact of wind on this containership could have been conducted by means of CFD. In that case, CFD presents many advantages, of which the most obvious is adequacy for flow visualization and for design optimisation of all surfaces of the ship above the sea-surface as well as cargo. However, proper selection of the choice of the CFD method as well as a grid convergence study should be adopted in first place to prevent results become affected by the mesh and input data selection. Hence, in this preliminary study a faster methodology has been adopted for demonstration purposes.

## Added Resistance in Waves and Speed Loss Estimation

As shown in Figs. (8) and (9), there is a fair agreement between Salvesen (1978) and Gerritsma and Beukelman (1979) numerical predictions of added resistance in head waves. In close or open quartering waves the added resistance curves obtained by Gerritsma&Beukelman (1979) present larger deviations and in the opposite direction practical experience of the authors as seafarers, therefore Salvesen (1978) is considered to provide more accurate predictions when compared with experiments, so that this will be the adopted methodology in this study.

**Figure 8:** Transfer functions of non-dimensional added resistance in wave ( $R_{aw} = R_{aw}/(\rho_{sw}gB^2/L_{pp}\zeta_w^2)$ ) versus ratio of wave to ship's length between perpendiculars ( $\lambda_w/L_{pp}$ ) in head waves ( $180^\circ$  in red dashed line), close quartering waves ( $150^\circ$  in green line) and open quartering waves ( $120^\circ$  in blue line with cross) of the containership at top speed, calculated by the Salvesen, 1978 method

**Figure 9:** Transfer functions of non-dimensional added resistance in wave ( $R'_{aw} = R_{aw}/(\rho_{sw}gB^2/L_{pp}\zeta_w^2)$ ) versus ratio of wave to ship's length between perpendiculars ( $\lambda_w/L_{pp}$ ) in head waves ( $180^\circ$  in red dashed line), close quartering waves ( $150^\circ$  in green line) and open quartering waves ( $120^\circ$  in blue line with cross) of the containership at top speed, calculated by by Gerritsma&Beukelman, 1979 method

Non-dimensional added resistance in waves estimates versus wave frequency for top speed ( $Fn = 0.26$ ) are shown in Figs. (8) and (9). Next, considering the design-point peak wave period and wave height along with Eqn. (15) the added resistance in waves for any wave condition encountered at sea with a certain relative incoming wave direction can be easily calculated. For example, considering the containership is facing the most statistically frequent wave train with a peak period around  $T_P = 9$  [s] and a significant wave height of  $H_S = 1.25$  [m], the resulting added resistance in head waves is 13.42 [kN], which represents 1.7% of the total resistance or 2.9% of the residuary resistance at top speed.

## Weather Routing Assumptions

Considering the effect of environmental conditions in the ship's resistance in otherwise calm water. Namely: wind, waves and ocean currents. The present implementation of VSA allows to find the route that minimizes global fuel consumption under the influence of these most relevant environmental conditions. Notice should be given to the fact that, at this initial stage, either synthetically generated or MOHID predicted environmental conditions are assumed to be steady, so that preliminarily testing of the developed algorithms and the proposed heuristic can be conducted via numerical simulations. The encoding of land presence and prohibited passage zones (e.g., marine traffic corridors) has been also added to the heuristic with the aim of equipping SOOS to handle such unavoidable and common restrictions in determining a realistic route. Programming this functionality involves assuming a practically zero speed of the ship in land or prohibited zones. The trajectory from point  $A$  to  $B$  is planned to be carried out at a ship's advance base speed  $V_0$  to reach the destination within the estimated or desired time. At this stage of the development of SOOS, the estimation of the effects of wind, waves, and ocean currents on speed and fuel consumption involved the formulation of some simplifications, namely:

- (i) In considering the effects of environmental conditions, the principle of superposition will be applied, i.e., implicitly linearity in the dynamic behaviour of the system in the neighbourhood of  $V_0$  and  $C_0$  is assumed. Hence, the variation (either increase or decrease) in speed or fuel consumption stemming from environmental conditions will simply be added to the base velocity  $V_0$  and the base fuel consumption  $C_0$ .
- (ii) In the calculation of wind, drift, and current effects it has been assumed that vessel's heading is equal to her course;
- (iii) Vessel drifting associated with wind loads has been neglected, and the wind loads will only impact the increased or decreased resistance to ship's advance. Consequently, leeway corresponds only to either increments or decrements to the base consumption  $C_0$ . The increased or decreased resistance to ship's advance is computed using the formalism condensed in Eqn. (4);
- (iv) The increases or decreases in speed along the course caused by ocean currents at the free-surface will simply be added to the ship's advance base velocity  $V_0$ . The leeway produced by ocean currents will be considered only as an increase in the base consumption  $C_0$ , i.e., the corresponding increase in the velocity to maintain the ship's advance base velocity  $V_0$  along the defined course over ground;
- (v) Waves will be characterised by significant wave height,  $H_S$ , spectral peak period,  $T_P$ , and a relative incoming incidence angle,  $\beta$ , which will induce an additional ship's resistance component. This ship's resistance component will be varying from a maximum to zero depending on a spreading function, which is defined by an incidence angle in the range  $-\frac{\pi}{2} \leq \beta \leq \frac{\pi}{2}$  radians, using the formalism exposed in Eqn. (15).

In the absence of wind, waves, and currents, let  $P$  be the power required to maintain speed  $V$ , let  $R$  be the resistance offered by the water and air to the displacement of the ship at speed  $V$ , and let  $C$  be the corresponding fuel consumption time rate, it has been assumed that:

$$P = a_1 V^2 + a_2 V^3, \quad (24)$$

$$R = a_1 V + a_2 V^2, \quad (25)$$

and

$$C = k (a_1 V^2 + a_2 V^3), \quad (26)$$

where  $k$ ,  $a_1$  and  $a_2$  are fitting coefficients to be computed from previously obtained using CFD or empirical data.

Combining Eqns. (25) and (26) it is obtained:

$$\Delta C \approx \frac{k (2a_1 + 3a_2 V_0) V_0}{(a_1 + 2a_2 V_0)} \Delta R, \quad (27)$$

and

$$\Delta C \approx k (2a_1 V_0 + 3a_2 V_0^2) \Delta V. \quad (28)$$

These expressions will be used to estimate the consumption increments,  $\Delta C$ , associated with the computed increases in resistance,  $\Delta R$ , and velocity,  $\Delta V$ , resulting from the effects of the above mentioned considered environmental conditions. It should be stressed that linearity in the dynamic behaviour of the system in the neighbourhood of  $V_0$ , has been assumed, so that the present formulation will only be valid in a context where the effects of wave wind and currents are sufficiently moderate.

At a later stage of this work, the results will be experimentally validated by means of sea-trials, so that simplifications made in the formalism used in here might be appropriately adjusted.

In the implementation of the VSA technique, synthetic environmental conditions have been defined in an appropriate spatial grid. Namely, a non-uniform wind velocity field having a maximum wind speed of approximately 23 [kts], an uniform ocean current of 2.14 [kts] with direction  $270^\circ$  and an uniform field of regular waves with direction  $270^\circ$  characterized by a significant wave height  $H_S$  of 1.25 [m] and period  $T_P$  of 10 [s] has been adopted. The starting point  $A$ , with Cartesian coordinates:  $(x_A, y_A) = (-100, 70)$  and the destination point  $B$  with coordinates:  $(x_B, y_B) = (100, -10)$  were also defined. Note these points were only approximately 215 [m] apart from each other to speed up the process.

The power curve ( $P$  in [kW] and  $V$  in [m/s]), given by:  $P = a_1 V^2 + a_2 V^3$ , and the fuel consumption time rate curve ( $C$  in [kg/s]), given by:  $C = k (a_1 V^2 + a_2 V^3)$ , used in the simulations were characterized by the following parameters:

**Table 1: Parameters defining the power and the fuel consumption time rate curves.**

$a_1$	-0.275
$a_2$	6.510
$k$	$5.0694 \times 10^{-5}$

The minimal global fuel consumption route was defined by 5 yaw points and the heuristic was executed in a set  $U$  with 200 routes evolving over 750 epochs.

In Fig. 10 the evolution of minimum global fuel consumption from epoch to epoch is shown. Also, the corresponding determination of the optimal path is represented in Figure 11. Notice should be given to the fact that in this particular simulation less than 100 epochs were necessary to obtain the minimal route.

**Figure 10: Evolution of minimum global fuel consumption from epoch to epoch.**

In Fig. 11 results provided by the heuristic under the aforementioned conditions are shown. It can be observed that minimal route exhibits a lower global fuel consumption than the global fuel consumption associated with the direct route. Actually, the fuel savings observed in the minimal route determined are, approximately, 9% with respect to the fuel consumed in the direct route, which is considered quite promising at the fuel prices nowadays.

**Figure 11: Minimal route from A to B in free ocean.**

As illustrated in Fig. 12, all the simulation conditions remained unchanged, an exception being made for the addition of an "island" to the original grid in an exact location corresponding to the passage zone of the minimal route represented in Fig. 11. In this new situation, as expected, the minimal route determined circumvents the island. Despite this change, the new determined route still allows for a fuel saving of approximately 8%, compared to the global fuel consumption over the direct route.

**Figure 12: Minimal route from points *A* to *B* with land zones.**

The simulation results are considered very satisfactory and highlight the potential of the developing application. The results obtained so far demonstrate that a rational weather routing is conducive to an increase in ship safety and energy efficiency. In fact, from these numerical simulations, the fuel consumption of a given voyage can be significantly reduced to 9% or 8% (see ratios of fuel consumed between optimal and direct route shown in Figs. 11 and 12). At the same time, fuel consumption reduction will create the double benefits of reducing the cost of ship operations while also reducing engine gas emissions that come from burning extra fuel, i.e., making the vessel compliant with new CII regulations proposed by IMO. In the near future, more simulations will be conducted with realistic environmental forecasts provided by a large circulation hydrodynamic model, such as MOHID (see (Neves, 1985)).

## CONCLUSIONS AND FUTURE WORK

In this study the development of an optimisation-based approach to reduce fuel consumption and emissions from shipping navigation has been presented. The current study demonstrates that hydrodynamic performance can be substantially improved by means of trim optimisation that allows ships to reduce fuel consumption and simultaneously operate in adverse weather conditions with minimum degradation of their mission effectiveness.

Firstly, from a set of synthetic environments some preliminary figures on the performance of this newly developed voyage planner based on Vectorized Simulated Annealing (VSA) method was assessed in terms of fuel consumption as a function of speed over ground due to ocean currents and wind loads. Next, the assessment of added-resistance in waves induced by local wave conditions was introduced still as a synthetic environment to check consistency of the fuel consumption results. The simulation results are considered very satisfactory and highlight the potential of the developing a practical application where land zones or traffic corridors are taken into consideration. Actually, the fuel savings observed in the minimal route determined are, approximately, 9% with respect to the fuel consumed in the direct route, which is considered quite promising at the fuel prices nowadays.

In the near future, using a real-case environment scenario the performance of the Ship Operation Optimisation System (SOOS) in terms of fuel consumption reduction along with its comparison with other commercial available tools will be obtained. Moreover, next results are expected to allow the containership operator to have confidence that this containership after mid-life refit to convert an existing anti-heeling tank into an anti-rolling U-type tank will be capable of meeting and in some cases exceeding their operational requirements in terms of energy efficiency due to its superior hydrodynamic performance in a real scenario sea conditions. Contrarily to other decision-support tools systems, SOOS will provide enhanced energy efficiency and roll stabilisation at zero as well as at any advance speed. Therefore, SOOS will be a very attractive option for vessels performing operations that require a large range of speeds. Moreover, the objective of describing the selection process of the most appropriate decision-support tool and roll stabilisation system at the ship's life cycle will be also

achieved.

Looking ahead, there is a significant potential for innovation in this field of providing the maritime transport sector with customised decision-support systems, and further applied R&D is necessary to develop this potential. This is reinforced by current trends toward increased automation and reduced manning of maritime operations and the regulation requirements in the European context.

## APPENDIX

The vessel studied in here corresponds to a 712 TEU geared containership, whose  $Fn = 0.26$ . As regards the case-study selection, containerships are the highest emissions producers in the world fleet due to their higher sailing speed that requires larger propulsion engines.

Considering the design load condition of 712 TEU, the main characteristics of the vessel are shown in Table 2.

**Table 2:** Main characteristics of the 712 TEU geared containership.

Length between perpendiculars	$L_{pp}$ , in [m]	119.50
Breadth, maximum	$B$ , in [m]	20.4
Draught, mean	$T_m$ , in [m]	7.75
Displacement, light condition	$\Delta_l$ , in [t]	3936
Crew	$N_{crew}$ , in [pax]	16
Gross tonnage	$GT$ , in [t]	7580
Cargo capacity	$N_{TEU}$ , in [TEU]	712
Crane elevation capacity (x2)	$C_{crane}$ , in [t]	40
Power (effective)	$P_E$ , in [kW]	4665
Power at MCR (shaft)	$P_S$ , in [kW]	7200
Propeller diameter (CPP)	$D_P$ , in [m]	4.2
Cruise speed	$U_{cruise}$ , in [kts]	16
Lateral projected area (above MWL)	$A_L$ , in [m <sup>2</sup> ]	1883
Transverse projected area (above MWL)	$A_T$ , in [m <sup>2</sup> ]	444

Fig. 13 shows a 3D geometric model which has been utilised to perform the CFD resistance and propulsion simulations and the semi-empirical wind loads calculations of the vessel. Considering the origin of the right handed system of coordinates located along the ship keel, in the symmetrical plan, at mean distance between the two perpendiculars, with  $z$ -axis pointing upwards and  $x$ -axis pointing through the ship bow.

# Functional analysis of speed, battery pack capacities and chargers of small electric ships - Adriatic Sea case study

Vedran Slapničar<sup>1\*</sup>, Jerolim Andrić<sup>2</sup> and Smiljko Rudan<sup>3</sup>

## ABSTRACT

*Electric propulsion refers to propulsion using a combination of an electric motor and batteries. Electric motors powered by batteries represent a significant solution within the broader context of sustainability, energy efficiency, and technological advancement. As energy containers, batteries are characterized by low energy and power density and are currently not considered suitable for use on large displacement ships. Consumption of electric ships depends on numerous factors and the performance of the vessel's energy system requires great attention. The basic limitations are the ship's size and speed, the built-in capacity of the batteries, charging infrastructure, and sailing distance. These limitations are discussed and justified in two case studies in which the existing diesel-powered ships are replaced with electric ones.*

## KEY WORDS

functional analysis; electric ships; batteries; chargers; speed

## INTRODUCTION

Today's challenging replacement of internal motor combustion with electric motors powered by batteries or other alternative energy sources includes many variables and we can say that it is very difficult to recommend the best solution. In principle, each case should be considered independently. In this paper, 9 shipping lines were analysed, namely 7 existing ones on which existing ships with diesel propulsion are already sailing, and 2 potentially new ones. For existing lines and potentially new lines, an analysis was made of which electric-powered ships could replace the existing ships. In this paper, batteries are treated as a potential energy source on board as an option that has already been applied. Considering the topicality of this issue, a relatively large number of papers have been published that consider the problem from various points of view but do not give a unique solution which is understandable. So, the literature review would take a quite lot of references without a serious sense of it. Here, we are referencing characteristic papers dealing with certain important topics. We can say that the sort of endless loop of solutions spins between the following topics, but not exclusively:

- Photovoltaic modules, solar energy
- Batteries
- Chargers
- Economics, cost
- Repowering, energy transition
- Operational profile, speed optimisation
- Coastal region, rivers, inland waters
- Lifecycle analysis

e-ISSN: 3050-4864

The possibilities of isolated energy systems of islands by the usage of photovoltaic power systems for charging battery-powered electric ferries are discussed in (Frković et al, 2022). The paper (Kortsari et al, 2022) aims to present and explore the economic performance of a pure electric ferry, E-ferry. The E-ferry prototype is a viable commercial solution from a purely economic standpoint, according to the results of the economic examination. The E-ferry prototype, for example, has greater building expenses, but it has far lower operating costs overall, especially when it comes to fuel and energy resulting in a 5-8-year payback period. Comparably, even while battery systems have contributed significantly to the cost of the E-ferry, the ongoing decline in battery prices positions completely electric ships as a sustainable option. The auxiliary charging system is another significant factor in the E-ferry prototype's overall cost. To conclude, this is valid for the specific routes and belonging infrastructure. Evaluation of the possibility of using alternative fuels for small ferries based on several parameters, including technical readiness, regulations, GHG emission reduction, capital expenditure, and operational expense is elaborated in the paper (Laasma et al, 2022). When concentrating on the ferry business, it is crucial to take regional peculiarities and chances for lines into account. To attain carbon neutrality in the area, the paper's conclusion calls for more research to be conducted, including case studies of more specialized ecosystems with more obvious answers and possible courses of action. Considering the repowering option with battery-electric technology authors of the paper, (Mao et al, 2021), found out that passenger ferries up to 55 m that sail on legs up to 50 NM would replace 50% of fossil fuel use with electricity. But it must be considered that they had considered 10 MW chargers, which is still very doubtful in most countries.

We can agree, with the general conclusion given in (Pense & Akinoglu, 2020), that in the era of intelligent transportation systems, fully electric drive systems in the maritime industry may represent a significant step toward safer, more environmentally friendly, and more sustainable shipping globally, particularly when paired with solar energy or other renewable energy sources. In recent years, the most flexible approach to ship decarbonization may have been to build an entirely electric, battery-powered vessel. Battery-powered ships have a lower energy redundancy and a higher initial investment cost than conventional ships. Thus, it is essential to have an energy management plan that may reduce operating costs while ensuring the safety of energy use. The non-linear ship energy and speed optimization model describes energy usage under various sailing circumstances and speeds (Sun et al, 2022). Batteries and the safety of usage are another important issue (Trombetta et al, 2024). To guarantee ship efficiency and ensure high survivability and reliability, battery systems and their auxiliaries must be arranged. This could be done by complexly designed integrated power and energy systems that can link, track, and manage numerous onboard systems, including those for cooling, heating, detecting, alerting, and firefighting. The Filipino study (Vakili & Ölçer, 2023) also examines the environmental effects of battery-powered versus traditional diesel ferries, revealing that eco-friendliness pivots upon the nation's electricity mix. Battery-powered ships show promise for decarbonizing local waterways, provided there is a shift toward cleaner energy sources. The authors present a novel location problem called the electric riverboat charging station location problem, which is inspired by river operations with an electric vessel (Villa et al, 2020). This problem considers the necessary infrastructure for an electric vessel to be able to perform a round trip. The size of the electric vessel battery system and the placement of the solar-assisted charging stations are designed to keep expenses to a minimum. It incorporates both the charging function and the variation of solar radiation as a nonlinear behaviour function.

A case study (Wang et al, 2021) of a battery-powered fast catamaran ferry is employed. The various ship life phases and activities are taken into consideration by LCA and LCCA to create a life cycle emission inventory and calculate the associated costs. The findings show that when grid mix electricity from 2019 is used, the battery-powered system has life cycle greenhouse gas emissions decreased by approximately 30% and life cycle expenses lowered by 15% when compared to a conventional power system. Finally, it is necessary to properly plan the service network to offer high-quality transportation services. Thus, under service time constraints, the study (Wang et al, 2022) concurrently examines the positioning of charge stations, charging plans, route planning, ship schedule, and ship deployment. A literature review shows us the importance of carefully planning the sailing route of a ship powered by electric energy, speed, and consumption, as well as the necessary infrastructure for a certain ship to sail smoothly on a certain line. An insight into the conditions and limitations of the application of electrically powered ships was intended to be given in this work.

In the following sections, the elaboration of the work follows. Section 2 elaborates basic features of the ships' electrical eco-system and gives a comparison of features of the electric ships. For the selected lines, existing and new ones, the analysis of passenger ships is done in Section 3. The estimation of power and energy for the passenger ships of 45 m and 17 m together with the case studies is given in Section 4. A preliminary proposal of technical specifications for the new battery-powered solar-electric passenger ships to be deployed on selected lines is presented in Section 5. Finally, at the end, the Conclusion is given.

# BASIC FEATURES OF THE SHIPS' ELECTRICAL ECO-SYSTEM

Electric drive refers to a system using a combination of an electric motor and a battery pack. Batteries, as energy storage, are characterized by low energy and power density and are currently not considered suitable for use on larger ships. In recent years, significant progress has been made in the development of batteries, especially when it comes to charging speed and reducing the memory effect of charging. Lithium batteries' current energy storage capacity is about 300 Wh/kg (Thunder Said Energy, 2024). In most batteries the critical metal is lithium and the world's lithium reserves are estimated at 23 million tons, most of which are stored in Chile (Statista, 2024). An alternative is to use magnesium, which is much more abundant, but it is still in the research phase. Table 1 depicts the advantages and disadvantages of using electric energy.

**Table 1: The advantages and disadvantages of using electric energy**

Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• Complete absence of greenhouse gas emissions during vessel operation.</li> <li>• Batteries seem suitable for powering smaller ships in the short to medium term.</li> <li>• In combination with other types of drives, it is possible to realize a hybrid drive, applicable for propelling smaller and medium-sized ships.</li> </ul>	<ul style="list-style-type: none"> <li>• The size and mass of the batteries currently limit the application of the batteries mostly to smaller-sized ships and very short distances.</li> <li>• Battery-powered ship's propulsion needs to be further developed, and even with significant progress, it is likely to expect the installation of such propulsion only on smaller-sized ships.</li> <li>• The battery pack must be replaced and disposed of at the end of its working life, which is determined by the total number of charging and discharging cycles.</li> </ul>

Consumption of electric battery-powered ships depends on numerous factors and the performance of the vessel's energy system requires great attention. The basic limitations are the built-in capacity of the batteries, the permissible percentage of battery discharge (DOD-Depth of discharge), the value of the upper limit of the battery charge, the speed and frequency of charging, the sailing route, weather conditions, and the way the vessel is operated. If we consider only navigation, energy consumption depends on a series of manoeuvres of acceleration, deceleration, docking, manoeuvring in the port, and an adaptation of the driving style to sea conditions, environmental temperature, and other conditions. Energy consumption needs to be compensated by charging battery systems, whereby chargers differ in terms of installed power and charging speed, ease of use, charging losses, etc. The construction of chargers is regularly associated with significant infrastructure costs and sometimes administrative and technical difficulties. It can be concluded that the electric battery-powered ship is part of an energy ecosystem in which each component of the system needs to be adjusted optimally for the system.

Designing an energy ecosystem for electric battery-powered ferries requires knowing the answers to the following related questions:

1. What are the prices of energy from the local utility?
2. Are there special prices for off-peak energy consumption or permitted service interruption?
3. What will be the infrastructure needed for shore charging?
4. Is there a large-capacity power supply on-site at the terminal?
5. Is there a possibility of a power supply at both ends or all parts of the route?
6. Who pays/finances the charging infrastructure?
7. What emergencies are allowed?
8. What happens if the energy grid is temporarily unavailable?
9. How "green" is the energy that is purchased/used?
10. What is the durability of batteries and what about their disposal?
11. What new technologies are in the pipeline that can improve performance and reduce costs?
12. How far is the location for the ship overhaul?
13. Does the vessel have to react to emergencies such as rescue actions?

The main part of the energy ecosystem, questions 1-9, should be addressed by governmental administrative activities and by building the infrastructure. Questions 10-11 depend on market development and certainly, the designer will choose the best batteries on the market when designing the battery system that satisfies safety issues and has valid certificates. Question 12 is the question for the ship operator, it depends on the specific area but also it is a part of the infrastructure because if we don't

have repair places nearby, then it will be almost impossible to deploy any ships on certain lines. Question 13 depends on some specific needs that could be prescribed by the classification rules and/or national statutory rules.

## Energy supply and battery systems for maritime applications

The supply of energy to ships that use batteries as the main or auxiliary energy source is only possible with the existence of a dedicated infrastructure. To be able to electrify ships on certain lines, it is necessary to provide infrastructure for fast/adequate battery charging at least at one of the endpoints of these lines. Therefore, energy supply must be ensured for each case within the framework of long-term transportation network planning.

One of the problems that should be stated is that the energy supply infrastructure, specifically intended for the supply of new solar-electric battery-powered ships on the selected existing and potentially new lines, currently doesn't exist, so the problem of deploying the new ships is even greater. Generally, the battery systems for maritime applications can be considered by very high reliability, large system capacity, modularity, and high safety in use. System certification is performed by classification societies and one of the most important tests includes a detailed heat transfer simulation. The risk of excessive heat transfer is reduced by the battery management system (BMS), integrated heat dissipation, and fire protection system. Although classification societies allow the use of new types of batteries with great caution, unlike lead batteries, due to the risk of ignition.

## Comparison of features of electric ships

Table 2 shows the part of the basic features of 10 electric ships that are publicly available. Some data were slightly different due to the different data sources, and some data were not even publicly available. Also, some inconsistencies in the data can be seen, although they are given on the manufacturer's website. Given the fact that only the data of installed engine power is available, and not the data of the required engine power for the corresponding service speed, it can be concluded that the power of the installed engines on some lines is quite higher than necessary, i.e. the larger power reserve was taken. Data in the table are presented in the wide range of ship length, 24.5 m -144 m, and number of passengers, 132 – 1250. It is also visible from the table that the sailing time is mostly less than 30 min., except in two cases.

## ANALYSIS OF PASSENGER SHIPS ON SELECTED LINES – EXISTING/NEW ONES

As stated in the introduction 9 lines listed in Table 3 were analysed, 7 existing ones and 2 potentially new ones. The first 4 are served by high-speed catamarans (Lines Nos. 1-4), with service speeds between 14.8 - 21.03 kn, while Lines Nos. 5-7 are served by slow-speed monohull ships, with service speeds between 10-11 kn. Based on the previous work it was decided to investigate the possibility of placing slow-speed catamarans on potentially new lines, Line Nos. 8-9, with a speed of 10 kn. Catamaran was chosen for potentially 2 new lines due to the size of the ferry ports at the destination points and because it has a relatively large available area for passenger accommodation about the ship's length. The paper aimed to analyse the feasibility of replacing the existing diesel-powered ships with fully electric ships using batteries as an energy source, but also, to deploy the same kind of ships on the new lines. In Table 3 the 2 values per shipping line are presented, namely, distance per trip and consumption per trip. Distance per trip represents the total distance that a ship navigates in one direction. Consumption per trip depends on the required engine power for the service speed, hotel consumption, maximum voyage time, and efficiency coefficient (from the battery to the propeller), taken here as 0.92. Required engine power is obtained by in-house software based on the Holtrop-Mennen method (Holtrop & Mennen, 1978),

**Table 3: List of analysed shipping lines**

	Line No.	Line name	Distance per trip NM	Consumption per trip kWh
Existing lines	1	9601-Split-Rogač-Stomorska-Sutivan-Milna	33.00	1706
	2	9602-Split-Milna-Hvar-Vis	29.80	2036
	3	9406-Zadar-Zaglav-Zadar	22.20	675
	4	9604-Split-Hvar-Vela Luka-Ubli	61.13	4870
	5	310-Mali Lošinj-Srakane Vele-Unije-Susak	36.83	1201
	6	505-Šibenik-Zlarin-Prvić Luka-Prvić Šepurine-Vodice	20.18	658
	7	807-Dubrovnik-Koločep-Lopud-Šipan	22.79	1068
New lines	8	Split-Postira-Omiš	16.80	229
	9	Gaženica-Zadar-Borik	8.40	115

All these lines with their schedules and existing ship data (Row Nos. 1-9) were preliminarily analysed as follows (Table 4):

- Considering the navigation route and the schedule, the real service speed was calculated since these values were not available (Row No. 10). The available data were the maximum speed and total engine power.
- Using the in-house computer program the required power for the service speed was estimated (Row No. 11).
- Considering the navigation route and schedule the navigation distance without charging is determined (Row No. 12)
- Considering the battery depth of discharge (80% DOD + 10% reserve), the losses in the system, the ship's speed, the required power for service speed, available charging time and assumed charger power, the capacity of the batteries was calculated (Row No. 13).
- The fuel oil mass was obtained from the available ship's documentation (Row No. 19).
- The mass of the required batteries was calculated conservatively by multiplying the capacity of the batteries with the coefficient 13 kg/kWh (Row No. 24).
- The ratio of the mass of the required batteries and the fuel oil mass obtained from the existing ship documentation was calculated. The criterion of the feasibility indicators for replacing energy sources from fossil fuels with batteries is set (Row Nos. 26 and 28).
- A Feasibility Indicator 1 shown in Figure 1 was introduced as the ratio of the required mass of batteries and the fuel oil mass of existing ships,  $m_{BATT}/m_{FUEL}$  (Row No. 26) . According to this indicator, the existing ship on the existing line is feasible if it is less than or equal to 1. The feasible lines are Line Nos 5,6,7, and 9, while Line No. 8 could be probably feasible with some additional adjustments.
- Another indicator, Feasibility Indicator 2 shown in Figure 2, is the relation between the energy source and deadweight. Namely, fuel oil mass and deadweight,  $m_{FUEL}/m_{DWT}$  (Row No. 27), and required mass of batteries and deadweight,  $m_{BATT}/m_{DWT}$  (Row No. 28). This indicator should be less than 35%.

Considering the Feasibility Indicator 1, the high-speed ships lines 9602, 9601, 9604, and 9406 are not feasible since the values of this indicator range from 3.0 to 7.1. To conclude, the lines on which it would be possible to replace energy sources from

fossil fuels with batteries must generally have lower speeds, larger charging time frames and shorter sailing distances. The sailing schedule must be harmonized to enable the daily charging of the batteries also, otherwise, the battery pack capacity needs to be too large. In any case, each line should be analysed individually with the existing parameters and limitations, and if the lines are not feasible, it is necessary to design a new ship considering the realistic requirements for passenger capacity, required speed, and sailing schedule to enable consumption of electric energy as low as possible. Last, but not the least, any changes to the existing sailing schedule and passenger capacities should be coordinated with the needs of the users and the local community. This is because they are already accustomed to a certain sailing schedule with existing passenger ships powered by diesel engines, so it is necessary to explain why changes would be necessary for the ships powered by batteries.

**Table 4: Preliminary calculation of capacity of the battery pack for the passenger ships on selected lines**

# ESTIMATION OF POWER AND ENERGY - CASE STUDIES

## Estimation of power and energy for a 45 m passenger ship

For a passenger ship with a length of 45 m for lines 310, 505, and 807, Table 4, Line nos. 5-7, the required engine power was estimated (Holtrop & Mennen, 1978) as shown in Figure 3. For the speed of 10 kn, the required engine power is 275.08 kW, while for the speed of 11 kn, the value is 449.19 kW. Considering that these values represent 90% of MCR (Maximum continuous rating), the built-in engines should have a total power of 300 kW, or 2 x 150 kW for the speed of 10 kn, and 500 kW, or 2 x 250 kW for the speed of 11 kn. The bow thruster power is assumed to be 20% of the main engine power, or 2 x 15 kW for the speed of 10 kn and 2 x 50 kW for the speed of 11 kn. Together with the required engine power, the required battery pack capacity as well as the required charger power were calculated for the original sailing schedules. To avoid unnecessarily high battery pack capacity as well as high charger power, an analysis of the schedule was performed. This analysis showed that the small changes in the schedule would enable daily charging of the batteries, and consequently lower battery pack capacities and charger powers. Regarding the gain of solar energy, the average daily value in kWh per 1 kW of installed photovoltaic module, for the location of Mali Losinj, is 3.21 kWh (PVGIS, 2024). The number of 350 W photovoltaic modules, considering the assumed allowable free superstructure roof area of 360.00 m<sup>2</sup> amounts to 180, and they provide 201.95 kWh, which is 9.4% of the battery pack capacity. Considering the electric motor voltage of 705.6 V, the battery pack has 2150.67 kWh with a total weight of 27.95 t. The battery pack consists of 42 modules and 10 strings, where each module has 32 battery cells of capacity 38.1 Ah and voltage 4.2 V.

Figure 3: Power-speed diagram for a 45 m passenger ship

Hotel consumption of a 45 m passenger ship (air conditioning, vessel devices, lighting) is assumed during navigation 25 kW, and by the night charging 10 kW.

## Analysis: Case study 1 - State line no. 807

“Case study 1” gives a detailed analysis of the state line no. 807 as an example of a 45 m passenger ship. The original sailing schedule for the high season is shown in Figure 4, and the navigation distance is 22.79 NM. Although the service speed for line 807 is 11 kn, the required battery pack capacities and chargers were calculated for 3 speeds (Table 5), so the battery pack capacity ranges from 3450 kWh to 6800 kWh and daily charger in Dubrovnik from 1000 kW to 3000 kW.

Figure 4: Original schedule for the state line no. 807

Table 5: Required capacity of battery packs and chargers for speeds of 10, 11 and 12 knots for the state line no. 807 - original schedule

V=12 kn	No schedule change
Sudurad: min charging power (kW)	<b>650 kW</b>
Dubrovnik: min charging power (kW)	<b>3000 kW</b>
Input: nominal battery capacity (kWh)	<b>6800 kWh</b>

V=11 kn	No schedule change
Sudurad: min charging power (kW)	<b>430 kW</b>
Dubrovnik: min charging power (kW)	<b>1850 kW</b>
Input: nominal battery capacity (kWh)	<b>4500 kWh</b>

V=10 kn	No schedule change
Sudurad: min charging power (kW)	<b>330 kW</b>
Dubrovnik: min charging power (kW)	<b>1000 kW</b>
Input: nominal battery capacity (kWh)	<b>3450 kWh</b>

It is necessary to provide two power chargers, a higher capacity charger in Dubrovnik for daytime charging and a lower capacity charger in Sudurad for overnight charging. Considering the very high required battery pack capacities and the chargers' power (Table 5), a slight modification of the original schedule is necessary. With a slightly changed schedule, the required battery pack capacities and chargers' power have been significantly reduced compared to the obtained for the original schedule (Table 6). This gives us an overview of the possible combinations for the speed options 10, 11, and 12 kn.

Table 6: Possible options for the battery pack capacities and chargers for speeds of 10, 11, and 12 knots for the state line 807 - slightly changed schedule

V=12 kn							
Sudurad: min charging power (kW)	260	280	315	345	375	400	430
Dubrovnik: min charging power (kW)	1630	1570	1480	1410	1330	1275	1200

					1243	534	709	

Daily charging in the Dubrovnik, 1000 kW charger

Overnight charging in Sudurađ, 7 hours including 10 kW for hotel consumption, 200 kW charger

## Estimation of power and energy for a 17 m passenger ship

For a passenger ship with a length of 17 m for lines Split-Postira-Omis and Gazenica-Zadar-Borik, Table 4, Lines Nos. 8 and 9, the required engine power was estimated (Holtrop & Mennen, 1978). For the speed of 10 kn, the required engine power is 110.49 kW as shown in Figure 6. Taking into account that this value represents 90% of MCR, the built-in engines should have a total power of 130 kW, or 2 x 65 kW. The bow thruster power is assumed to the 20% of the main engine power, or 2 x 12 kW. The required engine power, battery pack capacity, and charger power are calculated considering the following parameters:

- the assumed sailing schedule on the line Gazenica-Zadar-Borik is 11 departures per day, but the charging is done only in Gazenica port in 20 min. after each round voyage. Assumed nominal charger capacity is 450 kW and battery pack capacity 250 kWh.
- assumed sailing schedule on the line Split-Postira-Omis, 2 departures per day, charging is done in both ports after each voyage with the assumed nominal charger capacity of 350 kW and battery pack capacity of 430 kWh.
