Since these two lines are supposed to be completely new, considering the estimated engine power and hotel consumption, the required battery pack capacity as well as the required charger power the schedule proposal was given by the authors to avoid unnecessarily higher capacities. Regarding the gain of solar energy, the average daily value in kWh per 1 kW of installed photovoltaic module, for the location of Mali Losinj, is 3.21 kWh (PVGIS, 2024). The number of 350 W photovoltaic modules, considering the assumed allowable free superstructure roof area of 95.20 m<sup>2</sup> amounts to 48, and they provide 53.85 kWh, which is 12.5% to 21.54% of the battery capacity, depending on the line.

**Figure 6: Power-speed diagram for a 17 m passenger ship**

Hotel consumption of a 17 m passenger ship (air conditioning, vessel devices, lighting) is assumed during navigation 15 kW, and the night charging 5 kW.

### Analysis: Case Study 2 - Line Gaženica – Zadar – Borik

“Case study 2” gives a detailed analysis of the state line Gazenica-Zadar-Borik as an example of a 17 m passenger ship. The assumed schedule for the line Gazenica-Zadar-Borik and back takes 70 min. for a round trip including the necessary time for boarding and disembarking the passengers, with 30 min. for a break in Gazenica port, of which 20 min. is for charging (Table 8). For the speed of 10 kn the possible options of the combinations for the battery pack capacities and chargers are given in Table 9.

**Table 8 Voyage and charging description for line Gaženica – Zadar – Borik**

Harbour time, min	Trip	Charging= Harbour time- 10, min	Harbour time, hours	Battery trip start, kWh	Consumption per voyage, kWh	Battery trip ends, kWh	Available battery charger capacity, kWh
30	1	20	0.33	225	115	110	125
30	2	20	0.33	225	115	110	125
30	3	20	0.33	225	115	110	125
30	4	20	0.33	225	115	110	125
30	5	20	0.33	225	115	110	125
30	6	20	0.33	225	115	110	125
30	7	20	0.33	225	115	110	125
30	8	20	0.33	225	115	110	125
30	9	20	0.33	225	115	110	125
30	10	20	0.33	225	115	110	125
30	11	20	0.33	225	115	110	

Daily and overnight charging in Gazenica, 450 kW charger

**Table 9: Possible options for the battery pack capacities and chargers for the speed of 10 kn for the line Gaženica – Zadar – Borik**

V=10 kn

Gazenica: min charging power (kW)	425	405	390	365	450
Nominal battery capacity (kWh)	200	250	300	400	250

The consequence of the proposed schedule and charger option is that the batteries will be charged 12 times per day, so they will be replaced approximately within 3 years.

## PRELIMINARY PROPOSAL OF TECHNICAL SPECIFICATIONS FOR NEW SOLAR-ELECTRIC BATTERY-POWERED PASSENGER SHIPS ON SELECTED LINES

After the detailed analysis of all lines, in terms of rationalizing design and construction costs, it is proposed that the two types of fully electric battery-powered passenger ships could replace existing passenger ships on selected lines (Table 3)

- **Ship I** – monohull, length up to 45 m, for the service on existing lines 310, 505 and 807.
- **Ship II** – catamaran, length up to 17 m, for the service on new lines Split-Postira-Omis -Omiš and Gazenica-Zadar-Borik.

When proposing the preliminary dimensions of the new ships, the following aspects were considered:

- The technical specifications were chosen as an envelope of requirements for lines for which the same type of vessel is proposed.
- The proposed passenger capacity results from an analysis of the existing ships and shipping lines, which showed that the maximum capacity of the existing ships is sufficient to cover long-term needs on the selected lines.
- The speed of the ships, 10 to 11 kn, is specified in such a way that fits the schedule and as low as possible lower battery pack capacities and chargers.
- For lines 310, 505, and 807, the option for loaded cargo is 25 t, which can be breakbulk /pallet/container loaded by crane, together with the 3 medium-sized supply vehicles and 5 passenger cars loaded by a stern ramp.
- The proposed approximate dimensions of the larger ship, length up to 45 m, will be in line with the existing ships that currently operate on lines 310, 505, and 807. The passenger capacity for all lines is not the same and consequently, the length should not be the same, but since line 310 (Line No. 5, Table 3 and Table 4) is an open-sea line exposed to severe weather conditions that has by far the largest number of cancelled voyages, it is assumed that the same size ship should serve this line to ensure a reduction in the number of cancelled voyages.
- The proposed dimensions of smaller-sized ships consider the limitations of the potential berths at the ports of destination.

Table 10 provides a preliminary proposal for the technical specifications of new passenger ships on the selected lines.

**Table 10: Preliminary proposal of technical specifications of new passenger ships on selected lines**

	Ship I		Ship II	
	310, 505	807	Gazenica-Zadar-Borik	Split-Postira-Omis
<b>Type of vessel</b>	Pasenger ship		Pasenger ship	
<b>Classification</b>	HRB★50A1 IWS SD★M1 AUT3		HRB★50A1 IWS SD★M1 AUT3

<b>Type of lines</b>	Open sea	Open sea	Coastal	Open sea

\*Note: regarding the maximum permissible draft, when finalizing the project, it is necessary to consider in detail the max. the depth of the pier according to the latest data.

## CONCLUSION

Nine shipping lines were examined in this paper, 2 possibly new lines and 7 existing lines that are currently served by ships using diesel propulsion. An analysis was conducted to determine which electric-powered ships could replace the current ships on both existing and possibly new lines. Batteries are discussed in this paper as a potential onboard energy source that has already been used on certain lines and is a reasonably simple alternative to implement. In terms of the rationalization of design and construction costs, as previously stated, it is proposed to build two types of passenger ships, a 45 m Ship I and a 17 m Ship II, which could be deployed on selected lines with solar-electric-battery propulsion. The final dimensions and all technical characteristics of the ships will be defined by the initial design and technical descriptions, considering additional technical requirements and the actual depth condition at the intended piers. Some remarks must be stressed:

- The introduction of solar-electric battery-powered ships requires a deep analysis of the minimum necessary speed, for each line independently, to keep the energy consumption as low as possible.
- It is also necessary to harmonize the schedule to enable the daily charging of the batteries.
- For some existing lines, such as line 807 (shown as Case Study 1), the analysis showed that with a slightly changed schedule, the required battery pack capacity and charger power can be significantly reduced compared to the original schedule.
- Proposed changes to the sailing schedule should be harmonized with the needs of the users.
- The contribution of energy that can be obtained from photovoltaic modules installed on the superstructure roof area, ranges from 9.4% to 21.5%, depending on the particular line.
- The feasibility indicators are defined, as Feasibility Indicator 1 and Feasibility Indicator 2, and they must be within certain limits, i.e. under 1 and 35% respectively.

We see that electric energy for the propulsion of ships that use batteries as a potential energy source on board is not largely used and has not taken off as much as we might expect, in fact, its application, for now, is just on mostly very specific lines. The reason for this is the lack of infrastructure, the relatively small capacity of batteries and their large mass compared to diesel propulsion systems, engine rooms and supplies. Also, the cost of the batteries, as well as the problem of recycling batteries after a certain number of charging cycles is a real problem. In summary, the lines that may potentially replace energy sources from fossil fuel with batteries need to have slower speeds, longer charging times, shorter sailing distances, and with the sailing schedule carefully adjusted. In future work, it is planned to analyse the application of electric energy to larger ships that would have a hybrid drive, diesel-electric-battery, where the energy obtained from the batteries would be for ship departure and arrival, as well as during the ship's stay at the berth. The benefit of such a system would be the reduction of exhaust gases in the port as well as less noise.

# The Potential of Next Generation Nuclear Power for Marine Propulsion of Commercial Vessels

Niels de Vries<sup>1\*</sup>, Koen Houtkoop<sup>2</sup> and Zeno Leurs<sup>3</sup>

## ABSTRACT

*Nuclear energy has the potential to become one of the main alternatives to achieve sustainable marine shipping and reduce its greenhouse gas emissions. This study defines a power generation arrangement and evaluates design speed for nuclear powered vessels. Higher design speeds show promising economic results. This includes higher revenue and trade while maintaining a relatively low operational expenditures when compared with conventional powered ships. This study is carried out for a large container vessel and a large bulk carrier to support the implementation of nuclear energy technology. This study reviews reactors designed to a 25- to 75-year service life, using a fully electric power generation and propulsion layout.*

## KEY WORDS

Nuclear energy, commercial shipping, marine design, molten salt reactor, comparative study.

## NOMENCLATURE

B	Breadth	O&M	Operation and maintenance
CapEx	Capital expenditures	OpEx	Operational expenses
Cb	Block coefficient	Pb	Brake power
DWT	Deadweight	Pd	Propulsion power
EIRP	Energy Innovation Reform Project	Pne	Nuclear electrical power
FEU	Forty-foot equivalent unit	PWR	Pressurized water reactor
Fn	Froude Number ( $Fn = v / \sqrt{(g \cdot L)}$ )	sfc	Specific fuel consumption
GT	Gross tonnage	SMR	Small modular reactor
IAEA	International Atomic Energy Agency	T	Draft
Lbp	Length between perpendiculars	TEU	Twenty-foot equivalent unit
LSW	Lightship Weight	v	Ship speed
VLSFO	Very low sulphur fuel oil (0.5% Sulphur)	VHTR	Very high temperature reactor
MSR	Molten salt reactor	WNA	World Nuclear Association
NEA	Nuclear Energy Agency		

## INTRODUCTION

With the need for shipping to become more sustainable and reduce its harmful emissions, nuclear marine propulsion has potential to be one of the solutions. Earlier research (Houtkoop, 2022) has shown the initial potential of next generation nuclear technology for shipping with replacement of conventional power generation. However, the full potential of nuclear on marine applications, especially for new builds, is not fully known yet. Therefore, the goal of this study is to develop new build cases and explore their potential focusing on design speed, propulsion and power generation, and ship design.

This paper is built up as follows. The first section studies parts of nuclear power generation and propulsion and establishes a technically feasible basis for the propulsion configuration and arrangement. This is followed by a section introducing the case studies with their own background for further economic analysis in the second section. The third and fourth section elaborate on the speed-dependent total cost of ownership and shipping income respectively that serve as input for the analysis of the cases. The fifth section clarifies the overall calculation method to determine the most economic speed for the complete range investigated in this research. The sixth section presents the results with initial review followed by the seventh section discussing the results further. This final sections of this paper cover the conclusion and recommendations.

# POWER GENERATION AND PROPULSION

This section describes the considered and selected options to convert and distribute nuclear power to propulsion and other electrical consumers. It does so by reviewing the main topics covering reactor, shielding, heat exchangers, turbines, propulsion configuration, and arrangement.

## System Design

The system design of a nuclear power plant can be made in various ways. This study is not exclusive for one reactor type or one system design. Instead this study aims to be representative for a range of designs. For a better understanding of the principles of a nuclear power plant a basic system design is shown in Figure 1. It is based on primary loop going through the reactor, an intermediate loop and an open air loop. Two hypothetical options for the reactor and mediums for the respective loops are shown in Table 1. The reasoning for the respective design options are provided in subsections *Heat Exchangers* and *Turbines*. Alternative nuclear power plant designs with a different number of loops are also possible. Furthermore, different types of mediums with respective open or closed cycles are also possible. However, both are not further reviewed in this study.

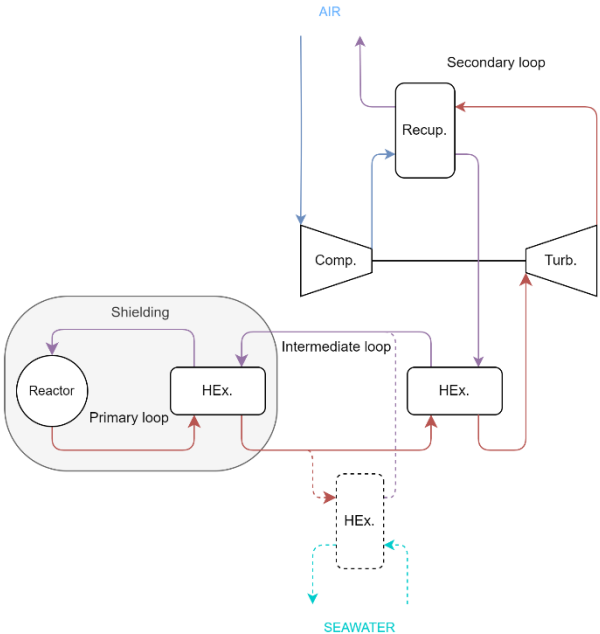

Figure 1: Basic system design of a nuclear power plant

Table 1: Hypothetical options for (V)HTR and MSR and heat transfer loop mediums

Hypothetical option	Reactor	Primary loop	Intermediate loop	Secondary loop
1	(V)HTR	Helium	Salt	Open Air
2	MSR	Salt	Helium	Open Air

## Reactor

This study is not exclusive to one reactor type, and researches a bandwidth of reactor capital expenditures (CapEx). As examples of reactor types, earlier research (Houtkoop, 2022) has indicated that for a number of reasons, (Very) High Temperature Reactors ((V)HTRs) and Molten Salt Reactors (MSRs) have a lot of potential for the maritime industry. An important reason is the passive safety properties which prevent issues with stability and thus ensures reactor safety without outside intervention. Another reason is the high burn-up of these reactor types. Burn-up is an effectivity measure indicating how much thermal energy the reactor can extract from a given quantity of nuclear fuel. A higher burn-up is favorable as it reduces the amount of required nuclear fuel and produced waste per power produced (Houtkoop, 2022). Furthermore, both these reactor types have the potential to (partially) use the thorium fuel cycle. In addition to thorium being three times more abundant than uranium, the thorium fuel cycle has a higher proliferation resistance, meaning it is a very unattractive route to create nuclear weapons with it. This eliminates (or greatly reduces) the potential of weaponization. With thorium, the high-level nuclear waste longevity can be reduced from more than 10,000 years to approximately 300 years (Hargraves, 2010).

### Shielding

The shielding around the reactor, to contain the respective forms of radiation, has a substantial mass and volume primarily consisting of water or concrete and additionally lead (Houtkoop, 2022). This partially clarifies why nuclear power generation onboard vessels is primarily interesting for large ocean-going vessels, as the shielding could become disproportionally large in terms of mass and volume for smaller vessels. This is further reflected upon in sub-section Background of section Case Studies. Future developments of making (reactors and) shielding more compact could change this. An example of this development for both reactors and shielding is Westinghouse and other parties developing SMR of the range of 5000kWe. This is believed to be ideal for the smaller size of ocean-going vessels (Petrakakos, 2024).

### Heat Exchangers

Heat exchangers are essential to transfer the heat from the nuclear reactor to the turbines as shown in Figure 1. In the earlier research (Houtkoop, 2022) three heat exchanger types were compared as shown in Table 2.

**Table 2: Summary of heat exchanger evaluation** (Houtkoop, 2022)

Heat exchanger → Property ↓	Shell and tube	Helical coil	Printed circuit
Heat transfer coefficient [W/m <sup>2</sup> ·K]	500	1000	2000
Surface density [m <sup>2</sup> /m <sup>3</sup> ]	75	80	1100

Printed circuit heat exchangers have the best volumetric power density. However, it has a low technical readiness level at the size under consideration. Therefore, helical coil heat exchangers are selected as the most suitable as these are more developed and proven.

The hypothetical option 1, as shown in Table 1, with (V)HTR, uses an intermediate salt loop. Hypothetical option 2, as shown in Table 1, with MSR, uses an intermediate helium loop. The main reason for this is the containment of radiation. In alternative designs supercritical CO<sub>2</sub> could also be considered.

### Turbines

In earlier research (Houtkoop, 2022) multiple turbine concepts have been investigated for marine nuclear power generation, namely:

- Rankine cycle (Steam)
  - Superheat
  - Superheat and reheat
  - Superheat and feedwater heating
- Closed Brayton cycle
  - Simple cycle
  - Recuperation
  - Intercooling and/or recuperation
- Open Brayton cycle
  - Simple cycle
  - Recuperation
  - Intercooling and/or recuperation

To evaluate these options, multiple performance indicators, being weight, volume, system complexity, and load response were used. The open Brayton cycle was found to be the most suitable as shown in Table 3.

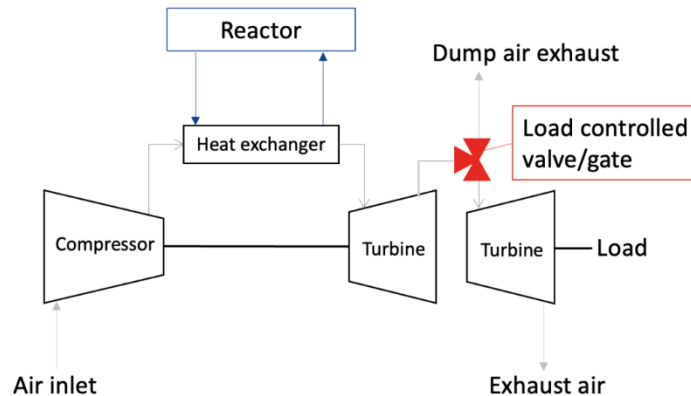

**Table 3: Summary of turbine evaluation** (Houtkoop, 2022)

Turbine → Property ↓	Rankine (steam)	Closed Brayton	Open Brayton
Efficiency	++	+	+
Volume (system)	-	+	0
Weight (system)	-	+	0
Complexity (system)	--	-	+
Load response	+	+	++

The open Brayton cycle turbine is, in terms of its development close to the current marine gas turbine, operating with air as the medium. The main difference with the conventional marine gas turbine is the use of a heat exchanger to supply heat instead of using a combustion process. One of the benefits of open cycle is that it does not require a condenser or heat exchanger for cooling, as the used air is simply rejected (Houtkoop, 2022). This however comes at the expense of having inlet and outlet ducting that are associated with performance and pressure losses and a space requirement (Stapersma, 2019).

For load response the open Brayton cycle turbine is again limited by the reactor and its heat exchanger. The aeroderivative open Brayton turbine can operate on far greater load responses than gas turbines operating on the combustion process. A greater load response similar to this can be achieved when considering load rejection strategies (Houtkoop, 2022). The resulting concept applying heat rejection to improve load response is shown in Figure 2. This configuration also shows the separation of compressor turbine and the load turbine. The benefit of this is that the compressor operation upon load change is not disturbed resulting in a larger load envelope (Stapersma, 2019). In alternative designs supercritical CO<sub>2</sub> could also be considered.

**Figure 2: Open Brayton, heat rejection and load turbine** (Houtkoop, 2022)

## Propulsion Configuration

To convert the power generated by turbine to propulsion multiple propulsion configurations can be considered. In principle this comes down to three options namely, turbine-direct, turbine-electric, or a hybrid form of both. For this study a complete electric propulsion is selected. By doing so, a conservative approach in terms of efficiency for the nuclear option is established, assuring that the results are not overly optimistic. Additionally, full electric propulsion offers flexibility in arrangement and options for easy integration of peak shaving with batteries for improved load response. Furthermore, it also offers options for reverse cold ironing while in port and easy integration of back-up power by means of diesel generators. Nevertheless, future studies are encouraged to review options to further optimize the nuclear option with, for example, turbine-direct propulsion or hybrid propulsion.

## Arrangement

Combining the found options discussed in each subsection, an initial overall arrangement is formed and shown in Figure 3. It has the reactor, shielding, and intermediate heat exchangers in the middle. There are two power generation rooms each with a primary heat exchanger, turbine, and generator. Furthermore, it has a redundant electrical propulsion system. This is supplemented with batteries and emergency diesel generators.

**Figure 3: Nuclear power generation and propulsion arrangement**

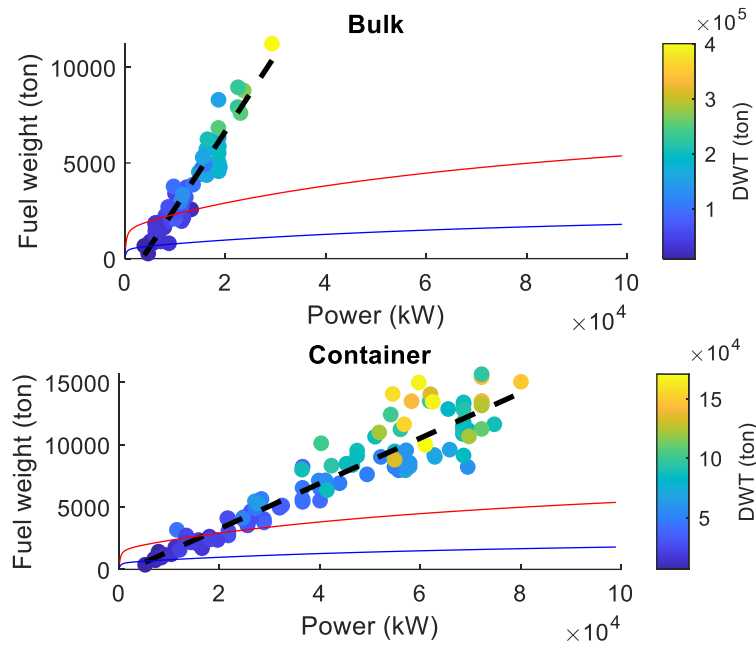

## CASE STUDIES

In this section the case studies to evaluate design speed are defined. In order to explain the selection of these case studies more background on nuclear energy and marine propulsion is reflected upon first.

### Background

Earlier research has shown that Generation IV (Gen-IV) nuclear reactors have a lot of potential to decarbonize the power sector effectively (Buongiorno, 2018). Furthermore, specifically Gen-IV Molten Salt Reactors (MSR) designs, which enable use of the thorium fuel cycle, are expected to be cost-competitive with other energy sources (Mignacca, 2020). In addition to onshore nuclear power plants other concepts are also being developed for floating nuclear power plants (Lobner, 2021). Additionally, studies have reviewed MSR application on vessels and have shown it to be economically competitive with other alternatives (Emblemsvåg, 2021) (Gennaro, 2020).

Furthermore, research work of (Houtkoop, 2022) *Nuclear reactors for marine propulsion and power generation systems* has shown that nuclear marine propulsion has a lot of potential for large ocean-going vessels to reduce harmful emissions. The completion of the study (Houtkoop, 2022) inspired to explore the potential of higher design speeds with nuclear marine propulsion. It could potentially make the ship more profitable. This is because fuel cost, as part of operational expenditures (OpEx), only grows marginally with higher speeds for nuclear powered vessels. Ultimately the main limiting factor would be the CapEx of the installation with more power. Additionally, the reactor can be used for a longer period of time by either reusing it in a new ship or by extending the service life of the initial ship. This would allow to depreciate the CapEx of the reactor over more years thus improving the economic model of the investment and enabling considerations for higher speeds further. Of the high potential ship types covered in (Houtkoop, 2022), two are selected for this study as new build cases, a container vessel and a bulk carrier. As shown in Figure 4, the weight of reactor and shielding is smaller than the conventional fuel weight, plotted as dots, for a ship set containing built vessels from the last decades, it would replace in like-for-like replacement. The blue and red lines represent the lower and upper weight estimates of the nuclear reactor and shielding. The dashed black line is a trend line of the respective data point. Therefore, the integration is considered to be manageable with limited design impact for large ocean going container and bulk vessels.

**Figure 4: Plots of vessels fuel weights vs reactor and shielding weight estimates** (*Houtkoop, 2022*)  
Blue and red lines: Lower and upper bound of weight estimates of the nuclear reactor and shielding  
Black dashed line: trend line of data points

## Container

To study container cases a market representative selection of ship size and route is made. For this study this results in the selection of a ship size of 20,000 TEU with two routes as described below in Table 4.

**Table 4: Container cases**

Case	Route (Baltic Exchange, 2023)	Distance [nm] (Ports.com, 2010-2023)	Port duration* [day]	Suez canal duration* [day]
I	North Europe – China/East Asia (FBX11 & 12)	11,999 (Rotterdam – Shanghai)	3	1
II	Europe – North America East Coast (FBX21 & 22)	3,918 (Rotterdam – New York)	3	Not applicable

\*No additional considerations are made with respect to port congestion that could result in waiting times. (C-Job Naval Architects, 2024)

## Bulker

To study bulk carriers cases a market representative selection of ship size and route is made. For this study this results in the selection of a ship size of 300,000-ton DWT with the vessel transporting iron ore along two routes, as described below in Table 5.

**Table 5: Bulker cases**

Case	Route (Baltic Exchange, 2023)	Distance [nm] (Ports.com, 2010-2023)	Port duration* [day]	Suez canal duration [day]
III	Tubarao, Brazil to Qingdao, China (C3)	13,555 (Tubarao to Qingdao)	5	Not applicable
IV	West Australia to Qingdao China (C5)	4,059 (Hedland to Qingdao)	5	Not applicable

\*No additional considerations are made with respect to port congestion that could result in waiting times. (C-Job Naval Architects, 2024)

## SPEED-DEPENDENT TOTAL COST OF OWNERSHIP

To determine the most economical speed, the speed-dependent costs need to be identified which then can be deducted from the shipping income. As a result, it will show where the optimal speed lies. The speed-dependent total cost of ownership is divided into capital expenditures and operational expenditures. In this calculation, only main contributors are considered. Cost components that are not (substantially) influenced by speed are not included in this analysis, as this is an initial evaluation for optimum design speed and its design implementation.

### Capital Expenditures

Speed-dependent capital expenditures (CapEx) are identified in two main components. The first is the nuclear reactor, which not only includes the reactor, but also its shielding, the heat exchangers, turbines, generators, and other respective auxiliaries. The second component includes electrical system elements, the electric motor, gearbox, propeller shaft and the propeller. Other components are not included in this study.

#### Nuclear Reactor

Small Modular Reactors (SMR), which are defined as nuclear reactors with 300,000 kWe or less, are the most suitable to establish a cost reference. Based on literature research, the estimated costs of SMRs are as presented in Table 6. Most references include estimated costs of Pressurized Water Reactors (PWRs) and only a few cover multiple reactor types. This study is not exclusive to one reactor type, as stated earlier, and instead it researches a bandwidth of reactor CapEx.

To estimate the nuclear reactor cost, the reactor size, in terms of power, needs to be defined. Referring to the range of installed brake power of large ocean-going vessels fitted with diesel engines, generally directly connected to the propeller shaft, as presented in Figure 4, the installed brake power ranges from 5,000 to 80,000 kW.

**Table 6: Nuclear reactor CapEx (Leurs, 2023)**

Source	Cost [\$/kWe]	Power [MWe]	Type
(Abdulla A., 2013)	*2,000-9,200	45	PWR
(Abdulla A., 2013)	**9,200-25,500	45	PWR
(Stewart W.R., 2022)	5,230	160	PWR
(Vegel Benjamin, 2017)	4,790	225	PWR
(EIRP, 2016)	2,053-5,855	<300	Various
(Lloyd, 2018)	5,720	300	PWR
(Lloyd, 2018)	5,000	400	PWR
(Lloyd, 2018)	4,500	500	PWR
(Lloyd, 2018)	4,225	600	PWR
(Stewart W.R., 2022)	4,059	685	PWR
(Black Geoffrey A., 2019)	3,611	720	PWR

\*11 experts

\*\*5 experts

As can be seen in Table 6 there is a relative cost decrease with higher power generated. Furthermore, there are still quite some deviations between the calculated cost estimates. Based on these results a bandwidth of 3,000-9,000 \$/kWe is selected for the analysis in this study. Respective decommissioning cost estimates show similar deviations as shown Table 7. For this analysis, since a large bandwidth of CapEx is investigated, the decommissioning cost is assumed to be included in the CapEx.

**Table 7: Nuclear reactor decommissioning cost (Leurs, 2023)**

Source	Cost [\$/kWe]
(NEA, 2016)	1,070-1,220
(The World Bank, 1990)	144-254
(Sayres and Associates Corporation, 2008)	3,153
(United States General Accounting Office, 1992)	242-432

**Other**

For the other CapEx items, design guidelines and estimations of C-Job are used. The resulting costs are shown in Table 8.

**Table 8: Other CapEx (C-Job Naval Architects, 2024)**

Item	Cost
Electrical System	500 \$/kW
Electric Motor	250 \$/kW
Gearbox	75 \$/kW
Propeller and Shaft	75 \$/kW

**Operational expenditures**

Yearly speed-dependent operational expenditures (OpEx) are identified in three parts. The first is fuel cost. The second is the operations and maintenance cost. The third cost aspect is the voyage cost including port, canal, pilot, and tug fees. Whereas the fuel and operation and maintenance cost are evidently speed dependent, the voyage cost is also directly proportional to the vessels speed, because with higher speeds, ports and canals are visited more frequently, resulting in a higher yearly costs.

**Fuel Cost**

To determine the fuel cost per kWh (\$/kWh), the respective specific fuel consumption (sfc) in g/kWh and cost of fuel \$/kg of the respective fuel needs to be established. The efficiency g/kWh can be defined by assuming a burnup (IAEA, 2020) of 45 GWd/tHM (Gigawatt per day per ton of heavy metal) and a reactor efficiency of 33% (Shultis, 2002), resulting in 0.0028 g/kWh. To put this in perspective, marine diesel engines are generally in the order of 170 g/kWh (MAN Energy Solutions, 2024) using Very Low Sulphur Fuel Oil (VLSFO).

The World Nuclear Association (WNA) divides the front-end fuel cycle costs into four categories. The natural uranium mining cost, the conversion cost, the enrichment cost, and the fuel fabrication cost. These account for 51%, 7%, 24% and 18% of the cost respectively (Leurs, 2023). In summary, an average of 2,500 \$/kg Uranium 5% enrichment was found (Leurs, 2023). Alternatively, in future work Uranium 20% enrichment or Thorium could also be investigated.

Combining 0.0028 g/kWh and 2500 \$/kg one can find 0.0070 \$/kWh as fuel cost for nuclear. To put this in perspective, for marine diesel engines this would be 0.102 \$/kWh, based on 600 \$/ton VLSFO (Ship and Bunker, 2024) and the earlier defined 170 g/kWh. With these prices, in terms of fuel cost, based on energy output, nuclear is roughly a factor of 15 cheaper than VLSFO.

**Operations & Maintenance Cost**

The operation and maintenance (O&M) cost of a nuclear power plant are the costs to maintain and operate a nuclear power plant. They consist of all non-fuel costs which are, for example, plant staffing, purchased services, replaceable materials, and equipment. Further, these can be divided into fixed and variable costs where fixed (plant staffing) are considered the biggest, which for a marine application will be assumed as nuclear power plant crew cost (Mignacca, 2020). The fixed costs are based on the installed electrical power and expressed in \$/kW per year. Furthermore, the variable costs are based on MWh output expressed in \$/MWh. An overview of O&M cost estimates is shown in Table 9. For this study, a round average is taken resulting in 130 \$/kW per year and 4.0 \$/MWh are used.

**Table 9: Nuclear O&M cost (Leurs, 2023)**

Source	O&M Fixed [\$/kW per year]	O&M Variable [\$/MWh]
(EIRP 2016)	96	3.0
(EIRP 2016)	158	5.0
(EIRP 2016)	206	6.5
(US Energy Information Administration 2022)	99	3.1
(US Energy Information Administration 2022)	114	2.8
(Vegel Benjamin 2017)	123	3.9
Round average	130	4.0

### ***Voyage Cost***

In this analysis the voyage cost consist of fees for ports, canals, pilots, and tugs. Based on reviews of the ports an average estimate has been established to be used in this analysis. An overview of the defined cost is shown in Table 10.

**Table 10: Voyage cost (Leurs, 2023)\*\***

Item	Cost
Port Case I & II (Rotterdam, Shanghai, New York)	0.50 \$/GT + *6.00 \$/TEU
Port Case III & IV (Tubarao, Qingdao, Hedland)	0.80 \$/GT
Pilotage Case I & II (Rotterdam, Shanghai, New York)	7,500 \$/per visit
Pilotage Case III & IV (Tubarao, Qingdao, Hedland)	20,000 \$/per visit
Tugs Case I & II (Rotterdam, Shanghai, New York)	6,000 \$/tug 3 tugs per visit
Tugs Case III & IV (Tubarao, Qingdao, Hedland)	15,000 \$/tug 3 tugs per visit
Suez Canal Case I	4.50 \$/GT

\*Based on 0.50 \$/ton per TEU and 12 ton per TEU

\*\*Rounded estimates from respective sources

## **SHIPPING INCOME**

In this study, a range of freight rates is investigated to determine their influence on design speed. To obtain a realistic and market representative range of freight rates, historical data of the past 5 years from the Baltic Exchange (Baltic Exchange, 2023) has been studied.

### **Container Case I & II**

Case I, with FBX11 and FBX12, and Case II, with FBX21 and FBX22, generally has an average freight rate between \$1,000-\$3,000 per FEU (Baltic Exchange, 2023). There are certain periods above and below this average range, but these are excluded from this study as they do not occur very often. Because container vessels do not always sail fully loaded, a utilization factor of 0.85 (Leurs, 2023) is used in this study.

### **Bulker Case III & IV**

Case III, with C3 and Case IV, with C5, generally have an average freight rate between \$5-\$30 per ton of ore (Baltic Exchange, 2023). Similar to container freight rates, ore freight rates have certain periods above and below this average range. However, these are not included in this study. For utilization of the DWT for cargo 0.98 has been defined. 1.3% (0.013) of the DWT, being 4000 ton, is deducted to compensate for additional lightship weight (LSW) of the nuclear power plant as derived from earlier work (Houtkoop, 2022). The remaining 0.7% (0.007) of the DWT, being 2000 ton, is available for the consumables. The reference conventional base case Brasil Maru (Royal Institution of Naval Architects, 2008) has approximately 7500 ton of its DWT allocated for VLSFO. VLSFO is no longer present on the nuclear option and other consumables are only a fraction of fuel DWT. Therefore, the 2000 ton is deemed more than sufficient for other consumables. It is recommended to study the consequences of the integration of reactor and shield on LSW. The reason for this is that the longitudinal strength for bending and shear is different than with VLSFO storage.

## DESIGN SPEED CALCULATION METHOD

In this section the design speed calculation method is clarified by defining the specifications of the ships. Furthermore, the economic speed determination is elaborated upon and illustrated showing how the cost are deducted from the shipping income resulting in a profit line.

### Nuclear Options

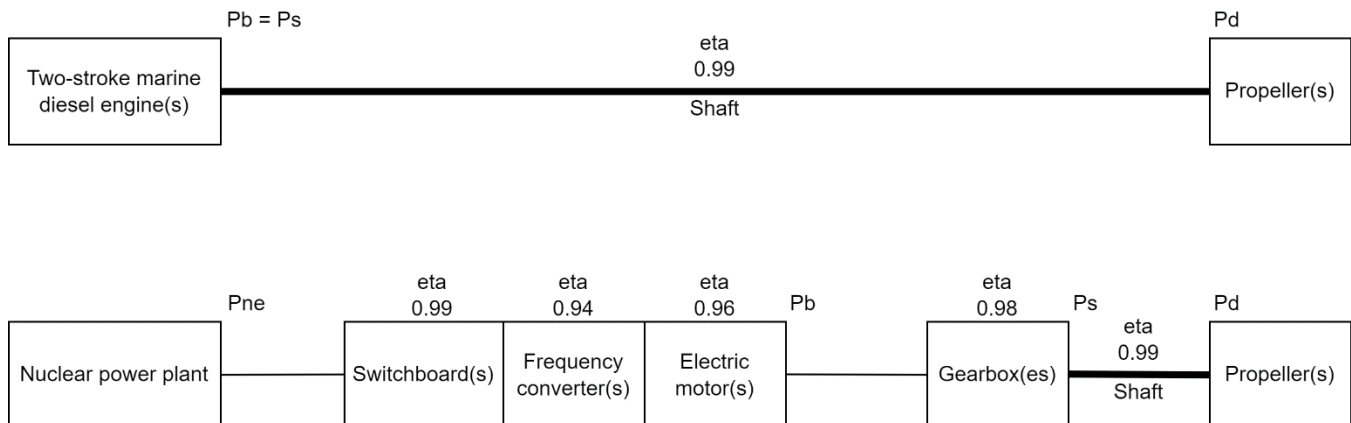

With the income and speed-dependent costs identified, various scenarios can be calculated for different freight rates, reactor CapEx, and speeds. To do this, the vessel's total resistance is calculated for various speeds. Because relative high speeds are the area of interest, with large ocean going vessels, wave making resistance is a substantial part of the total resistance. To calculate it in a preliminary design stage a smaller vessel (Maersk-B Class (Leurs, 2023)) of the same type with a high Froude number is scaled up to the size and capacity of interest. Keeping the Froude number constant the total resistance is calculated. By doing so, for speeds up to the respective Froude number, it can be stated that the wave making resistance is not underestimated, which is considered a conservative approach for the initial designs. These estimates are then compared to Holtrop & Mennen (Leurs, 2023) to validate the order size of the respective resistance for the actual calculations. The initial estimates for the container cases are shown in Table 11.

**Table 11: Initial design estimates container (Leurs, 2023)\***

Container	Model	Ship
Name	Maersk-B Class	Nuclear Container
Lbp x B x T [m]	278.20 x 32.18 x 12.20	475.72 x 55.03 x 20.86
Cb [-]	0.59	
Displacement [ton]	66,051	330,255
Froude number [-]	0.29	
Speed [kts]	29.2	38.2
Capacity [TEU]	4,000	20,000
Scale factor [-]	1.71	
Pd [MW]	68.0	444.3
Pb [MW]	68.6	457.9
Pne [MWe]	-	512.6

\*Further clarified with power figures.

The power listed is brake power (Pb) for the existing vessels, listed under Model. Pb is the power provided by the engine on the shaft. The listed power for the nuclear option, listed under Ship, is the installed nuclear electrical power (Pne). This is calculated by correcting the translated Pb with 0.89 which is clarified in Figure 5.

**Figure 5: Conventional and nuclear power train (applied in this study) (C-Job Naval Architects, 2024)**

The gearbox is included as a conservative approach but it might not be needed. This study aims to represent a broad range of designs. To make this tangible with a hypothetical speed of 30 knots it would result in roughly 249 MWe pne. For a hypothetical vessel that uses two electric motors, this would translate into a power output of roughly 111 MWe per electric motor. The impact of the size of such electric motors without gearbox is not fully known. Additionally, similar to the selection of full electrical propulsion, adding the gearbox, with efficiency loss, contributes to a conservative approach in terms of efficiency. By doing so there is additional margin that assures that the results are not overly optimistic for the nuclear option. Therefore,

the gearboxes are included in this study, in addition to making sure that the size of the electric motors are manageable. Nevertheless, future studies are also encouraged to review options to further optimize the nuclear option with (full) electrical propulsion without gearbox in addition to other propulsion configurations.

The same method used for scaling the container vessel has been used for the bulk carrier using Golden Wealth bulk carrier as reference vessel which has  $F_n$  0.25 with 18,842 ton DWT (Ship Spotting, 2011). However, it was found that the resulting economic speeds were not in the high speed region ( $F_n > 0.2$ ) but clearly in the lower speed region ( $F_n < 0.2$ ). Therefore, using this reference vessel and method was not found suitable as the results were reasonably accurate on the high speeds but too conservative for the lower speeds. Therefore, a different reference vessel was selected, Brasil Maru, with a lower Froude number and larger deadweight resulting in a smaller scale factor. Here it should be noted that any potential results above this Froude number could be considered too optimistic. The initial estimates for the bulker cases are shown in Table 12.

**Table 12: Initial design estimates bulker**

<b>Bulker</b>	<b>Model</b>	<b>Ship</b>
Name	Brasil Maru*	Nuclear Bulker
Lbp x B x T [m]	325.00 x 60.00 x 18.10	336.31 x 62.09 x 18.73
Cb [-]	0.85**	
Displacement [ton]	307,508	330,255
Froude number [-]	0.15	
Speed [kts]	16.0	16.3
DWT [ton]	270,728	300,000
Scale factor [-]	1.03	
Pd [MW]	23.4	26.4
Pb [MW]	23.6	27.2
Pne [MWe]	-	30.4

\*Data Brasil Maru: (Royal Institution of Naval Architects, 2008) & (Class NK, 2023)

\*\*Estimate based on trend line derived from (C-Job Naval Architects, 2024)

As discussed in the background section of this study, the service life of nuclear reactors, approximately 75 years, are substantially longer than the service life of a conventional vessels, approximately 25 years. A first consideration would be to extend the service life of the vessel to make the use of nuclear reactor more attractive economically. However, an alternative form of economic use of the nuclear reactor is to decommission the ship, at its service of life of 25 years, and preserve the nuclear reactor which can then be used for a new vessel. Reviewing the options, this study views that the selection of either option on how to extend the use of the nuclear reactor, is independent on the design speed analysis. Therefore, in this study only the potential of extended use of the nuclear reactor is investigated with 50 and 75 years in addition to the conventional 25 years of service life of a vessel as illustrated in Figure 6. This study does not include evaluation of either option on how to extend the service life of the ship with nuclear reactor as illustrated in Figure 7. Future studies are encouraged to review these options, including all aspects of the ship and nuclear reactor, in order to determine the most attractive strategy.

**Figure 6: Service life options nuclear reactor (investigated in this study)**

**Figure 7: Service life options ship with nuclear reactor 75 years (not investigated in this study)**

### Conventional Option

To determine whether the resulting speeds of the nuclear options are actually higher compared to conventional configurations, as anticipated, a conventional option as reference is established. This conventional option will use the parameters as per Table 13 based on established design guidelines.

**Table 13: Conventional option parameters**

Item	Parameters	Source
Income	Same as Nuclear	-
CapEx: Marine diesel engine (2-stroke)	350 \$/kW	(C-Job Naval Architects, 2024)
OpEx: Fuel cost (VLSFO) Specific fuel consumption	300-800 \$/ton 170 g/kWh	(Ship and Bunker, 2024) (MAN Energy Solutions, 2024)
OpEx: O&M Fixed per year	35 \$/kW	(Leurs, 2023)
OpEx: O&M Variable	10 \$/MWh	(Leurs, 2023)
OpEx: Voyage	Same as Nuclear	-

## Case Calculations

With the shipping income, and all cost components defined each case can be evaluated accordingly to determine the maximum profit and thus the optimum speed. An example of an individual scenario calculation is shown in Figure 8 which regards Case I, Nuclear, service life 75 years, freight rate \$2000 per FEU, reactor CapEx \$6,000 per kW. By combining all maximum profit scenario results an overview can be made with most economic speeds. These results are presented in the next section for all 4 cases with 3D graphs.

**Figure 8: Example of individual scenario calculation**

(Case I, Option Nuclear service life 75 years, scenario freight rate \$2000 per FEU, reactor CapEx \$6,000 per kW)

## DESIGN SPEED RESULTS

Results covering the entire range of scenarios are presented in 3D graphs per case. Additionally, three specific scenarios are listed in tables for further considerations as shown in Table 14. For the conventional option, three specific scenarios are defined as per Table 15, similarly as with the nuclear options.

**Table 14: Specific nuclear scenarios**

Scenario	Freight rate	Nuclear reactor CapEx
A	High	Low
B	Average	Average
C	Low	High

**Table 15: Specific conventional scenarios**

Scenario	Freight rate	Fuel cost
A	High	Low
B	Average	Average
C	Low	High

## Container

In this subsection the results of the container cases are presented and initially reflected upon. More extensive evaluation is covered in the section *Discussion*.

### Case I

Using the figures of shipping income and speed-dependent cost with the described calculation method, Case I can be calculated with the results shown in Figure 9 (where the color gradient covers the resulting speed levels). The principal coding to generate these figures is sourced from (Leurs, 2023) and is adjusted with refined assumptions for this study. Furthermore, the results of the specific scenarios of nuclear with both 25, 50, and 75 years of service life, and the conventional VLSFO reference with 25 years are shown in Table 15.

**Figure 9: Case I, Nuclear, service life 75 years (color gradient covering speed levels)**

**Table 16: Case I design speed results of specific scenarios [kts]**

Scenario	VLSFO 25y	Nuclear 25y	Nuclear 50y	Nuclear 75y
A	22.9	24.3	27.0	28.2
B	14.6	17.2	19.9	21.2
C	8.0	10.5	12.6	13.7

As can be seen in the nuclear options, 25, 50, and 75 years of service life, have higher economic speeds than the conventional VLSFO case of 25 years. Results of scenario A and B seem realistic as the conventional VLSFO case with speeds from 15 to 23 knots is considered very representative to current container vessel operation. For example, the Triple-E class of Maersk has a service speed of 16 knots and a maximum speed of 23 knots. Reviewing scenario C, which is the low-speed scenario, it should be noted that the current resistance estimate is done with a basic initial approach aiming for a good accuracy for the higher speed range, as explained earlier in the section Design Speed Calculation Method. As a result, it is too conservative for lower speeds (meaning speeds below 14 knots  $F_n < 0.2$ ). Hence the lower resulting speeds for scenario C. Furthermore, nuclear with 75 years of service life has an increase in economic speed compared to nuclear with 25 years of service life. This confirms the earlier statement about its potential and quantifies the additional gain. Additionally, freight rate seems to have the biggest influence whereas reactor CapEx has a less substantial role in the range investigated in this study.

### Case II

For Case II, the results are shown in Figure 10 and the results of the specific scenarios are shown in Table 17.

Figure 10: Case II, Nuclear, service life 75 years

Table 17: Case II design speed results of specific scenarios [kts]

Scenario	VLSFO 25y	Nuclear 25y	Nuclear 50y	Nuclear 75y
A	35.9	33.9	37.3	38.8
B	24.6	25.6	29.2	30.9
C	15.3	17.8	21.0	22.6

With Case II covering a substantially shorter distance than Case I, the resulting speeds are clearly higher. This can be explained by the investigated ranges of cost and freight rates. The freight rates are kept the same resulting in the same amount of income. On the other hand, lower cost associated with a shorter distance, lead to higher economic speeds. So, in general similar trends can be observed compared to Case I, where the actual speeds are higher. However, scenario A does not seem representative for Case II for current container vessel operations with speeds up to 36 knots for the VLSFO case. One might consider those respective conditions to be too optimistic with a very low likelihood of occurring. Here the results of scenario B and C are deemed more representative.

**Bulker**

In this subsection the results of the bulker cases are presented and initially reflected upon. More extensive evaluation is covered in the section Discussion.

**Case III**

For Case III, the results are shown in Figure 11 and the results of the specific scenarios are shown in Table 18.

**Figure 11: Case III, Nuclear, service life 75 years**

**Table 18: Case III design speed results of specific scenarios [kts]**

Scenario	VLSFO 25y	Nuclear 25y	Nuclear 50y	Nuclear 75y
A	15.2	16.5	18.3	19.1
B	8.9	10.8	12.5	13.3
C	3.7	5.2	6.2	6.8

As can be seen in the nuclear options, 25, 50, and 75 years of service life, have higher economic speeds than the conventional VLSFO case of 25 years. The result of scenario A of the conventional VLSFO case, with 15 knots, are deemed representative as current bulk carrier operations are considered to generally range between 11 and 16 knots. Additionally, freight rate seems to have the biggest influence whereas reactor CapEx has a less substantial role in the range investigated in this study.

### Case IV

For Case IV, the results are shown in Figure 12 and the results of the specific scenarios are shown in Table 19.

Figure 12: Case IV, Nuclear, service life 75 years

Table 19: Case IV design speed results of specific scenarios [kts]

Scenario	VLSFO 25y	Nuclear 25y	Nuclear 50y	Nuclear 75y
A	23.2	21.8	24.1	25.0
B	14.5	15.2	17.3	18.4
C	6.5	8.1	9.6	10.4

As can be seen in the nuclear options, 25, 50, and 75 years of service life, have higher economic speeds than the conventional VLSFO case of 25 years for scenario B and C. Scenario A does not seem representative for current bulk carrier operations with speeds up to 23 knots for the VLSFO case. Besides that, the shorter distance in Case IV logically has also higher speeds than Case III since the freight rates are kept the same and the effective cost is lower for the shorter distance. The result of scenario B of the conventional VLSFO case, with 15 knots, is deemed representative with respect to current bulk carrier operations.

## DISCUSSION

In this section the results are further reflected upon. Additionally, an outlook is given on the design development including considerations for propulsion configurations.

### Design Speed

This sub-section evaluates the design speeds of both cases for both ship types and envisions a guideline for future research.

#### *Container*

Reviewing the container cases with the specific scenarios, the range between scenario A and B for Case I and the range between scenario B and C for Case II seem most representative for the current container vessel operations. Considering the respective results of these cases and scenarios, it is found that 28-31 knots with a service life of 75 years would be a good range to explore nuclear powered container vessels further. This is a considerably higher speed than conventional container vessels. This is based on the assumption that the service life of the reactor is 75 years which is derived from existing nuclear power plants (Petrakakos, 2024). If the service life of the reactor changes, this design guideline would need to be revisited. As this is an initial design review, further analysis is recommended to cover more details, reduce uncertainty, and confirm or adjust these findings accordingly.

#### *Bulker*

Reviewing both bulker cases, similar principle results as with the container cases can be observed. Namely, both nuclear options, 25, 50, and 75 years of service life, have higher economic speed than the conventional VLSFO case, expect in scenario A of the shorter distance case. Furthermore, nuclear vessels with 75 years of service life have an increase in economic speed compared to nuclear vessels with 25 or 50 years of service life. Additionally, freight rate seems to have the biggest influence whereas reactor CapEx has a less substantial role. Considering the respective results of these cases and scenarios, it is found that 18-19 knots with a service life of 75 years would be a good range to explore nuclear powered bulk carriers further. This is a somewhat higher speed than conventional bulk carriers. This is based on the assumption that the service life of the reactor is 75 years which is derived from existing nuclear power plants (Petrakakos, 2024). If the service life of the reactor changes this design guideline would need to be revisited. As this is an initial design review further analysis is recommended to cover more details, reduce uncertainty, and confirm or adjust these findings accordingly.

#### *Sensitivity*

This study analyzed a bandwidth of reactor CapEx and freight rate and studied its impact on design speed. Besides these factors, also other cost aspects were quantified based on various references and design guidelines. Primarily the OpEx is considered of interest to be studied further to identify its sensitivity with respect to the design speed. This includes, but is not limited to, operations and maintenance cost of the nuclear power plant, and nuclear fuel cost, which is derived from the level of enrichment, the burnup and the price per kilogram. Further sensitivity analysis will help improve the robustness of the overall assessment. This will support the decision making process for the design speed of nuclear powered vessels.

## Design Development

In this section the design development considerations for both the container vessel and bulk carrier are given. This covers main dimensions, resistance, and hybrid propulsion configurations.

#### *Container*

For this analysis the main dimensions of the container vessel exceed current port restrictions. Furthermore, a volume and displacement check needs to be done to confirm the cargo capacity (TEU), and adjust main dimensions where needed, to assure it is not too large. Therefore, for further design development it is envisioned to change the dimensions as shown in Table 20.

**Table 20: Container vessel development of main dimensions**

Parameter	Nuclear Initial	Nuclear Iteration 1	Nuclear Iteration 2*	Port restriction (Leurs, 2023)
Lbp [m]	475.72	475.72	399.90	Rotterdam
B [m]	55.03	55.03	61.50	Rotterdam
T [m]	20.86	20.86	15.00	Shanghai
Cb [-]	0.59	0.59	TBD	-
Froude number [-]	0.29	0.23	0.25	-
Speed [kts]	38.8	30.0	30.0	-

\*Envisioned dimensions based on port restrictions

Reviewing this design development it is noted that the length over breadth ratio is reduced from 8.6 to 6.5 which is less favorable with respect to wave making resistance. However, at the same time, the actual Froude number is also reduced as the initial

speed of 38.8 knots is reduced to 30.0 knots (derived as rounded average from the earlier identified range of 28-31 knots) based on the economic analysis. Thus, this also implies that the relative part of wave making resistance is reduced in the total resistance. So, these changes are not expected to change the overall total resistance significantly. Regardless, it is recommended to further develop the design, starting with the second iteration to reduce uncertainty, and confirm or adjust these findings accordingly.

Besides the envisioned development in main dimension, the propulsion can also be studied further. It might be possible that the initial defined arrangement of two propellers, as shown earlier in Figure 3, is not optimal for the considered speeds. The speed of 30 knots will require a substantial amount of thrust which thus might opt for a three propeller arrangement to reduce thrust loading coefficients and improve overall efficiency. An initial design of a 3 propeller arrangement is shown in Figure 13.

**Figure 13: Initial design 3 propeller arrangement** (*C-Job Naval Architects Visualization Discipline, 2024*)

The proposed arrangement with more propellers would offer further potential for hybrid propulsion configurations such as, but not limited to:

- 2 electric driven shafts + 1 direct turbine driven shaft
- 2 electric pods + 1 direct turbine driven shaft
- 1 electric driven shaft + 2 direct turbine driven shafts
- 3 hybrid driven shafts (turbine + power take in/off)

To further visualize this vision an initial integrated design of 3 hybrid driven shafts (turbine + power take in/off) is shown in Figure 14, Figure 15 (and Figure 16 under the acknowledgement).

**Figure 14: Initial ship design with integrated nuclear power and 3 hybrid driven shafts (turbine + power take in/off) part 1** (*C-Job Naval Architects Visualization Discipline, 2024*)

**Figure 15: Initial ship design with integrated nuclear power and 3 hybrid driven shafts (turbine + power take in/off)**  
**part 2** (*C-Job Naval Architects Visualization Discipline, 2024*)

### ***Bulker***

Reviewing the bulk carrier dimensions, no adjustments seem absolutely necessary based on port restrictions. Furthermore, the considered speed range of 18-19 knots, defined in the earlier discussion, would suggest two propellers are adequate. Based on that a number of hybrid propulsion configurations can be considered, such as, but not limited to:

- 2 hybrid driven shafts (turbine + power take in/off)
- 1 electric pod + 1 direct driven shaft line

### **Contribution and Future Work**

The work of (Houtkoop, 2022) identified the initial potential of next generation nuclear technology for shipping with replacement of conventional power generation. The work of (Leurs, 2023) expanded on this for container vessels by developing new build cases and explore their potential focusing on design speed, propulsion and power generation, and ship design. As additional expansion, this study also added the bulk carriers focusing on the same aspects. With this combined material, this study aims to inspire other naval architects and marine engineers to look beyond conventional design and operations, and punch technical boundaries to ultimately make shipping more sustainable.

## CONCLUSION

Both nuclear options, 25, 50, and 75 years of service life, have higher economic speeds than the representative conventional VLSFO case. Furthermore, nuclear with 75 years of service life has an increase in economic speed compared to nuclear with 25 and 50 years of service life. Additionally, freight rate seems to have the biggest influence whereas reactor CapEx has a less substantial role. Besides that, the shorter distance cases logically also have higher speeds than longer distance cases since the freight rates are kept the same and the effective cost are lower for the shorter distance.

Considering the respective results of the container cases it is found that 28-31 knots with a service life of 75 years would be a good range to explore nuclear powered container vessels further. For the bulkier cases it is found that 18-19 knots with a service life of 75 years would be a good range to explore nuclear powered bulk carriers further. This is based on the assumption that the service life of the reactor is 75 years which is derived from existing nuclear power plants. If the service life of the reactor changes this design guideline would need to be revisited.

In the initial review of options on how to convert nuclear power to propulsion and electrical power each part was evaluated. A primary and intermediate loop was used for heat transfer to the secondary loop to assure containment of radiation. For the turbines, an open Brayton cycle concept with load turbine and heat rejection capability was found to be most suitable, as it has improved load response capabilities and is relatively compact.

## RECOMMENDATIONS

In this section the recommendations are given which serve as inspiration for future research and are part of the authors vision and understanding of the topic acknowledging various aspects that require more attention for the next steps.

### Cost

The studied bandwidth of reactor CapEx, which included decommissioning cost in this study, is still quite broad and should be narrowed down further to reduce the uncertainty on the total cost of ownership. To do so, more detailed input from nuclear power plant developers is required to evaluate initial investment cost and the connected decommissioning cost at the end of the service life. Additionally, the effects of inflation on these costs over longer periods, considering the 75 years that is investigated in study, should also be incorporated in future work to reduce the uncertainty.

Besides CapEx, also OpEx of nuclear power plants should be studied further to reduce the uncertainty on the total cost of ownership. Especially, operations and maintenance cost of the nuclear power plant, and nuclear fuel cost are considered to be very relevant in future studies.

The effect of higher speeds and potential longer service life of other ship cost components such as the steel hull and other components besides the nuclear power plant should also be included in future studies. Despite the fact that these cost components are anticipated to be smaller than the nuclear power plant, incorporating them will improve the accuracy of the total cost of ownership which is the foundation for investment decisions.

Another cost component that requires more attention is the insurance. At this time, the difference in ship insurance cost between conventional and nuclear-powered ships is unknown and is not included in this study. Nevertheless, considering the sensitive nature of nuclear power, it deserves more attention from an insurance perspective as well. Therefore the respective insurance cost should also be studied.

### Regulatory Framework

The current regulatory framework for nuclear powered vessels are outdated and considered a hurdle for nuclear power to be applied in (commercial) marine applications. Therefore, further development of nuclear power on marine applications is needed to clarify various parts on national and international level. This development should include all involved stakeholder such as, but not limited to, equipment manufacturers, ship designers, shipyards, classification societies, shipowners, local governments and nuclear regulators.

### Main Particulars

The studied container vessel design has main dimensions that exceed current port restrictions. Furthermore, a volume and displacement check needs to be done to confirm the cargo capacity (TEU). Therefore, it is recommended to further develop the design, starting with the second iteration to reduce uncertainty, and confirm or adjust these findings accordingly. Furthermore, it is recommended to do a more detailed resistance analysis to reduce the uncertainty.

## **Propulsion Configuration**

In this study a fully electric the propulsion configuration was selected as it offers flexibility in arrangement and options for easy integration of peak shaving with batteries for improved load response. Furthermore, it also offers options for reverse cold ironing while in port and easy integration of back-up power by means of diesel generators. Nevertheless, future studies are encouraged to review options to further optimize the nuclear option with for example turbine-direct propulsion, hybrid propulsion or full electrical propulsion without gearbox.

## **Operational Challenges**

Where conventional VLSFO fueled vessels have low CapEx for their marine engines, it is observed that big(ger) engines can be installed with relatively little additional cost. With that, one gains the operational flexibility to adjust speed economically based on freight rate and fuel cost, as part of OpEx. For nuclear powered vessels this operational flexibility is limited as the CapEx of the nuclear reactor is relatively large. Therefore, it is recommended to further study all costs of nuclear marine propulsion where the share of CapEx, fuel, O&M, and others are better understood. Based on that the economic risks can be better assessed in order to determine the actual design speed for a nuclear-powered cargo vessel. An additional challenge, for the container vessel cases, considering their high speeds, is heavy weather conditions were it could be the case that ship speed needs to be temporary lowered to avoid damages caused by such conditions at higher speeds. The potential effect of this should be further studied.

## **Service Life**

The service life of nuclear reactors is understood to be approximately 75 years and thus substantially longer than the service life of a conventional vessels, with approximately 25 years. So in general it seems logical to use the full service life of 75 years of the nuclear reactor on one or more vessels. This is further supported by findings of higher operational speeds, and thus more profitability, for service life of 75 years. However, it is not known what option, on how to facilitate utilization of the nuclear for 75 years, on one, two or three vessels is most economical. Therefore, future studies are encouraged to review these options in order to determine the most attractive strategy.

## **Ship Types**

Besides container vessels and bulk carriers, it is recommended to consider other ship types, such as, but not limited to, tankers and offshore vessels, to further explore the potential of nuclear marine propulsion.

## DECLARATION OF GENERATIVE AI AND AI-ASSISTED TECHNOLOGIES IN WRITING

No AI or AI-assisted technologies have been used by the authors in the receptive research or in writing this paper.

## CONTRIBUTION STATEMENT

**Author 1, Niels de Vries:** Research of the bulk carrier cases, supervision of nuclear marine propulsion and power generation research, supervision of the container vessel cases research, writing and editing of this paper.

**Author 2, Koen Houtkoop:** Research of nuclear marine propulsion and power generation, writing the referenced thesis report (Houtkoop, 2022) and reviewing this paper.

**Author 3, Zeno Leurs:** Research of the container vessel cases, writing the referenced thesis report (Leurs, 2023) and reviewing this paper.

## ACKNOWLEDGEMENTS

Multiple versions of this paper have also been reviewed by Harilaos Petrakakos, Rick Ashcroft and Roy de Winter and provided constructive feedback. Therefore, the authors would like to thank all of them and acknowledge their contribution to this paper. Furthermore, we would like to thank the support of the C-Job Visualization Discipline to develop the various renders presented in this study.

# Simulation Method of Decarbonization of International Shipping for Evaluating the Impact of Possible Regulation Limiting GHG Intensity of Marine Fuels

Shinnosuke Wanaka<sup>1,\*</sup>, Kazuo Hiekata<sup>2</sup>, Tomohito Takeuchi<sup>3</sup> and Masanobu Taniguchi<sup>3</sup>

## ABSTRACT

*This study explored how the GHG fuel standard (GFS) regulation affects international shipping quantitatively by simulating future fleet transformation, fuel consumption, and well-to-wake GHG emissions based on an inputted GHG fuel intensity pathway and scenario of transportation demand, fuel availability and costs, and technology availability. The method comprises three steps: calculating the amount of scrapped and built ships, allocating fuel type and mix, and calculating fuel consumption. We simulated how the regulation changes fleet composition and the mix of fuel consumption. From the perspective of feasibility and alternative fuels' availability, some meaningful insights to implement the GFS regulation were delivered.*

## KEYWORDS

Simulation of fleet transformation; GHG fuel standard; Decarbonization of shipping.

## INTRODUCTION

In 2023, the International Maritime Organization (IMO) revised its GHG reduction strategy to include net-zero emissions by 2050 (IMO MEPC, 2023). The strategy includes targets for introducing green fuels and total emission reduction, that is, the indicative checkpoints. These checkpoints were set for 20-30% and 70-80% reduction by 2030 and 2040 respectively. However, the technology to achieve decarbonization is in the R&D stage and has not yet been established. Although various fuels have been studied as marine fuels such as ammonia (Kim et al, 2020; Inal et al., 2022), biofuels (Tan et al. 2022), eMethane, eMethanol, and hydrogen (Shi et al., 2023), it remains undetermined which fuels and energy sources will be used in international shipping (Balcombe et al., 2019) and the fuels' availability is highly limited (Grzelakowski et al., 2022).

To encourage technological and infrastructure development to achieve this goal, various regulations, including technical and economic elements, are being discussed by the IMO. As for the economic elements, market-based measures (MBM), such as feebate and carbon levy, are being considered (Psaraftis, 2021), and the impact and implementation of these measures have been studied. For example, Wang et al. (2015) developed an economic model and evaluated the emission-trading scheme (ETS). They compared open-ETS and maritime-only ETS and discussed the economic impacts on container and bulkcarrier shipping. Metzger (2022) evaluated the impact of carbon pricing on the valuation of investments in

greening technologies using the fuzzy pay-off method. Masodzadeh et al. (2022) discussed MBM complications and proposed a new hybrid MBM to fill the gap between short-term measures and the MBM.

However, mid-term technical measures, such as the GHG fuel standard (GFS) have not yet been studied. The GFS is a regulation that requires ships to use fuels with well-to-wake (WtW) GHG intensity ( $\text{gCO}_2\text{eq/MJ}$ ) below the defined limit called the GHG fuel intensity (GFI) (IMO, 2021). A similar regulation will be introduced in FuelEU Maritime (ClassNK, 2023), which is a local regulation to be introduced in EU/EEA Member States in 2025. The framework is considered to be a certain promise, and the impact should be evaluated before implementation. When discussing the GFS, one of the important issues is whether to introduce a flexibility mechanism that allows the ships to share their GHG emission reductions in the fleet. Without this mechanism, all ships must individually comply with the GFS. However, with the flexibility mechanism, ships using better fuel than the required GFI can provide a surplus to ships that cannot comply with the required GFI. This means that the overall fleet complies with the regulations. As the path to shipping decarbonization varies depending on whether the mechanism is introduced, the impact of the flexibility mechanism must be evaluated. Moreover, the IMO's indicative checkpoints are based on total emissions from the fleet, and a macro analysis of the fleet is necessary to determine whether the GFS adequately contributes to the IMO's target.

Modeling and simulation are powerful tools for quantitatively evaluating the impact of future regulations. Eide et al. (2011) built a model to assess the cost and GHG reduction of various measures by combining a fleet projection model with activity-based  $\text{CO}_2$  calculations and evaluated the amount of GHG reduction and the required cost by using the marginal abatement cost curve (MACC). Halim et al. (2018) developed a future  $\text{CO}_2$  estimation model combining the International Freight Model and Activity, Structure, Intensity, and Emission factor methods and conducted impact assessments of various GHG reduction measures until 2035. Wada et al. (2021) used system dynamics to model the shipping and shipbuilding market and forecast future shipbuilding demand affected by the EEDI, slow steaming, and penetration of LNG to reduce GHG emissions. Zwaginga et al. (2022) pointed out that future uncertainties including regulation make designing ships difficult and utilized three methods to deal with the deep uncertainty in designing alternative fueled ships: dynamic adaptive policy pathways (DAPP), responsive system comparison (RSC), and robust decision making (RDM). By comparing the three methods, it demonstrates what insight could be obtained and how the ship design is affected by the uncertainties. However, a simulation method that can model GFS regulation and analyze its behavior, to the best of our knowledge, has not yet been developed.

The objective of this paper is to study how the GFS regulation affects international shipping in the future, and a simulation method is proposed for this purpose. The simulation projects future fleet transformation, fuel consumption, and well-to-wake (WtW) GHG emissions based on an inputted GFI pathway and enables us to study the regulation quantitatively from the perspective of feasibility, fuel, technology availability, and so on. In the case study, we assumed a GFI pathway considering the revised IMO GHG reduction strategy and simulated several cases with and without the flexibility mechanism. By comparing these results, we have analyzed how international shipping is affected by the presence or absence of the flexibility mechanism. Moreover, another case shows how the simulation can be used to search for GFI pathways that are feasible and contribute to GHG reduction as much as possible and demonstrates that the proposed method can support the design of the GFS regulation.

## **SIMULATION METHOD**

### **Overview of the Method**

Figure 1 shows an outline of the proposed simulation method, which consists of three parts: a model of shipbuilding and scrapping, a model for selecting the introduced ships and calculating the fuel mix, and a calculation of fuel consumption. The proposed method requires fleet composition data that defines the initial fleet status and five scenarios as follows: transportation demand, ships' survivor rate to age, GFI pathway that defines how WtW emission regulation in the simulation will be tightened, ship data including ships using alternative fuels, and fuel data including costs, emission factors, and availability. In this simulation, the GFS is defined by the GFI pathway, and ships and fuels are operated on the assumption that the GFI is not exceeded. The figure describes what data and scenarios are required for each part, and what kind of output is produced by the part. The simulation flow is run iteratively from 2021 to 2050 with a timestep of one year and outputs WtW emissions, WtW GHG intensity ( $\text{gCO}_2\text{eq/MJ}$ ), and costs including those of fuel and ship. In addition, the amount of shipbuilding and scrapping, the ships' fuel type introduced at each time step, and the fuel mix

utilized for the operation were considered. The remainder of this section explains the data and calculation procedures for each part.

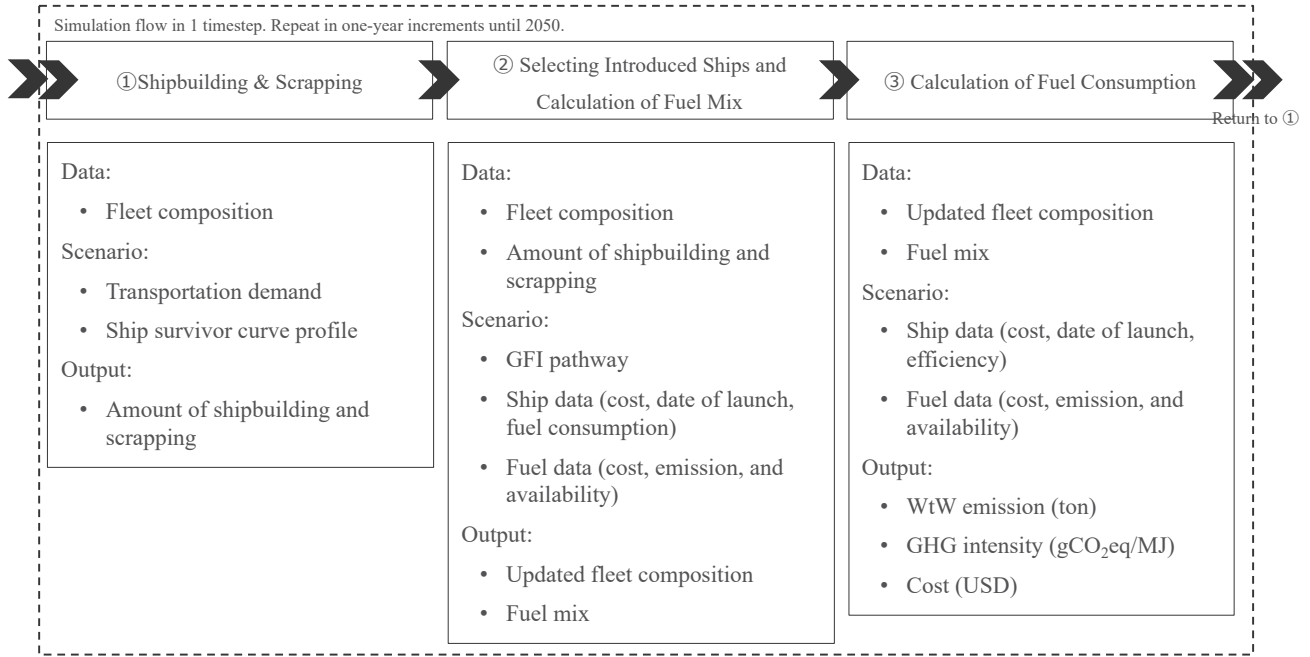

Figure 1: Outline of the proposed simulation flow

## Models of Shipbuilding and Scrapping

As for the model of shipbuilding and scrapping, the method assumes that shipbuilding is related to transportation demand, and the amount of scrapping is related to ship age distribution. First, the amount of scrapping was calculated based on fleet composition data defined by age, ship type, and the number of ships. The number of ships scrapped  $Scrap_{t,a}^{type}$  is shown in equation 1. The fleet data are represented by  $Ship_{t,a}^{type}$ , which indicates the number of ships whose age is  $a$  and ship type is  $type$  at time  $t$ .  $Sr(a)$  is the survivor rate at the ship age. The ship type is a label indicating the fuel that the vessel can use, such as LNG, NH<sub>3</sub>, and Methanol. Note that the fuel type in the method mentioned afterward is a more detailed fuel label such as eAmmonia(Blue), eAmmonia(Green), and so on, and is different from the ship type. Ship type defines a set of fuels that can be utilized. This is described in more detail in the “Case Study” section.

$$Scrap_{t,a}^{type} = Ship_{t,a}^{type} \cdot (1 - Sr(a + 1)/Sr(a)) \quad [1]$$

The number of newly built ships was calculated by adding the number of new buildings to meet the growth in transportation demand to the amount of scrapping calculated by Equation 1. The number of newly built ships  $B_t$  is calculated by Equation 2.

$$Built_t = \sum_{type} \sum_a Scrap_{t,a}^{type} + \sum_{type} \sum_a Ship_{t,a}^{type} \cdot (1 - Transportwork_{t+1}/Transportwork_t) \quad [2]$$

$Transportwork_t$  is the amount of transport work (billion-ton mile) that is supposed to be transported by the fleet at time  $t$ . Through this process, the amount of scrapping for each ship type and age and the amount of shipbuilding for the fleet are calculated. Because the objective of this method is to analyze the regulation’s behavior from a macro perspective, the fleet is represented as a set of averaged vessels with no distinction between cargo and size, and the average size of the vessels is constant in the future.

## Model of Selecting Introduced Ships and Calculation of Fuel Mix

In this subsection, a model is used to select the ship types that will be built for the shipbuilding volume calculated in the previous step and to calculate the fuel mix consumed by the fleet in the next time step. The process differs in the GFS with and without the flexibility mechanism. First, the model in the case without the flexibility mechanism is explained, followed by the differences in the case with the mechanism.

Without the flexibility mechanism, each ship in the fleet complies with the regulations and does not share the emission reductions. The model for selecting the introduced ship types and calculating the fuel mix consists of four steps: take  $n$  types of ships from the set of ship types that can be introduced and create a list of combinations of these types a pre-defined share rate, optimize the fuel mix in the fleet as each combination is introduced, and extract the combination with the lowest cost among all combinations. The ships to be introduced are selected according to their costs, including ship and fuel cost. The details of the equation in the optimization are as Equations 3 – 8, where  $FU_{fuel}^{type}$  is the percentage of fuel mix used by a specific ship type, is  $DFC$  is fuel consumption (MJ) by a ship in 1 year,  $Ship_t^{type}$  is the number of ships whose type is  $type$ ,  $FP_{fuel}$  is fuel cost(USD/MJ),  $SP_{type}$  is ship cost (USD),  $CI_{fuel}$  is carbon intensity (gCO<sub>2</sub>eq/MJ) of each fuel,  $GFI$  is a defined GFI value for the regulation,  $Limit_{fuel}$  is the fuel's availability (MJ),  $FUEL$  is the set of fuel being calculated, and  $SHIP$  is the set of ship types defined in the simulation.

$$\min \sum_{type} \left( \sum_{fuel} FU_{fuel}^{type} \cdot DFC \cdot FP_{fuel} + \frac{1}{20} SP_{type} \right) \cdot Ship_{t+1}^{type} \quad [3]$$

s.t.

$$\sum_{fuel} FU_{fuel}^{type} \cdot CI_{fuel} \leq \frac{GFI}{100} \cdot CI_{LSFO} \quad [4]$$

$$\sum_{type} FU_{fuel}^{type} \cdot DFC \cdot Ship_{t+1}^{type} \leq Limit_{fuel}, \forall fuel \in FUEL \quad [5]$$

$$\sum_{fuel \in MAIN, PILOT} FU_{fuel}^{type} = 1, \forall type \in SHIP \quad [6]$$

$$\sum_{fuel \in MAIN} FU_{fuel}^{type} \leq 1 - pfr, \forall type \in SHIP \quad [7]$$

$$\sum_{fuel \in PILOT} FU_{fuel}^{type} \geq pfr, \forall type \in SHIP \quad [8]$$

Equation 3 represents the objective function to be minimized, which is the total cost including the fuel cost and the ship cost. As for the ship cost, the value is depreciated over 20 years. Equations 4 and 5 represent constraints, respectively, to comply with the regulation, and of fuel availability. Equations 6-8 are constraints around fuel usage. *MAIN* is the set of fuels primarily used on the ship, and *PILOT* is the set of pilot fuels. For example, in a dual-fuel ship of LNG, LNG, eMethane, and BioMethane are primarily used, and LSFO and bio-heavy fuel oil (BioHFO) are used as pilot fuels. *pfr* is the pilot fuel rate required to operate; in the simulation, it is defined as 0.05 until 2040 and 0.03 thereafter.

In the case with the flexibility mechanism, ships in the fleet can share their emissions to comply with the regulation so that Equation 4 in the optimization differs as shown in Equation 9.

$$\sum_{type} \sum_{fuel} FU_{fuel}^{type} \cdot CI_{fuel} \cdot Ship_{t+1}^{type} \leq \frac{GFS}{100} \cdot CI_{LSFO} \cdot \sum_{type} Ship_{t+1}^{type} \quad [9]$$

All possible combinations are optimized, and ships with the lowest minimized cost are selected for construction. For the calculation, it is necessary to determine the number of types of ships that will be introduced in the future and the market share of these types. To simplify the calculation, we assume that three types of ships have constant market shares of 50%, 30%, and 20%, respectively. Although it is difficult to establish the market situation in the future, the authors interviewed multiple shipping companies in Japan and developed the above-mentioned assumptions. This step outputs

the types of newly built ships and the percentage of fuel utilized by each type of ship in the fleet. Once the type of newly built ships is determined, the updated fleet composition for the next year's operation can be calculated. When using the model, depending on the input GFI pathway and fuel availability scenario, no optimization solution may exist, which means that the input GFI pathway cannot be complied with by the scenario. In this case, to continue the calculation, the constraint on the GFI is removed (Equation 4) and a penalty for emissions is added to the objective function. This minimizes costs and emissions. As for the penalty, this simulation applied the penalty of FuelEU Maritime, which is calculated by multiplying the energy consumption that exceeds the regulation value by 0.06 EUR/MJ.

## Calculation of Fuel Consumption

The fuel consumption is calculated based on the updated fleet composition and fuel mix obtained in the previous step. After calculating the fuel consumption, the WtW emissions, WtW GHG intensity, and costs were calculated. Equations 10–13 represent the calculation, where  $FOC_{fuel}$  is the fuel consumption (MJ) of each fuel,  $FU_{type}^{fuel}$  is the fuel mix used by a specific ship type,  $Emission_{WtW}$  is WtW emissions (ton),  $Emission_{intensity}$  is a the GHG intensity of the fleet normalized by the LSFO's intensity, and  $FuelCost$  is the fuel cost of the fleet. The consumption of each fuel is calculated by multiplying the fuel mix, average fuel consumption per ship, and the number of ships. Because there are fuels that can be used in multiple ship types, such as LSFO, aggregation by ship type is performed. In the output cost data, CAPEX is added to the fuel cost as the total cost. For the CAPEX, only the ship cost is considered and 1/20 of the total ship cost is accounted for, assuming that the depreciated period is 20 years.

$$FOC_{fuel} = \sum_{type} FU_{type}^{fuel} \cdot Ship_{t+1}^{type} \cdot DFC \quad [10]$$

$$Emission_{WtW} = \sum_{fuel} FOC_{fuel} \cdot CI_{fuel} \quad [11]$$

$$Emission_{intensity} = \sum_{fuel} (FOC_{fuel} \cdot CI_{fuel}) / (CI_{LSFO} \cdot \sum_{fuel} FOC_{fuel}) \quad [12]$$

$$FuelCost = \sum_{fuel} FOC_{fuel} \cdot FP_{price} \quad [13]$$

## CASE STUDY

### Overview and Scenarios

This case study aims to demonstrate how the proposed method of this paper evaluates the GFS, and what kind of insight can be delivered. In this paper, two cases are conducted. In Case 1, a comparison of the GFS with and without the flexibility mechanism was conducted. When the GFS is applied without the flexibility mechanism, all vessels should align with the GFI pathway. However, when the GFS with the flexibility mechanism is applied, not all vessels need to align with the GFI pathway, rather, the GFI pathway should be achieved at the fleet level. The comparison demonstrates that the proposed method enables a quantitative evaluation of the advantages of the flexibility mechanism. In Case 2, a GFI pathway that achieves as much decarbonization as possible and does not have much impact on the shipbuilding market is explored in a more severe scenario. The GFI pathway to achieve IMO's indicative checkpoint depends on the transportation demand scenario, and the higher the transportation demand, the more stringent the GFI pathway should be set. However, setting too stringent a GFI pathway would make it difficult to adapt to existing HFO vessels and would greatly reduce the regulation's feasibility. If existing vessels cannot be adapted, conversion or replacement can be considered; however, too much conversion or replacement will have a significant impact on the shipbuilding market. In Case 2, we input several GFI pathways, and explore which pathway can best lower GHG emissions and does not require conversion or replacement. The remainder of this subsection summarizes the scenarios of transportation demand, fuels, and ships used in the case study.

### Ship scenarios

In this case study, 32275 vessels with a gross tonnage of 5000GT or more that operate worldwide were set as the initial fleet. The dataset is based on the IHS Sea-web (S&P Global, 2023), which is the largest web-based ship database service and is generated by excluding offshore-related ships, tugs, barges, and patrol ships from all vessels listed in the database. In this case study, ships of various cargoes and sizes are averaged, and the fleet is represented only by the number of ships, ship age, and ship type. Figure 2 shows the initial fleets' age distribution. To calculate the fuel consumption and emissions, it is necessary to define the average fuel consumption per ship, which is defined as  $2.85 \times 10^8$ (MJ) in this case study. This setting is based on the IEA reporting that energy consumption in international shipping in 2022 is 9.2 (EJ) in total (IEA, 2023). Fuel consumption will be improved in the future because energy efficiency regulations such as EEDI and EEXI are applied, and to align the regulations, propulsion technology is refined. In this case study, based on fuel efficiency in 2008, the efficiency would improve by 22%, 40%, and 50% in 2018, 2030, and 2050, respectively. This assumption is based on the 4<sup>th</sup> IMO GHG Study (Faber et al, 2020) and the IMO GHG reduction strategy adopted in 2018(IMO, 2018). The 4<sup>th</sup> IMO GHG Study reported a 22% improvement in the annual efficiency ratio in 2018 compared with that in 2008, and the reduction strategy adopted in 2018 targeted a 40% improvement in energy efficiency by 2030.

**Figure 2: Ship age distribution of the initial fleet**

This case study considered the following five types of ships, heavy fuel oil ship (HFO), dual fuel ship of HFO and LNG (DF(HFO, LNG)), dual fuel ship of HFO and Ammonia (DF(HFO, NH<sub>3</sub>)), dual fuel ships of HFO and Methanol(DF(HFO, Methanol), and H<sub>2</sub> fueled ship. DF(HFO, LNG) has already been widely used and the DF(HFO, Methanol)'s technology is considered sufficiently mature. However, DF(HFO, NH<sub>3</sub>) and H<sub>2</sub>-fueled ships are at the R&D stage and are unlikely to be implemented soon. In this case study, it is assumed that DF(HFO, NH<sub>3</sub>) and H<sub>2</sub>-fueled ships can be introduced in 2028. This assumption is based on Japan the Ministry of Land, Infrastructure, Transport and Tourism of Japan's development roadmap (MLIT, 2021), which shows that the implementation of the alternative fuel technology will begin to be introduced in 2028 at the earliest. In the proposed simulation method, the introduction rate of each ship type can be inputted as a scenario. For the near future, it is possible to estimate the percentage of ships introduced from the information in the order book. Based on the Clarkson Shipping Intelligence Network (SIN) data (Clarkson, 2023), a scenario was developed for the percentage of ships that will be deployed from 2022 to 2026. The SIN provides data on deliveries and orderbooks. By aggregating data on containers, bulkcarrier, tankers, PCC, and general cargo, the percentage of each ship type was calculated. The results are shown in Figure 3. The proportion of both LNG- and methanol-fueled ships has increased.

**Figure 3: Percentage of ships introduced from 2022 to 2026**

Figure 4 shows the setting of the ships, which was assumed based on the IHS Seaweb's ship cost data and references from the IMO 4<sup>th</sup> GHG Study's MACC calculation. The values at the top of the bars in the figure indicate the ratio of the costs when based on HFO-fueled ships. DF(HFO, Methanol) ship was set as the cheapest ship and the H<sub>2</sub>-fueled ship was set as approximately 40% more expensive than the HFO ship.

**Figure 4: Setting of ship costs in case study**

Figure 5 presents the survivor curve profile for this case study. Historical data on scrapped ships from the IHS Sea-web database were compiled to create a relationship between age and scrapping, with the maximum age set at 50 years old.

**Figure 5: Survivor curve profiles for the case study**

### Fuel scenarios

To conduct a simulation based on the proposed method, it was necessary to define the fuel WtW emission factors, future costs, and availability. Although it is difficult to predict future trends in fuels owing to significant future uncertainties, the simulation in this study was based on the results of the JTTRI internal study in which scenarios were developed based on the literature and available data.

Table 1 presents the assumed WtW GHG emission intensity (gCO<sub>2</sub>eq/MJ). The fuels' tank-to-wake (TtW) GHG emission intensity does not vary with time because of its chemical properties, but the WtT GHG emissions can change based on trends in the decarbonization of the energy production industry, such as renewable energy penetration.

Therefore, the case study assumes that the WtW emission intensity changes with time. The IMO's newest GHG reduction strategy describes decarbonization around 2050, which is based on the IEA NZE scenario and the WtW GHG intensity of biofuels and e-fuels (green) decreases to 0. Table 2 presents the assumed fuel costs (USD/GJ).

**Table 1: WtW GHG intensity (gCO<sub>2</sub>eq/MJ) setting of 2030, 2040, and 2050.**

Fuel label	2030	2040	2050
LSFO	90.0	90.0	90.0
LNG	71.7	65.1	58.3
BioHFO	4.9	2.4	0
BioMethane	7.5	3.1	0
BioMethanol	6.9	2.9	0
eMethanol(Brown)	91.7	90.8	90.7
eAmmonia(Brown)	114.2	112.3	111.2
H <sub>2</sub> (Brown)	93.1	91.1	90.2
eMethane(Blue)	28.4	13.5	5.4
eMethanol(Blue)	31.4	14.7	5.9
eAmmonia(Blue)	15.6	7.3	2.9
H <sub>2</sub> (Blue)	13.3	6.1	2.4
eMethane(Green)	4.6	0	0
eMethanol(Green)	5.8	0	0
H <sub>2</sub> (Green)	5.3	0	0

**Table 2: Fuel cost (USD/GJ) setting for 2030, 2040, and 2050.**

Fuel label	2030	2040	2050
LSFO	6.8	5.9	4.9
LNG	14	13.8	13.7
BioHFO	63.2	60.2	57.6
BioMethane	32.3	29.2	26.2
BioMethanol	24.6	21.6	18.7
eMethanol(Brown)	13.8	13.2	12.6
eAmmonia(Brown)	19.2	18.7	18.2
H <sub>2</sub> (Brown)	40.2	37.7	35.2
eMethane(Blue)	39.3	38.4	37.5
eMethanol(Blue)	35.3	34.1	32.9
eAmmonia(Blue)	23.8	23.3	22.7
H <sub>2</sub> (Blue)	44.2	41.7	39.1
eMethane(Green)	40.7	38.2	35.6
eMethanol(Green)	40.8	37.6	34.4
H <sub>2</sub> (Green)	35.9	33.3	30.8

As for the fuels' availability, we assumed two kinds of scenarios, "High Bio" and "Low Bio". Biofuels are essential alternative fuels for the shipping decarbonization. Fuels are also promising for the aviation and land transportation industries. In the high-biofuel scenario, assuming that other industries would implement more decarbonization through electrification, the availability of biofuels was set. However, it was assumed that biofuels would be used more in other industries and that their availability in the maritime industry would be significantly reduced. Figure 6 shows the fuel availability for each scenario.

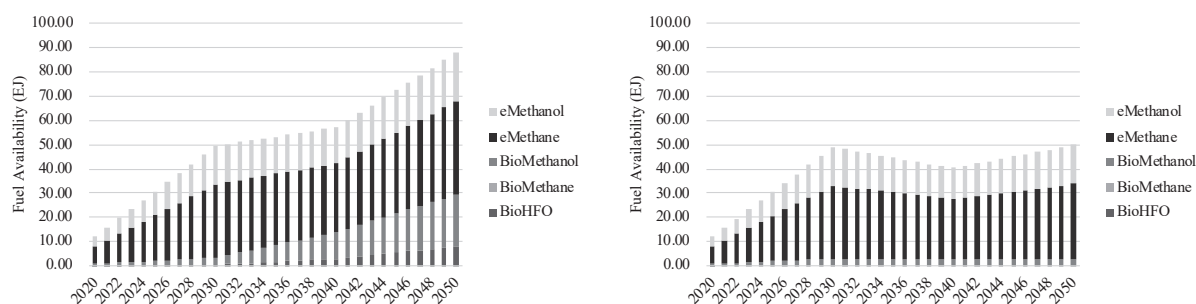

Figure 6: Fuel availability scenarios (Left: High Bio, right: Low Bio)

### Other Scenarios

For transportation demand, two scenarios were chosen from the 4<sup>th</sup> IMO GHG Study’s assumptions; RCP2.6 OECD and RCP2.6 SSP2. They are called “Low” and “High” in this paper. Various scenarios were considered in the IMO study. From these scenarios, we selected the maximum and minimum scenarios to comply with the 2°C target of the Paris Agreement. The indicative checkpoints in the 2023 IMO target are defined for the total GHG emissions from international shipping; thus, the GFI pathways for implementing them have different individual values for each transportation demand. In this case study, the indicative checkpoints were defined as a 20%, 70%, and 100% reduction in 2030, 2040, and 2050, respectively, in WtW emissions compared to that in 2008. Table 3 summarizes the transportation demands and GFI pathways used in the case study. Notably, the GFS regulation is under discussion at the IMO, and the GFI pathways described in the table are based on the assumption that the IMO indicative checkpoints are achieved by GFS regulation alone.

Table 3: Transportation demand and GFI pathways of 2030, 2040, and 2050

Transportation demand label		2030	2040	2050
Low	Demand (billion ton mile)	$6.7 \times 10^4$	$7.6 \times 10^4$	$8.2 \times 10^4$
	GFI (LSFO = 100)	95.2	34.7	0
High	Demand (ton mile)	$8.2 \times 10^4$	$1.0 \times 10^5$	$1.2 \times 10^5$
	GFI (LSFO = 100)	78	26	0

## Results

### Case 1: Comparison of cases with/without the flexibility mechanism

In Case 1, simulations of cases with and without a flexibility mechanism were conducted, and the impact of the flexibility mechanism was evaluated by comparing the results. The fuel availability scenario was set as High Bio, and the RCP2.6 OECD (scenario: low) was selected for transportation demand. For the notation, the case without the flexibility mechanism is Case 1-1, and the case with the flexibility mechanism is Case 1-2. Figure 7 presents the result of Case 1-1, which shows fuel consumption and WtW emissions from the overall fleet until 2050. The WtW emissions are normalized by the 2008’s emission. The bar chart shows each fuel consumption (EJ=10<sup>12</sup>MJ). In this case study, 15 fuels were assumed to be potential candidates for alternative fuels; however, by selection based on the cost, fuel decomposition can be expressed by the seven fuels in the figure. HFO-fueled ships are adapted to the GFS regulations by using BioHFO as a drop-in fuel. The DF(HFO, LNG) utilizes a combination of LNG and eMethane(Green) as the most cost-effective option. The DF(HFO, Methanol) primarily consumes BioMethanol. The DF(HFO, NH<sub>3</sub>) was operated mostly with a mixture of LSFO and eAmmonia(Blue) and eAmmonia(Green) was used only in the last two years of the simulation. Especially for HFO-fueled ships, biofuels must be utilized to adapt the regulation in the case without the flexibility mechanism. Based on the simulation result, 0.30 EJ of BioHFO will be required as of 2030. Moreover, owing to the insufficient availability of BioHFO, the GFI pathway cannot be implemented from 2033 to 2036, as indicated by the shaded areas in the Figure 7.

This implies that more BioHFO is required for HFO ships to comply with the GFI pathway. Although the indicative checkpoints for 2030, 2040, and 2050 are achieved, it is a possible risk factor that parts of the pathway cannot be achieved.

Figure 7: Fuel consumption and WtW emissions (Case 1-1, case without flexibility mechanism)

Figure 8: Fuel decomposition (Case 1-1, case without flexibility mechanism)

Figure 8 shows the results of the fleet decomposition from 2021 to 2050. The vertical axis represents the number of ships operating annually. From 2026 to 2028, the introduction of DF(HFO, NH<sub>3</sub>), DF(HFO, LNG), and DF(HFO, Methanol) penetrated the fleet to adapt to the GFS regulation. Finally, DF(HFO, NH<sub>3</sub>), DF(HFO, Methanol), and DF(HFO, LNG) were introduced in that order. This is due to the total cost of CAPEX and fuel cost, and the high availability of inexpensive BioMethanol.

The results of Case 1-2 are shown in Figures 9 and 10, respectively. They are the results of the flexibility mechanism. As shown in Figure 10, there is not much difference in the fleet decomposition to comply with the GFS regulation, except that the introduction period of HFO ships is extended by two years. However, Figure 9 indicates that the fuel consumption composition is significantly different from that in Case 1-1. While in Case 1-1, HFO-fueled ships utilized BioHFO to comply with the regulation, in Case 1-2 with the flexibility mechanism, HFO-fueled ships did not utilize biofuels, and ships fueled by others compensated to achieve the GFI pathway. In this scenario, although BioHFO is more

expensive and not as abundant in supply as other green fuels, the results indicate that it is possible to promote emission reduction by ships fueled by other fuels and implement the GFI pathway for the entire period.

Figure 9: Fuel consumption and WtW emissions (Case 1-2, case with flexibility mechanism)

Figure 10: Fleet decomposition (Case 1-2, case with flexibility mechanism)

A cost comparison between Cases 1-1 and 1-2 is shown in Figure 11 to illustrate the effect of the flexibility mechanism in more detail. Figure 11 indicates that the fuel cost is affected by the flexibility mechanism, especially for 2040. When the flexibility mechanism is applied, the fleet can select a more cost-effective fuel mix according to fuel costs and availability beyond the constraints of the fuel type of individual ships, thereby, reducing transportation costs in the overall shipping market when complying with the regulations.

**Figure 11: Comparison of costs between Cases 1-1 and 1-2 in 2030, 2040 and 2050**

### **Case 2: Exploration of feasible GFI pathway**

Shipbuilding can take years; thus, the replacement cannot proceed rapidly, and deployment of the fuel supply chain is an unaddressed issue. Therefore, setting the GFI pathway incorrectly would render the GFS regulation unfeasible. In this case study, assuming that a severe scenario is applied (transportation demand is “High” and “Low Bio”), a GFI pathway that is feasible and contributes most to GHG emission reduction should be explored.

The exploration process is as follows: First, in addition to the GFI pathway presented in Table 3, four pathways with less restrictive GFI values were prepared. The FuelEU Maritime reduction target was adopted as the most feasible pathway. Each of these pathways was input into the simulation to examine their feasibility for 2030 and 2040. A feasible line that contributes as much as possible to GHG emission reductions up to 2040 is defined as a solution. The final GFI target for 2050 is the input in increments of 5 from 0 to 20 to find a feasible point that contributes to GHG emission reduction as much as possible. The input GFI pathway candidates are listed in Table 4.

**Table 4: Input GFI pathways of 2030, 2040, and 2050 for Case 2.**

Year	2030	2040	2050
GFI candidates (LSFO=100)	94	69	20
	90	58.25	15
	86	47.5	10
	82	36.25	5
	78	26	0

The discovered solution pathway is presented in Figure 12. For reference, the GFI pathways that comply with the IMO GHG reduction strategy and FuelEU Maritime are also illustrated. As a result of the exploration, the pathway that complies with the IMO’s reduction indicative checkpoint until 2030, passes between FuelEU Maritime and the IMO target, and finally reduces the GFI by 80% compared to LSFO was found. This result means that if the transportation demand becomes high, and biofuel availability is low, it is difficult to achieve the IMO’s indicative checkpoint using only the GFS regulation. When the proposed pathway is applied, 26% more reduction in 2040 and 25% more reduction in 2050 by other measures such as the MBM, is required to achieve the IMO’s indicative checkpoints.

Figure 12: Exploration result of the feasible GFI pathway under a severe scenario

## DISCUSSION

Case 1 compares the GFS regulation with and without the flexibility mechanism via the simulation. In addition to introducing alternative fuel ships, it is important to consider how existing ships comply with the regulations. The results of the comparison show that the presence of the flexibility mechanism can eliminate the period of non-compliance with the regulations owing to the availability of BioHFO. Moreover, the cost comparison shows that the flexibility mechanism can reduce the costs, especially fuel costs, required to adapt to the regulation. This results from the flexibility mechanism, allowing the fleet to utilize not only BioHFO but also more diverse and cost-effective fuels to adapt existing ships to the regulations. While these results are limited to the specific scenario assumed in the case study, the general insight from the results is that the flexibility mechanism can diversify options to comply with the regulation, especially for the existing ships, and thus promote more efficient decarbonization across the fleet.

However, the introduction of the flexibility mechanism has disadvantages, as it requires a more complex implementation, such as an emission trading mechanism. Decisions on whether to introduce the mechanism should be based on a consideration of these advantages and disadvantages. The proposed method allows for a quantitative evaluation of its advantages and is useful for supporting the decision-making processes.

In Case 2, a feasible GFI pathway that contributes to decarbonization as much as possible was explored with a higher transportation demand and lower biofuel supply than in Case 1. The results show that the proposed method can support the design of the GFS, as it can output a feasible GFI pathway and the amount of the GHG reduction required to achieve the IMO's indicative checkpoints by other measures such as MBM.

The case study in this paper is based on a specific scenario out of many future scenarios, and a more detailed consideration of future uncertainties is required in the actual regulation design. Specifically, the transport demand, fuel costs, and availability scenarios are highly uncertain, and the results of the case studies can change if the scenario is different.

Lagouvardou, et al. (2020) pointed out the uncertainty of the market conditions, and it is estimated that there are deep uncertainties in the fuel scenario, the cost of alternative fuel ships, and transportation demand. The results of the case study should be read with this limitation, and it is one of the future works to consider the impact of such deep future uncertainty. Hiekata et al. (2015) generated large scenarios based on a binomial lattice model and utilized the Monte Carlo simulation method to evaluate the scenarios. Irena et al. (2021) considered the uncertainties by sensitivity analysis when calculating the MACC of CO<sub>2</sub> mitigation measures for the decarbonization of shipping. The approach used in these studies will be useful for future research.

In addition, improving the model for the share of fuel ship types in the simulation is a topic for future research. It is difficult to model this behavior because there has never been a situation in international shipping where multiple fuels have been candidates for use, and they constitute market share. However, at present, various fuels are being handled in development projects for alternative fuel ships, and because best practices have not yet been established, they are considered to form a market share. In automotive studies, discrete choice models such as logit models are utilized to model users' behavior in choosing vehicle and fuel types based on preference data and interviews with users (Hess et al., 2012;

Khan et al., 2020; Yoo et al., 2021). Incorporating the current shipping company's preferences into the model through surveys and the modeling is a possible direction for the model improvement.

## CONCLUSIONS

This study quantitatively examined how the GFS regulation affects international shipping through simulations that project future fleet transformation, fuel consumption, and WtW GHG emissions based on an inputted GFI pathway and scenario of transportation demand, fuel availability and costs, and technology availability. The method consists of three models, shipbuilding and scrapping, fuel and ship selection, and calculation of emissions and cost, and enabling us to study the regulation quantitatively from the perspective of feasibility and cost. The fuel and ship section model can express the difference between the cases with and without the flexibility mechanism, and in the simulator, it is possible to quantify the differences. Two case studies were conducted using simulation. First, we compared the simulation results with and without the flexibility mechanism. It was shown that the introduction of the flexibility mechanism allows more options for achieving the regulation as of 2030, especially for existing vessels, and that there are benefits for the cost of overall international shipping. In the second case, GFI pathways that are feasible and contribute to GHG reduction as much as possible were explored by using the simulation. As shown in the results of Case 2, the simulator can search the pathways by inputting transportation demand, fuel availability scenario, and candidates of GFI pathways, demonstrating that the proposed method is useful in designing the feasible GFS regulation according to the transportation demand, and fuel availability.

# Design Lab: a simulation-based approach for the design of sustainable maritime energy systems

Kevin Kusup Yum<sup>1,2,\*</sup>, Sadi Tavakoli<sup>1</sup>, Torstein Aarseth Bø<sup>1</sup>, Jørgen Bremnes Nielsen<sup>1</sup> and Dag Stenersen<sup>1</sup>

## ABSTRACT

The process of achieving decarbonization in the maritime industry relies on tackling complex issues related to ship design. Designers require tools that can integrate the processes of providing relevant operational profile, configuring a target design, evaluating the design and exploring possibilities. Design Lab framework innovatively addresses this need by creating realistic operational profiles, simulating vessel performance and machinery systems, and providing comprehensive system evaluations.

The framework promotes a comprehensive design process that starts by creating an operational profile. This profile is used to simulate the vessel's propulsion power considering statistical weather conditions. Then, machinery systems are configured and simulations are performed. The performance of these systems is evaluated against key performance indicators such as total cost of ownership, carbon intensity indicator, etc., and the process is iterated with new design candidates.

A case study of a hydrogen-fueled RoPax vessel is presented to validate the framework and demonstrate its capabilities. By focusing on simulation-based predictions and performance indicators, it provides a quantitative assessment, thereby supporting the decision-making process for stakeholders.

## KEY WORDS

Maritime energy system; Simulation-based design; Decarbonization; Design framework

## INTRODUCTION

The shipping industry plays a crucial role in our endeavors to address climate change. It is imperative to achieve significant reductions in carbon emissions within this sector. To meet the goals set by the International Maritime Organization (IMO) IMO (2023), we must focus on two key areas: improving energy efficiency and adopting alternative technologies that produce little or no greenhouse gases. This includes a variety of strategies, such as reducing ship speed, better route planning based on weather conditions, maintaining and upgrading propellers and engines, using carbon capture and storage onboard the ships Tavakoli et al. (2023), taking care of the ship's hull Yuan et al. (2016), and using alternative low-carbon fuel.

In addition, as the regulations evolve and a broad spectrum of technological options emerge, designers need tools capable

<sup>2</sup> HD Hyundai Europe R&D Center, Düsseldorf, Germany; \* Corresponding Author:  
kevin.koosup.yum@gmail.com

of incorporating future scenarios, including fuel price fluctuations and potential carbon taxes, into total cost of ownership calculations.

To explore the impact of various technologies and the effectiveness of alternative fuels on marine power systems, a framework can be established. This framework will facilitate the optimal design and operation of ship propulsion systems, providing a comprehensive assessment of their technical and economic performance. A study by Thaler et al. (2022) explored the optimal design and operation of maritime energy systems that use renewable methanol and closed carbon cycles. They focused on the integration of onboard carbon capture technologies in shipping, evaluating both pre- and post-combustion carbon capture methods. The study employs a mixed integer optimization framework to analyze the techno-economic performance of these systems on a case study of a ferry operating in the Baltic Sea. The findings reveal cost advantages and robustness against various technological and economic conditions for systems that employ closed carbon cycle strategies. Furthermore, Buonomano et al. (2023) studied a new approach to energy design for ships with the aim of reducing fuel consumption and environmental impact. They integrated two methods, Building Information Modeling (BIM) with Building Energy Modeling (BEM), to create a dynamic, 3D physics-based simulation of a ship's energy performance under real operating conditions. The case study named "Allure of the Seas", a 6000-passenger cruise ship, was used to analyze energy performance and potential waste heat recovery. Significant primary energy savings and reduced emissions are highlighted, demonstrating the effectiveness of the methods in sustainable ship design and operation.

The study by Hansson et al. (2020) investigates the viability of ammonia as a marine fuel compared to other fuel options. It combines energy systems modeling to assess cost-effectiveness in achieving climate targets and multi-criteria decision analysis (MCDA) to rank marine fuels based on various criteria including fuel performance and stakeholder preferences.

The study by Bordin and Mo (2019) optimized the battery lifetime in vessels using a developed model. The model helps to make battery investment decisions, considering factors such as battery degradation and desired lifetime. It was designed to evaluate how the different operating modes of a vessel influence investment choices in energy storage.

Moreover, Tang et al. (2018) presented an exploration of energy management in green shipping by examining the challenges posed by emission regulations that sometimes limit or even prohibit the use of diesel in ports, necessitating alternative power sources such as shore power. The study focuses on ships equipped with onboard photovoltaic (PV) systems and how the management of a hybrid energy system (HES) combining PV, battery, diesel, and cold-ironing can lead to significant electricity cost reductions.

Therefore, the design of the entire marine propulsion system plays a central role in predicting and optimizing the power requirements of maritime vessels. An integrated system design considers not only the engine's performance but also the interaction of various components such as propellers, hull shape, and energy recovery systems. This holistic approach enables accurate power predictions, essential for fuel efficiency and reducing emissions. In addition, it allows for the adaptation of innovative technologies such as hybrid power systems and alternative fuels, ultimately leading to more sustainable and cost-effective maritime operations.

The primary objective of this paper is to present the development of a comprehensive framework designed to analyze the power system of a ship power plant, focusing on its operational profile and general arrangement using a case study as a reference. Thus, in the following section, we will introduce and discuss this framework in more detail. Subsequently, the chosen case study will be described, highlighting its specific operational profile. The core aspects of the framework, which are central to our analysis, will be elaborated upon in the following. Finally, the results derived from applying this framework to the case study will be thoroughly presented and examined in the last section, providing information on the practical implications and effectiveness of the proposed system analysis.

## DESIGN LAB AND PROCESSES

Design Lab is a framework developed to evaluate the performance of the vessel with realistic operational scenario and ship models that account for all relevant technical aspects of the vessel. The evaluation process is shown in Figure 1 in an iter-

that provides spatial information for the vessel. In addition, the metocean data within the area of vessel operation can be added to the operational profile to estimate the environmental load on the ship. These information will be provided to the next step of the process, ship performance simulation.

In the ship performance simulation, the main purpose is to estimate the required power demand on the vessel, including the propulsion and hotel load. The information from the operational profile defined in the previous stage will be used as main input for the process. The hull resistance and propulsion model is created using the specific information of the design candidate such as main dimensions of the hull form and particulars of the propellers. The hull resistance and propulsor model can be as simple as a speed power curve from a model test or can be a parametric model extracted from computational fluid dynamics (CFD) models. For the propulsor model, it can be a static efficiency value, Wageningen "B" series propeller model or a open water characteristic curve extracted from the CFD analysis. If the environmental load should be considered, added resistance due to wave and wind should be considered. One can either just add a sea margin, use an empirical model or use potential-theory-based methods to calculate the vessel response which converts to the resistance. At the end, the hull resistance and propulsor model will convert the location, heading, speed and the time of the vessel into the propulsion power. The output may be a time series, a histogram or a single value depending on the type of the input values.

In the machinery simulation, the main purpose is to calculate total fuel consumption, emissions and the degree of usage of power sources. The required power for propulsion and hotel load is the input for the simulation. A machinery system is a system that converts the energy source to usable form of energy such as shaft work or electricity and deliver them to the consumers. The machinery system can be described as a single conversion efficiency or a full blown system in which each energy converter and consumer is modeled. If various energy converters are used such as gensets, fuel cells or multiple fuels are used, there must be a control strategy for the system how the energy is shared among them. Together with the system configuration, this control strategy will affect the performance of the machinery system in terms of fuel consumption and emissions. For the purpose of calculation of fuel consumption and emissions, it is usually sufficient to use only efficiency of each component or brake specific fuel consumption to model the component. For a sophisticated system model with multiple energy converters, the component should be described with the mode of energy sharing and whether the power source is available.

When the total fuel consumption and emissions are simulated with the machinery model, one can now calculate relevant KPIs. A common KPI is total cost of ownership (TCO). TCO must entail all the cost incurred in the lifetime of the vessel. It is usually divided into capital expenditure (CAPEX) and operational expenditure (OPEX). CAPEX comprises mainly of the cost related to build a ship, and, retrofitting cost if necessary. OPEX comprises mainly of the fuel cost traditionally, and other cost for crewing, maintenance, insurance and administration is added. In recent development of carbon tax, pricing and penalty, additional cost for emissions may be considered. Regulation related KPIs such as the carbon intensity indicator set by IMO can be considered for the design evaluation. Other qualitative KPIs such as safety, complexity and maturity can be considered if the design involves novel technology. At the end of the analysis, the designer makes decision if the design candidate is satisfactory to the requirements. Otherwise, the designer should create a new candidate and start a new process of evaluation. A new evaluation process can be evoked by an update of the design or when more detail information is available for more sophisticated modeling and evaluation.

## **CASE STUDY AND OPERATIONAL PROFILE**

The case study focuses on the Stena Hydra, a conceptual ship designed to push the boundaries of marine engineering by incorporating hydrogen fuel cells.

As shown in Figure 2, the Stena Hydra design blueprint shows the integration of hydrogen fuel cell technology into its structure (light green boxes).

The main specifications of Stena Hydra, listed in Table 1, include an overall length of 212 meters and a beam of 26.7 meters, ensuring ample space for both cargo and passenger facilities.

The requirement for the design is defined as follows:

1. The ship shall travel back and forth between Göthenburg and Fredrikshaven for the given time table as of today.
2. The speed of the vessel shall be determined to meet the time table given.
3. The vessel shall be able to perform three crossings without bunkering fuel.
4. The vessel shall be able to provide at least 22 MW power for the ship to operate in the harsh weather.
5. The vessel shall be powered by hydrogen fuel cells of mature technology and achieve zero emission operation.

The use of hydrogen as the primary fuel in large ships presents a series of technological challenges.

While the core technology for such storage is readily provided by various suppliers, the maritime adaptation of this technology requires specialized systems, particularly for efficient bunkering operations within the strict time constraints specific to the type of ship in question. The low volumetric density of hydrogen makes storage a significant challenge; It requires containment in a liquid state at  $-252\text{ }^{\circ}\text{C}$  or as a pressurized gas at  $350\sim 700\text{ bar}$  to enhance density, both of which entail substantial installation costs. Consequently, identifying the optimal storage capacity is essential to ensure the economic feasibility of the system.

Currently, Proton Exchange Membrane Fuel Cells (PEMFCs) are commercially available for maritime applications. These fuel cells (FCs) are provided as modules with a typical rated power of 200kW. Furthermore, FCs have different efficiency characteristics from diesel engines. The efficiency is typically highest in the low load range and lower as the load increases. This is almost opposite to the case for diesel engines. Therefore, fuel cell operating should be different from diesel engines, especially for determining the optimal number of modules to engage for a given load. The configuration of fuel cell modules according to the power level will affect the size of the fuel cells and the fuel consumption.

The last challenge is the cost of fuel and fuel cells. They are expected to be much higher than conventional fuel and diesel engines. The size of the power capacity of the power plant should be determined to minimize the total cost of ownership. To do this, a system model that simulates the power demand for the vessel and power distribution depending on the power load and fuel consumption at each fuel cell is needed. The power demand should be realistic and stochastic to reflect the real operation requirement and the environment conditions.

The main purpose of the design study is to size the fuel cell based power plant that provides the lowest total cost of ownership. Fuel cells will ensure that the vessel will emit no emissions for the energy conversion as long as the hydrogen is coming from green sources. One of the challenges with utilizing hydrogen fuel cell is sizing. The typical efficiency curve of a fuel cell has highest efficiency at 30% and the lowest at the rated power. The study will address the challenges mentioned to arrive at the reasonable design. The following steps will demonstrate how the design lab framework is implemented to perform such a complex design evaluation process.

**Figure 2:** Ship design drawing of the hydrogen fuel cell concept named Stena H2YDRA.

**Table 1:** Main specification of the case study.

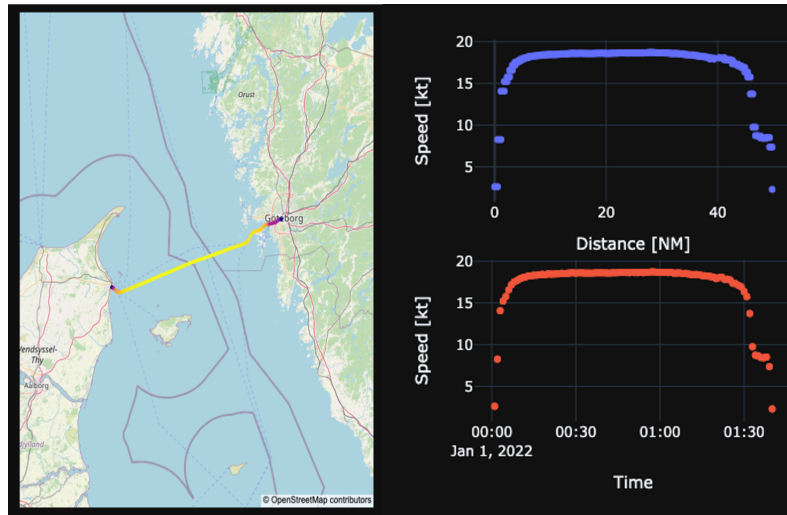

Item	Value
Length O.A. (meters)	212.0
Length P.P (meters)	201.9
Beam (meters)	26.7
Design Draft (meters)	6
Scantling draught (meters)	6.3
Propulsion power	15 MW
Operational range	150 NM
Speed	22 kn
Deadweight (metric tons)	6000
Payload (metric tons)	4500
Lane meters	2500
Passenger facilities	Day ferry

### Definition of the operation profile

The frequency of travel and the transit time from one place to another are determined from the weekly time table of the current operation of the vessel, Stena Jutlantica. However, it doesn't provide exact way points and actual speed profile along the path including maneuvering in the confined water and transit. In order to find such detailed information, AIS data were used to create a representative operational profile. The AIS data were collected from Kystdatahuset Kystverket (2024) for Stena Jutlantica for the entire year of 2022. 339002 points were collected with many missing points in between. Figure 3 shows the spread of the points in the space with the speed of the vessel presented in a color map. The spread is rather wide, and to get the representative route of the ship, a machine learning method to find a piece-wise spline regression curve was used. The route is represented with 100 points between two ports. For the speed profile, the speeds of AIS points that are nearest to a point on the representative route are averaged and assigned to the the point. Figure 4 show the route on the map and the speed profile along distance and time.

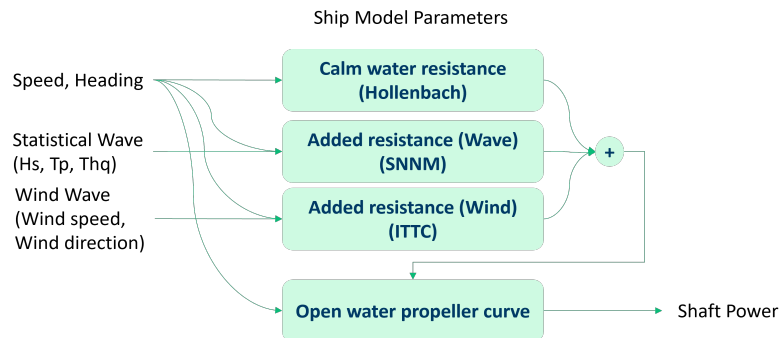

**Figure 3:** Actual positions and speeds of the ship on multiple voyages between Frederikshavn and Gothenburg.

**Figure 4:** The representative route presented on the map and the speed profile along the length and time of the voyage

## Ship Operational Simulation

With the input of the operational profile, a vessel performance simulation is performed to reproduce the propulsion power time series for entire year of 2021 and 2022. Trips are scheduled according to the weekly time table of the real operation. Each trip from one port to the other is simulated along the way points where a specific time for a way point is determined with the given speed profile. Metocean data from the Norwegian Meteorological Institute (Institute (2023)) is used to find the wave and wind information at the way point at that specific time. The speed and the heading of the vessel together with the metocean information are provided as an input to the hull resistance model. The total resistance calculated will be converted to the shaft power using the propulsor model. In this case study, Hollenbach method is used for estimation of the calm water resistance, SNNM method by Wang et al. (2021) for added resistance due to waves, ITTC method for wind resistance and open water propeller curve for converting the required thrust to shaft power. The ship propulsion performance model is presented in Figure 5

**Figure 5:** Components of the hull resistance models and the propulsion model used in the case study and their interfaces

The result of the ship propulsion performance simulation is shown in Figure 6. The simulation includes 2400 one-way trips from Frederikshavn to Gothenburg and vice versa throughout the year. The variation among each trip accounts for various weather conditions that the ship encounters in different time and location. There are a couple of trips where the maximum power is over 15 MW that is the maximum propulsion power of the vessel. The limitation of the simulation is that there is no involuntary speed loss due to weather condition where the speed cannot be achieved due to limitation of the installed power. However, such cases accounts less than 0.1% of the trips and, therefore, statistically.

To validate the result, the result is compared to the measured total power on the STENA Jutlandica in year 2021 and 2022 that was provided by STENA as shown in Figure 7 and 8. The results are generally in good agreement while there are some difference for high loading region. The differences are results of both model uncertainties and discrepancy in operational profile. The resistance models are based on the statistical dataset for various vessels that may lead to a certain degree of errors, and having a static speed profile may have led to inaccurate boundary conditions for the model.

**Figure 6:** Prediction of the propulsion power from the simulation given as a time series for all trips in 2021 and 2022

**Figure 7:** Histogram of the predicted propulsion power from the simulation for all trips in 2021 and 2022

**Figure 8:** The histogram of the power load on gensets of STENA Jutlandica measured in 2021 and 2022.

## Machinery Simulation using FEEMS

FEEMS (Fuel Energy Emissions Calculation for Machinery System) is a modeling framework designed for marine power and propulsion systems, created by the Author. It is available as a open source Python library (<https://github.com/SINTEF/FEEMS/tree/main>). It calculates fuel consumption, emissions, and energy balance by considering various operating modes and external power loads. The framework allows modelers to configure power systems using a component library and a single line diagram. It supports different types of power and propulsion systems, including hybrid/conventional diesel electric propulsion, hybrid propulsion with power take-in/power take-off (PTI/PTO) and mechanical propulsion with a Separate Electric Power System. The unique advantage of using FEEMS is that it will be possible to apply energy management strategy to the power sources such as load dependent start/stop of power sources, load smoothing/peak shaving operation with batteries, PTI/PTO operation, and choosing optimal power sources depending on the power demand, availability, and criticality of the operation. At the same time, FEEMS is designed to handle a large set of inputs, such as a year-long operational profile, with a short calculation time. Typically, it will give the result of calculation with over 100,000 points input within a couple of seconds. In FEEMS, a system model is created in a bottom-up approach starting with a component model to create a subsystem of components and then a system of subsystems. The system model holds both the architecture of the system and the components as objects. Typical information required to create a component model is the rated output power, the type of component in terms of functionality and power, and a load-dependent efficiency curve. For an engine component, a load-dependent brake specific fuel consumption (BSFC) curve should be given instead of the efficiency curve. For the component that converts fuel to energy, fuel information and/or emissions information should be specified as well.

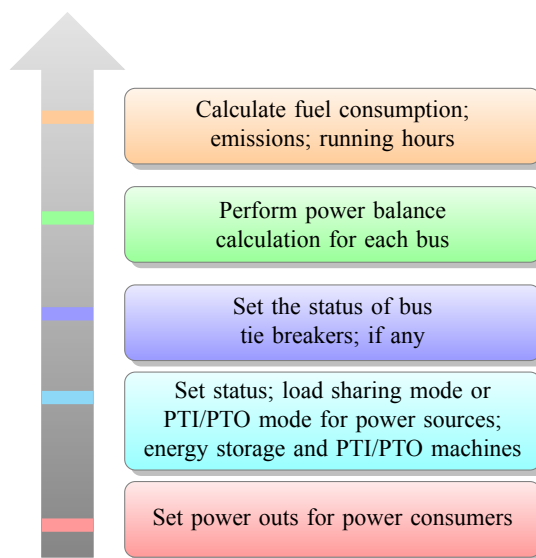

When the system model is all specified, one needs to go through the following steps to arrive at the result. The first step is to define the load input for power consumers, such as propellers and auxiliary loads. Following this, it is essential to specify the operational status (either 'on' or 'off') and the load sharing mode for each power sources and energy storage units. If there are PTI/PTO machines, it is also necessary to specify the same for them as well as their PTI/PTO mode. Additionally, if the electric system includes a bus tie breaker, its status (closed or open) must be set.

Once all these settings are in place, the system model can perform a power balance calculation. This calculation is carried out for a bus and a shaft line. It involves determining the total power consumption at the switchboard or shaft line level. This process takes into account power losses in each component. The total power consumption is then distributed among power sources, energy storage units, and PTI/PTO machines. This distribution is based on their respective statuses, load-sharing modes, and PTI/PTO modes.

After completing the power balance calculation, the output power values for each power source are obtained. From these values, it is possible to calculate the fuel consumption, emissions, and running hours for the system. The final result is given as structured data that contains:

1. Duration of the operational profile input,
2. Total fuel consumption for each kind of fuel,
3. Total GHG emissions as CO<sub>2</sub> equivalent value,
4. Running hours of power sources, PTI/PTO machines, and batteries,
5. Net energy saved in the energy storage units,
6. Total energy consumption of propulsion and auxiliary loads,
7. Above information for each power source, PTI/PTO machines and batteries.

These steps are shown in the visualization way in Figure 9.

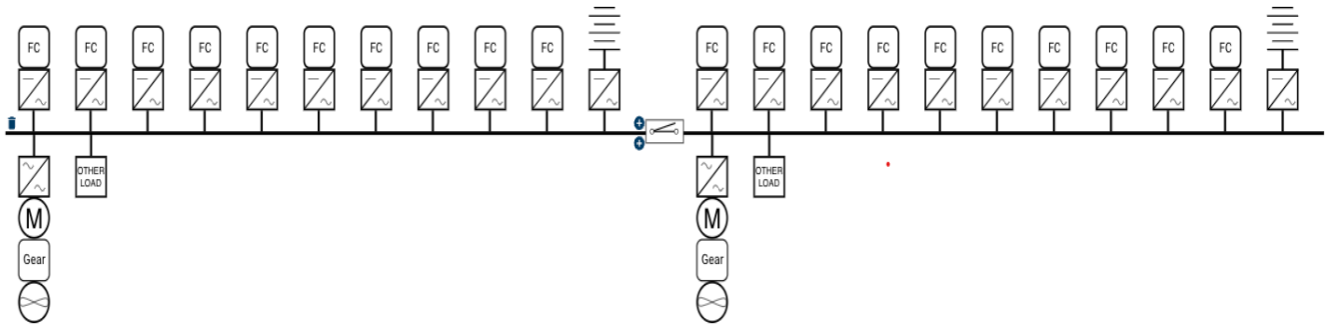

**Figure 9:** Procedure of calculation of the vessel's fuel consumption and corresponding emissions.

The base configuration of the machinery system has the total installation power of 20MW from fuel cells. Each fuel cell model has rated power of 200 kW. Five fuel cells are connected to a common DC link that is connected to a switchboard by a DC/DC converter. This means that there are 20 groups of fuel cell modules in total. There are two propulsion drives that are connected to each switchboard. Other load at each switchboard represents hotel and auxiliary load. The configuration is shown in Figure 10

The fuel cell group will be turned on and off depending the load level of the power sources to achieve the optimal number of fuel cells. Because the fuel cells have the best efficiency between 20% and 30% of their rated power, the number of fuel cells providing power will be determined so that the number is minimum where the power load on each fuel cell does not exceed 30%. Using this simple energy management makes sure that the plant can run at the best efficiency point depending on the load.

The fuel consumption for each trip and accumulated consumption for three consecutive trips are shown in Figure 11

**Figure 10:** A machinery system with 20MW installed power from fuel cells as a base case for the design study

**Figure 11:** Fuel consumption for each trip and three consecutive trips from the machinery simulation using FEEMS

## Analysis and redesigns

Among other KPIs, total cost of ownership (TCO) is a single value that expresses the system efficiency, capital cost and emissions as a single value. The calculation of TCO can be done with the input of the system configuration, fuel consumption results and running hours of fuel cells from the machinery simulation. The overall analysis is shown in Figure 12.

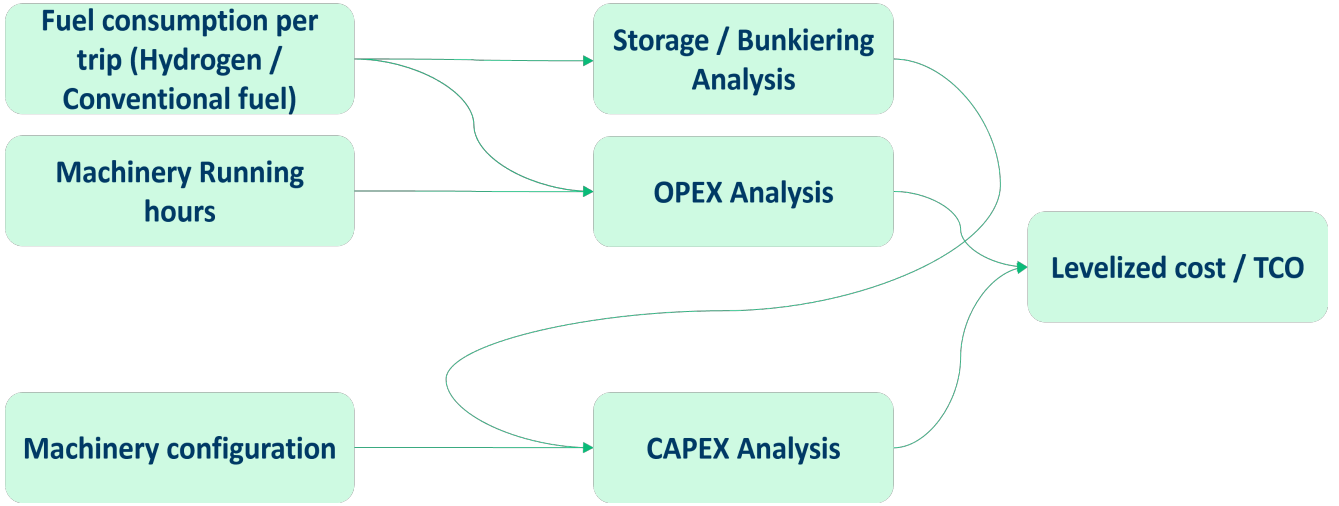

For hydrogen powered vessel, the cost of hydrogen storage constitutes a significant part. Deciding capacity based on the simulation results, therefore, prevent the system from over- and under-sizing of the storage. From the design requirements, the vessel must be able to make three trips without bunkering. In Figure 11, accumulated fuel consumption for three consecutive trips are presented. The maximum value is 9.2 tons. Therefore, storage capacity of 10 tons will be capable of fulfilling the design requirement while it is kept in a reasonable range.

The TCO is calculated as a levelized cost, cost per trip. The cost is calculated only for the machinery system using the following equation.

$$LC = \frac{CAPEX + \sum OPEX_i \cdot (1 + r)^{-i}}{\sum n_{trip} \cdot (1 + r)^{-i}}$$

$$CAPEX = 1.2 \cdot (P_{rated} \cdot C_{PS} + M_{storage} \cdot C_{storage})$$

**Figure 12:** Analysis of the simulation results to arrive at the total cost of ownership for the design case

**Table 2:** Calculated TCOs for three design cases with different intalled power

	20MW	25MW	30MW
CAPEX [mEUR]	46.3	54.1	62.1
OPEX [mEUR/year]	18.308	17.497	17.008
Number of trips per year	1,353	1,353	1,353
Energy production [kWh/trip]	38,458	38,458	38,458
Fuel consumption [ton/trip]	2.36	2.241	2.168
Levelized cost [EUR/trip]	16,392	16,271	16,403

$$OPEX_i = m_{fuel} \cdot (C_{fuel} + c_{CO_2} \cdot C_{CO_2}) \cdot n_{trips} + E_{PS} \cdot C_{mt}$$

where,

$r$ :	Discount rate
$n_{trip}$ :	Number of trips per year
$P_{rated}$ :	Total installed power of power sources [kW]
$C_{PS}$ :	Unit cost for the power plant [EUR/kW]
$M_{storage}$ :	Storage capacity [ton]
$C_{storage}$ :	Unit cost for storage [EUR/ton]
$m_{fuel}$ :	Fuel consumption per trip [ton]
$C_{fuel}$ :	Fuel unit cost [EUR/ton]
$c_{CO_2}$ :	CO2 conversion factor for fuel [kg/kg]
$C_{CO_2}$ :	Cost of CO <sub>2</sub> emission [EUR/ton]
$E_{PS}$ :	Energy production per year [kWh]
$C_{mt}$ :	Maintenance cost [EUR/kWh]

The overall procedures are performed in three design cases: 20MW, 25MW and 30MW for total installed power. With the assumption of fuel cost of 5 EUR/kg, fuel cell cost of 1400 EUR/kW, maintenance cost of 0.045 EUR/kWh and storage cost of 1,000,000EUR/ton, the TCOs are calculated as shown in Table 2.

## RESULTS AND DISCUSSION

Within the maritime industry, the transition to hydrogen fuel is based on a wide range of economic factors. Figures 13 through 16, complemented by detailed specifications based on our case study, form a comprehensive analytic structure. The Design Lab framework enables the assessment of the operational costs associated with this innovative vessel. Sensitivity analysis underscores the crucial role of hydrogen pricing, which emerges as a primary determinant of overall costs, more than the purchase of fuel cells. This paper has conducted a sensitivity analysis focusing on the three key factors:

- Fuel cell unit cost: 800 – 1400 EUR/kW
- Fuel cell maintenance cost: 0.02 – 0.045 EUR/kWh
- Hydrogen cost: 3-9 EUR/kg

The cost analysis further suggests that hydrogen pricing provides valuable insights into determining the most suitable size of the vessel's power plant. Reduced hydrogen prices support the selection of a power plant with smaller installed capacity to reduce initial investment, whereas higher hydrogen prices may favor a larger power plant to capitalize on economies of scale. The main goal is to create maritime energy solutions that maintain environmental and economic sustainability. The Stena Hydra serves as a model or example, highlighting the necessity for strategic power configuration and smart energy management for the promotion of environmentally friendly maritime operations.

The graphical representation in Figure 13 correlates the levelized cost of maritime transport with the fluctuating prices of marine gas oil (MGO), in the context of diverse CO<sub>2</sub> pricing under the European Union Emissions Trading System (ETS). This relationship highlights the financial consequences of carbon emissions within the maritime sphere and the requirement for shipping companies to develop strategies that can effectively address the potential effects of carbon pricing on their operational expenses. Figure 14 also shows a visualization of the effects of the MGO price on maritime transport costs per kWh, further analyzed under different ETS CO<sub>2</sub> price scenarios. Moreover, Figure 15 represents the impact of the price of liquid hydrogen on the levelized transport costs in different vessel power capacities. The increasing prices of liquid hydrogen have a direct impact on the levelized cost, particularly for vessels that require more energy. This emphasizes the significance of taking into account fuel costs in the early stages of ship design. The diagram illustrates a comprehensive evaluation of liquid hydrogen prices and fuel cell prices, represented by the colored shapes, within the 800 to 1400 EUR/kW range. As demonstrated, the rate at which the levelized price increases is reduced as the size of the power plant increases. The reason behind this is the influence of reduced fuel usage in the larger machinery setup of the case study, despite the additional investment in the power plant, by the increased capacity of the fuel cell from 20 to 30 MW. Lastly, Figure 16 shows the assessment of levelized transport costs per kWh in the context of liquid hydrogen prices and fuel cell prices.

## CONCLUSION

In summary, the Design Lab has emerged as a key tool, providing a robust and iterative framework to evaluate the designs of maritime vessels that use hydrogen fuel cells. The ability to analyze AIS data has resulted in the creation of operational profiles, which offer a comprehensive understanding of vessel behavior in real-world scenarios. These profiles serve as the basis for the design process. Furthermore, the semi-empirical approach enables the prediction of power requirements that are statistically validated, ensuring that the design of the ship is robust to the variation of maritime environments. Meanwhile, simulations conducted via FEEMS offer detailed insights into the machinery's performance, revealing system efficiency and fuel consumption patterns across a spectrum of operational loads.

Economic analysis has made it clear that while hydrogen-fueled propulsion systems currently cost more than conventional fossil-based solutions, it is possible to achieve a balance. As technological advancements continue and carbon taxation becomes a global norm, the cost of operating hydrogen-powered vessels is expected to decrease, potentially aligning with those of traditional maritime fuels. This shift would mark a significant milestone in the maritime industry's journey towards

sustainability, positioning hydrogen as a viable and environmentally responsible fuel choice for the future of global shipping.

## **Part 6:**

# **UNMANNED AND AUTONOMOUS TRANSITION**

# Large Uncrewed Surface Vessel: An opportunity for Energy Transition?

T Beard<sup>1,\*</sup> and J Rigby<sup>2</sup>

## ABSTRACT

*Driven by the IMO target to make the maritime industry net-zero in its carbon emissions by 2050, the maritime industry now has the question of how to create both technically feasible and economically viable solutions. While many are looking at how this can be achieved for currently crewed vessels, even those service vessels such as naval combatants, there is also a real benefit that could be had by combining autonomy with the challenge of meeting the energy transition. Without people onboard there are options to completely change assumptions on layout, deck height and operations that could provide greater available space and counter energy density challenges. Additionally the removal of human life could open the line for other fuels such as ammonia with significant toxicity concerns. This paper investigates the benefits and difficulties that a Large Unmanned Surface Vessel (LUSV) utilising alternative fuel can bring, building on the recent BMT LUSV vision.*

## KEY WORDS

Autonomous Vessels; Energy Transition; Alternative Fuels; Modularity.

## INTRODUCTION

The maritime industry accounts for ~3% of global emissions (EU Horizon, 2022), if it were a country it would rank 6th, although accounting for ~90% of global trade. Clearly reducing maritime emissions will have a significant impact on global warming. The updated IMO GHG emissions strategy is for a ~50% reduction by 2030 and net zero by 2050 (IMO, 2023). There is also a clear ambition globally to maximise the opportunity of autonomy, thus reducing people in hazardous scenarios and increasing the ability to conduct tasks in a world with a skills shortage across many industries (World Economic Forum, 2023).

BMT have created a vision known as the Large Uncrewed Surface Vessel (LUSV). This is exploring not only an autonomous vessel, but how it can contribute to the maritime net zero targets. By combining autonomy with the energy transition there are many advantages to be gained. However, there are some technical challenges that must be overcome to ensure not only compliance with regulations, but also ensuring safe operation.

This paper introduces the BMT LUSV concept, which while it has been designed for a specific purpose the lessons learnt are applicable across the autonomous vessel range of operations and sizes. The advantages an LUSV has for supporting the energy transition are explored, alongside the general technical challenges.

One of the major advantages of autonomy is the removal of people. This not only provides more space it also has the added benefit of significantly reducing the energy demands of a vessel. This is due to the reduction in hotel load, which could around 15% of the required power compared to a crewed vessel and is explored in more detail in subsequent sections.

This provides two options for an owner/operator. The vessel could be reduced in size or endurance while cargo capacity could also be increased. Although it is likely that a combination of both of these will be sensible. However, one of the likely key drivers when starting out is acknowledging that the key ship impact of fuel would no longer be internal space but the impact of the mass of the fuel at the start of deployment.

## LARGE UNCREWED SURFACE VESSEL (LUSV)

The LUSV vision is a simplified supporting vessel that can utilise the full benefits of autonomy to help reduce costs. The concept of a LUSV is not new; LUSVs have been seen as the key component of the United States (US) Navy's ASW Continuous Trail Unmanned Surface Vessel programme since 2010. More recently, the US Navy has also looked at LUSVs to address the projected reduction in vertical launch strike missile capacity as their Ticonderoga Class cruisers are retired. The key element which makes these systems "large" is their requirement to operate on open ocean and higher sea states as well as the scale/size required to host the modular capability and support it for long durations of time. While the Royal Navy is keen to integrate and exploit uncrewed systems and is making significant progress in areas such as mine warfare and maritime air power, it has yet to formally consider the use of LUSVs to enhance its surface fleet. This means there is an opportunity to take a holistic design approach to the challenge; to outline the design drivers and help fuel discussion on the topic.

This LUSV vision has been created predominantly with an Anti-Submarine Warfare (ASW) application in mind but it could be utilised for a range of other surface warfare functions. ASW is especially appealing as it is a resource intensive endeavour. In order to counter a threat from entering a sensitive area, such as the Greenland Iceland UK (GIUK) Gap, a mixed fleet approach will often be used deploying a combination of submarines, Maritime Patrol Aircraft and expensive, high-performance front-line warships (UK Defence Journal, 2023). In the future LUSVs could be deployed to cover the GIUK Gap or similar maritime area on a permanent / near-permanent basis as required by intelligence-led indicators and warnings. Equipped with towed array and sonar buoys, these vessels would be capable of proceeding to a patrol station and maintaining a pre-planned patrol pattern (or respond to remote orders) to conduct either barrier operations or search functions. They would be capable of exchanging real-time data with both shore-based control centres and other assets (crewed and uncrewed) including those from other NATO countries. In this scenario, the crewed assets need only be activated once a positive detection is made. This means other more complex assets spend less time away from other, planned, commitments and the impact on personnel is also reduced.

### Key Requirements

Following the creation of a potential Concept of Operations (CONOPS) for the LUSV, Table 1 below outlines the key driving requirements for the vessel that became the input to the vision.

Title	Requirement	Measure of Performance
Endurance / Duration	Remain on mission for the duration of a mission with no physical maintenance or support required	Threshold 1 month
Seaworthiness	Maintain all systems operation in deep ocean conditions and survive extreme conditions,	Upper SS6 full performance
Speed loiter	Maintain a loiter speed on mission for extended duration	10kts – 12kts
Speed cruise	Deploy to AoA or maintain deployment with TG ships	20kts
Speed sprint	Sprint speed for short period to avoid obstacle or threat	Objective 25kts
Payload	Provide ability to deploy towed array over the stern and flexible mission modules	Space for 6+ TEU
Above Water Signature	Low observable, IR, and radar signature	tbd
Below Water Signature	Low in water acoustic noise and magnetic signature	Commercial ICES standard with margin
Command and Control	A constant connection to a human in/on the loop is required, this drives the need for a layered approach to communication and connection.	tbd
Offboard Systems	Although the primary function does not require an organic airborne capability it may be advantageous to facilitate modular drone capabilities.	tbd
Cost	Provide added mass to the fleet at less than half the cost of a traditional vessel. Through Life Cost should also be minimised, although onboard crew may be removed from the scenario, there is still a significant shore based maintenance crew.	£50m - £100m per vessel UPC TLC tbd

**Table 1: Key Requirements**

The LUSV concept is not constrained by the requirement to have humans onboard; there will be humans in the loop but not onboard. This unlocks huge potential to design a flexible and adaptable ship optimised for its operational roles, free of the compromises usually made to accommodate humans. Additionally it breaks the link between fleet mass and number of trained personnel; not all LUSVs need to be exercised all the time and they can be kept ready for a future surge in requirement (with suitable minor re-activation/work up). Autonomy opens the door to synergies that combine to bring significant operational, financial, sustainability and safety benefits.

Whilst there are benefits, there are also a number of challenges to overcome in order to provide a credible autonomous solution. These include, the increased cost of autonomy, ongoing ethical, security risk of capture and a requirement for a person in the loop for command and control. As part of our wider work we looked at all of these issues, categorising them into six key themes of development as outlined in Figure 1.

**Figure 1: The Six Core Challenges of a Large Uncrewed Surface Vessel**

Although six different and complex challenge areas have been investigated as part of the project, this paper only explores one, the engineering systems and the opportunity for future fuel insertion.

## Engineering Systems

By creating a vision for the future, it is important to consider that the regulatory and operational environment of the future will likely require alternative power and energy solutions. The LUSV provides an opportunity to incorporate alternative fuel solutions, without the same safety concerns of a crewed vessel. Although removing people from the vessel allows a re-evaluation of space for machinery and/or fuel, the energy density of alternative fuels still causes a significant headache for Naval Architects, with the alternative being more frequent replenishment. The minimum requirement is for 30 days operation, but greater endurance could provide even greater capability and perhaps reduce the number of hulls required.

To future proof the vessel and allow for through life alterations, an all-electric propulsion solution is proposed; this has the primary benefit of reducing mechanical maintenance, but it will also allow for changes in the power generation plant as technology develops. In addition, by utilising modular prime movers it can simplify the maintenance process in port allowing the key equipment to be removed and replaced with working items, this has an added bonus of enabling greater flexibility in the choice of future fuel. This modular design allows for the use of Fuel Cells, which would decrease vessel signatures whilst

allowing for improved maintainability and reliability. However, it should be noted current fuel cells (e.g. Proton-exchange membrane) require dehydrogenation for any alternative fuel except pure (99.999%) hydrogen. Solid Oxide Fuel Cells (SOFCs) can utilize various alternative fuels such as methanol, LNG or ammonia. Although the technology readiness level is lower, with a score of 7 given by IEA Fuel Cells (2024).

As previously discussed, removing people frees up space for more fuel, but the hull size will still limit the weight. Different fuels change the volume, weight and energy density balance, but alternatives to fossil fuels will have a lower volumetric energy density and this will create a challenge when the objective is to increase range beyond the baseline 30days at 10kts. It is also hard to select a specific fuel option as the apparent best systems are also the most immature.

The energy demand for the vessel will be different to a crewed variant, whilst the propulsive power required is anticipated to be equivalent or similar, the hotel load profile will vary. A comparison between crewed and uncrewed vessels for key sub-categories of the hotel load is provided in Table 2. This is an average over three operating climates and as such there is some variability for some of the sub-systems.

Hotel Load Sub Category	Crewed Energy Demand (%)	Uncrewed Energy Demand (%)
Hull	5	5
Propulsion & Generation	8	8
General Distribution & Lighting	5	0
Command & Control (including Communication)	15	20
Auxiliary Systems	30 ± 10	30 ± 10
HVAC	30 ± 10	15
Outfit & Furnishings	2	0
Armament	5	5
<b>TOTAL</b>	<b>100</b>	<b>83</b>

**Table 2 Hotel Load analysis and comparison for Crewed and Uncrewed vessels**

The following steps are a breakdown of the energy demand changes for the hotel load due to the removal of people, this is the view of the authors.

1. Hull load is likely to remain constant with potential for a minor decrease;
2. Propulsion & generation is likely to remain constant, although this could decrease as less power is required overall;
3. General distribution and lighting will be negligible;
4. Command and Control will increase due to a requirement to relay more information as well as computing power to execute decisions;
5. Auxiliary systems will remain constant, there is variability depending on the operating climate.
6. HVAC will decrease but there will still be a requirement for some HVAC to be onboard. This is because there will be a need to maintain suitable conditions for machinery and equipment;
7. Outfit & furnishings will be negligible as no people are onboard;
8. Armament is kept constant for this analysis but could change increase to account for the decrease in other demand.

This change in the energy demand is likely to result in a reduction required to maintain the vessel, which could be leveraged for the energy density reduction of the novel fuels. Conversely, this could lead to an increase in the mission systems onboard the vessel.

# FUEL OPTIONS

**Figure 2: Cross section of potential LUSV**

The LUSV has the space to potentially consider almost an entire deck for alternative fuel. Basing the fuel quantity on volume would provide circa 1000 m<sup>3</sup> of space for liquid (stored at or near ambient conditions), based on a LOA of 80m and a beam of 10m. However, when accounting for standalone storage tanks (pressurised or cryogenic/refrigerated) then the space significantly decreases to ~300 m<sup>3</sup>. However, the volume available is no longer the driving case for the quantity of fuel, instead the mass is now the driver. When accounting for mass of fuel required, one should be cognisant not to base any calculations on diesel alone and should at least account for the gravimetric energy density ratios.

There are a number of potential future fuel options offering different levels of future viability:

- Methanol is a viable alternative but is not completely emission free, emitting carbon locally and only being low carbon when the production is taken into consideration, but it remains a near term solution.
- Compressed or liquid forms of hydrogen are not considered viable due to the spatial constraints of stand-alone tanks.
- Ammonia may have potential if it can be stored in such a way that it can avoid the stand-alone tanks, this is only possible on a LUSV due to the lack of people onboard. Utilising associated Solid Oxide Fuel Cells (SOFC) would also overcome the challenges of dehydrogenation as it is not required.
- Liquid Organic Hydrogen Carriers (LOHC) could be the best long term solution. It supports the vessel efficiency by having a minimal impact on trim due to storing the dehydrogenated carrier liquid onboard. However, it will always require dehydrogenation but this could be supported with associated technology developments.

The fuels chosen for investigation on the LUSV to be operating at end of life are ammonia and Liquid Organic Hydrogen Carriers (LOHCs). This is because methanol can only be net zero, whilst these have the potential to be truly zero. Hydrogen was ruled out due to the spatial constraints previously mentioned since it requires standalone tanks.

Whilst normally ammonia requires standalone tanks, there is potential to utilise pressurised ammonia rather than refrigerated. Pressurised ammonia at ~10 bar has similar storage to refrigerated ammonia (Engineering Toolbox, 2024). This would require the plate structure to be 23 mm thick, for a plate with spans 2100mm long and 600mm wide. This could be optimized by altering the stiffener spacing such that it can withstand this pressure and any operating constraints as well.

The use of a LOHC provides an opportune method to utilise hydrogen whilst having minimal impact on the vessel design. This is also truly zero since only hydrogen is utilised. LOHCs are generally aromatic carbon compounds that are cyclic in nature. They hydrogenate (replace carbon double bonds with hydrogen) and dehydrogenate (replace hydrogen with carbon double bonds)

However, it is acknowledged that these fuels may not be available in the near future, or at least not globally. Therefore the use of modularity for power generation should be incorporated into the design. This allows the vessel to be designed to utilise any ambient liquid fuel through the life of the vessel. The use of modularity for power generation does require an electrical architecture for the propulsion system. However, this is now encouraged to minimise risk of obsolescence and ability to change prime mover moving forwards.

Placing power generation equipment just below the weather deck is advisable, since it is then possible to locate soft patches to support the removal of the equipment when required. This also minimises the spatial impact on the cargo/equipment onboard the LUSV.

## BENEFITS & RISKS

There are several benefits to utilizing a uncrewed vessel but there are also risks that need to be accounted for, both of which will be expanded on further within this section.

### BENEFITS

Electric propulsion allows the use of modular power generation. This provides flexibility of the fuel, which mitigates the risk of availability. Whilst this requires changes to the prime movers, this can be achieved via suitable removal routes and soft patches. This also gives a planned route to net zero if the chosen fuel is not available at time of build or during in operation.

The fuels chosen for the long term solution are LOHC or ammonia, whilst there can be transitions from MGO via methanol to the end solution. Currently the difference between the fuel is determined by the energy density and storage conditions. The ability to alter fuel through life, allows greater flexibility to accommodate emerging technologies and provides the flexibility to be included in a fleet-wide solution.

The use of the modular power generation provides an increase to the maintenance of the vessel and systems. The removal of equipment also means that there is less risk to operators conducting maintenance.

The removal of crew provides additional power due to the reduction in the hotel load. This could be used to offset the energy density or increase the capability of the vessel.

### RISKS

Currently firefighting and damage control are significantly human intensive actions. A USV will require far more information to be created, assessed and actioned to ensure a vessel is operationally still effective. However, the removal of people allows the potential to utilise different firefighting techniques due to a lack of requirement to sustain human life (Savage & Glockling, 2023). The potential to loss of situational awareness and by extension control is a key risk and issue for any autonomous vessel, but more so during the event of damage and fire. The use of hypoxic environments could be a beneficial way to mitigate the fire risks, reducing the oxygen content below 12% v/v for conventional fuels (Savage & Glockling, 2023).

Recoverability is split into seven areas, as shown in Figure 3, some of which are far more difficult to mitigate on a USV. Whilst technology can support some elements, for example situational awareness, it is more difficult to recover the vessel with no humans onboard. The use of external assistance to support recoverability could be more difficult when using novel fuels.

Figure 3: Pillars of recoverability (Savage & Bartlett, 2023)

The recoverability could be supported by the use of robots which could be stored onboard and activated as required. Although this seems like science fiction, humanoid or other robots could support the recoverability and remove potential risks to human life during an emergency.

Similar to crewed vessels inspections would still be required. However, it is possible to utilize drones to support this and as such remove the risk to people. The other option would be to ensure the system is fully safe, by the removal of fuel and ensuring there is no hypoxic environment.

The vessel is designed for no humans onboard and if this were required then it would likely need to be on the mission deck. Otherwise, it removes the benefits of operating a LUSV and the potential benefits that are offered.

## CONCLUSIONS

This paper presents a vision for a LUSV that has the potential to significantly contribute to the maritime industry's net-zero targets. The LUSV concept, which combines autonomy with alternative fuels, is adaptable and affordable, and is capable of performing a variety of surface warfare functions, with a particular emphasis on anti-submarine warfare. The engineering systems and fuel options for the LUSV, such as ammonia and liquid organic hydrogen carriers, have been thoroughly examined, and the benefits and risks of operating an uncrewed vessel have been discussed. In conclusion, the LUSV appears to be a promising and feasible solution that could enhance the mass and capability of future blue water fleets, while addressing the challenges associated with the energy transition.

A review of the concept is required to ensure optimal energy transition fuels are more realistic, due to many vessels originally being designed based on mass rather than volume of fuel. The main challenge is the mass of the new fuel which will have a lower energy density. The removal of people supports this due to the decrease in hotel load and increase in available space. Although this doesn't meet the full decrease in energy density when moving from diesel.

A secondary challenge is the recoverability of such an asset if damage were to occur. Smarter systems are required that can reduce the risk of the asset being lost. For example flood alarm switches that are linked to pressure to allow more information about the state of flooding, that is lost with the removal of people. Graceful degradation of systems would enhance the time for recoverability and allow for human intervention as required.

The use of autonomy has significant potential to support the energy transition of vessels by allowing the use of less energy dense and potentially more hazardous fuels to be used.

# Simulation for Designing the Transition to Autonomous Shipping – Japanese Coastal Shipping -

Kazuo Hiekata<sup>1</sup>, Yuki Maeda<sup>1,\*</sup>, Takuya Nakashima<sup>1</sup>

## ABSTRACT

*In Japanese coastal shipping, there is a need to introduce automation technology to alleviate the shortage of seafarers, but its introduction has an indirect impact on coastal shipping due to the interaction between transportation demand and freight rates in a market with a variety of stakeholders. Therefore, it is difficult to make decisions about its introduction. This study uses a simulator that mimics the Japanese cargo market to evaluate the impact of the deployment. The results show that the introduction of autonomous vessels, even in the middle of development, may bring benefits, and that remote maneuvering technology with a crew on board may not produce positive impacts.*

## KEY WORDS

Simulation, Autonomous ship, Technology adoption, Mobility transition, Coastal Shipping

## 1. INTRODUCTION

### Background

On a kilometer basis, more than 90% of Japan's domestic freight transportation is by automobile. However, on a ton-kilometer basis, coastal shipping accounts for about 40%, and coastal shipping plays a large role, especially in long-distance transportation (MLIT, 2022). However, coastal shipping is facing a serious shortage of labor, which is reflected in the fact that in recent years the ratio of effective job offers to applicants has consistently exceeded 2 and is even above 2.5 (MLIT, 2019). The aging of the seafarer population is also a problem, with about half of the seafarers over the age of 50 (MLIT, 2021). The number of seafarers is expected to decrease further soon. Therefore, the introduction of automation technology is expected to reduce the demand for seafarers and secure a stable supply of new seafarers. In addition to reducing the demand for seafarers, the introduction of automation technology is also expected to reduce accidents caused by human error, which is estimated to account for 80% of maritime accidents and reduce carbon dioxide emissions by reducing fuel consumption through optimization of routes and vessel shapes.

For these reasons, various projects are underway in Japan and abroad to develop automation technology. In Japan, a project called MEGURI2040 was launched in 2020 with the goal of commercializing unmanned vessels by 2025 and of having half of all domestic vessels operated by unmanned vessels by 2040 (The Nippon Foundation, 2022). At the same time, the Maritime Unmanned Navigation through Intelligence in Networks (MUNIN) project is one of the big projects held in 2015-2020 outside of Japan. Project Report (MUNIN, 2015) concluded that autonomous vessels are feasible, although some barriers still remain. The MUNIN project is not only developing the technology but is also investigating the economic evaluation of autonomous vessels and discussing their feasibility. According to Bellingomo et al. (2023), the technology to develop autonomous vessels has been well developed by these projects, and it is technically feasible to introduce autonomous vessels in the near future.

The economics of autonomous vessels were analyzed by MUNIN (2015) and Kretschmann (2017). They compare the operating costs of autonomous vessels with conventional vessels for the bulk vessels envisaged in the MUNIN project. Akbar (2019) analyzes the total costs of introducing autonomous vessels on Norwegian coastal routes, based on actual routes and cargo volumes. These studies show that autonomous vessels are economically profitable, and when operated on actual routes,

---

<sup>1</sup> Graduate School of Frontier Science, The University of Tokyo, Japan,

\* Corresponding Author: maeda-yuki086@g.ecc.u-tokyo.ac.jp

costs can be further reduced through route optimization. Dantas et al. (2023) compare the operating costs of a typical Norwegian short-haul vessel with those of a conventional autonomous vessel (TAS), and a new configuration of autonomous vessels (NGAS) with reduced crew living space and other functions made unnecessary by unmanned autonomous vessels and concluded that the reduction of crew facilities on autonomous vessels helps to reduce costs. As for the impact of automation technology on crewing demand, Kretschmann (2017) proposed a system in which instead of crewing autonomous vessels, autonomous vessels are monitored from a remote operations center (ROC). They estimate that 112 people would be needed for one ROC, including standby operators, watchkeepers, and managers. It also estimates that one ROC can operate 90 vessels. Kooij (2021) also conducted a study on the impact of the introduction of automation technology, analyzing the tasks required to operate a 750 TEU container ship with a crew of 12 and the tasks that could be replaced by the introduction of automation technology. The analysis showed that the number of seafarers required was reduced by only one second officer, but the workload of the seafarers was significantly reduced. Therefore, the study concluded that for shipowners, the economic benefit of reducing automation technology is small because it does not significantly reduce the demand for seafarers, but the reduction in workload improves the working environment and contributes to a reduction in maritime accidents, which account for 80% of all maritime accidents due to seafarer fatigue. Further research on policies that promote automation technology includes Nakashima et al. (2023). This study estimated that a combination of deregulation and appropriate assistance could hasten the introduction of fully autonomous vessels by more than 10 years.

Although the introduction of automation technology in coastal shipping is ongoing due to the background described in the previous part, the introduction of autonomous vessels with no crew on board will not be possible anytime soon. Therefore, until the introduction of autonomous vessels becomes feasible, one measure to maintain the market share of coastal shipping and ensure stable transportation is to eliminate the shortage of seafarers by utilizing the automation technology to be introduced in autonomous vessels and reduce the number of seafarers required. On the contrary, if automated technologies are rapidly introduced, a rapid drop in the demand for seafarers could lead to an oversupply of seafarers, which could worsen the employment environment for seafarers, and an oversupply of seafarers could lead to extra labor costs. Under these circumstances, it is desirable to introduce automated technology to match the shortage of seafarers. However, while there have been studies on the economics of autonomous vessels and the number of seafarers that would change with the introduction of automation technology, few studies have analyzed the impact of the introduction of such technology on seafarer employment and how the early introduction of automation technology used on autonomous vessels would improve shipping capacity by reducing the seafarer shortage in the transitional period.

## **Purpose of this study**

The introduction of automation technology also has a direct impact on seafarer demand and operating costs and an indirect impact on coastal shipping due to the interaction between transportation demand and freight rates in a market with a variety of stakeholders. In the presence of such complex factors, it is difficult for coastal shipping to make decisions to introduce automation technology more quickly while maintaining its transportation capacity as an industry in terms of employment and economics. Therefore, this study aims to support this decision-making process through a simulator that models the costs of coastal shipping and car transport in Japan and designs the transition to autonomous shipping driven by the introduction of automation technology.

## **2. PROPOSED METHOD**

### **Overview of the proposed method**

We propose a method to evaluate the impact of the introduction of automation technology by shipping companies. As shown in Figure 1, the method begins by developing a simulator that models the domestic freight market in Japan, including the estimated parameters. The simulator models how to calculate costs and set freight rates for coastal shipping and automobile transport, and at each step, decisions are made on factors related to the calculation of costs, such as investment in facilities and hiring of employees for each transportation demand. In addition, changes in the determined freight rates change the transportation demand for each means of transport in the next step. These complex interactive demands represent the Japanese freight market. Next, the case study is conducted as shown below using the simulator developed. The inputs to the case study are a combination of a shipping company's decision-making strategy regarding the introduction of automation technology and future trends in total transportation demand. The strategy regarding the introduction of automation technology relates to whether to introduce each of the four stages of technology envisaged as stages in the development of automation technology. The future trend of total primary demand is a set of future trends in total transportation demand from 2010, the starting year of the simulation. Based on these inputs, the simulation is run for a one-time step of 1 week between 2010 and 2070, and output results include the transition of shipping costs. Finally, the result is transformed into three indexes between 2025, when we assume that automation technology can be implemented, and 2070, when the simulation ends, as the NPV considered for the time discount rate, the total lost transportation opportunity ratio, and the cumulative early retirement crew ratio, by total transportation demand. After that, they are plotted on a scatter plot. The scatter plots are plotted on the

horizontal axis with the cumulative percentage of early retired seafarers on the right decreasing, and on the vertical axis with the percentage of lost transportation opportunities on the bottom decreasing. The color of the plotted points expresses the NPV of the shipping company's ton-kilometer-based costs and the larger the costs are, and the closer to yellow, the smaller the costs are red. The above methodology is proposed in this study as a method for evaluating the impact of shipping companies on the adoption of automation technology.

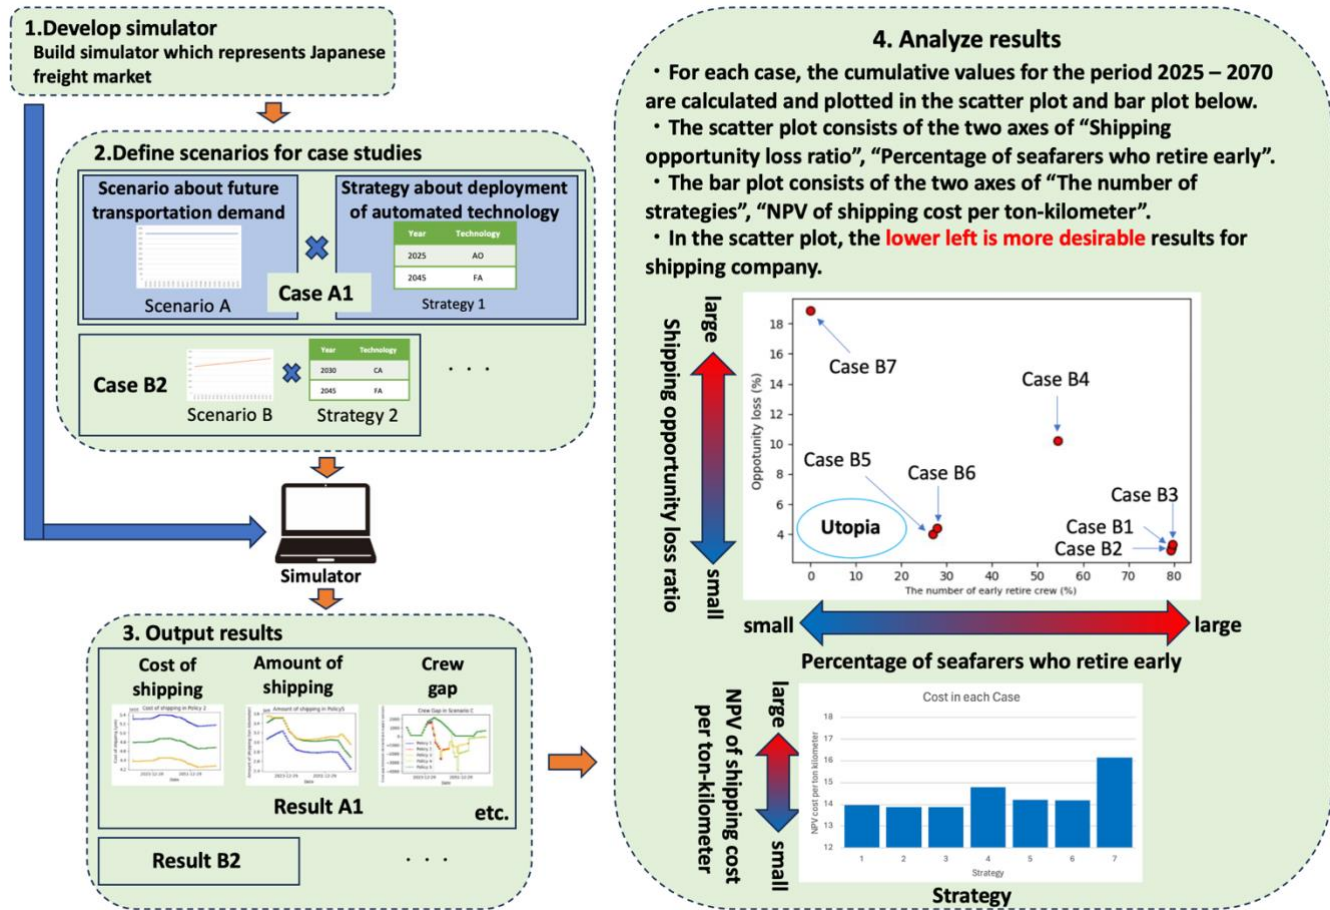

Figure 1: The abstract of proposed method

### Simulation calculation flow

In the previous part, we proposed a method to provide decision support to shipping companies regarding the introduction of automation technology. In this section, we describe the specific computational flow of the simulator. Firstly, variables that are considered necessary for the simulator to be developed are selected based on previous studies and will be described later in subsequent parts. At each time step, the variables for the next time step are also calculated. As shown in Figure 2, the simulator was conducted with a time unit of 1 week from 2010 to 2070, the year when autonomous ships and self-driving cars are expected to be widely used. The simulator is divided into two parts: a transportation demand estimation model and a transportation cost estimation model. The transportation demand estimation model calculates transportation demand by transportation agency according to the freight market conditions. Then, based on the transportation demand, the transportation cost estimation model calculates transportation costs for each transportation. The relationships between the variables represented by the arrows in Figure 3 were developed based on previous studies. The sequence of calculations in the transportation cost estimation model is likewise shown in Figure 3.

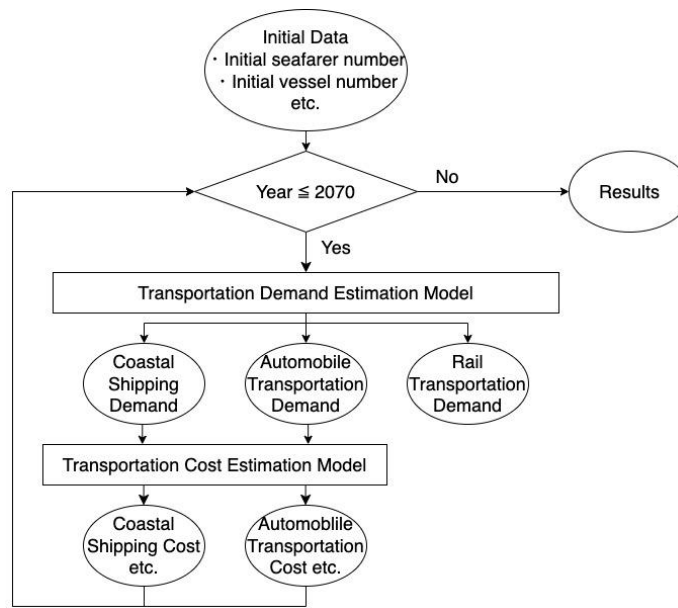

Figure 2: The abstract of simulator

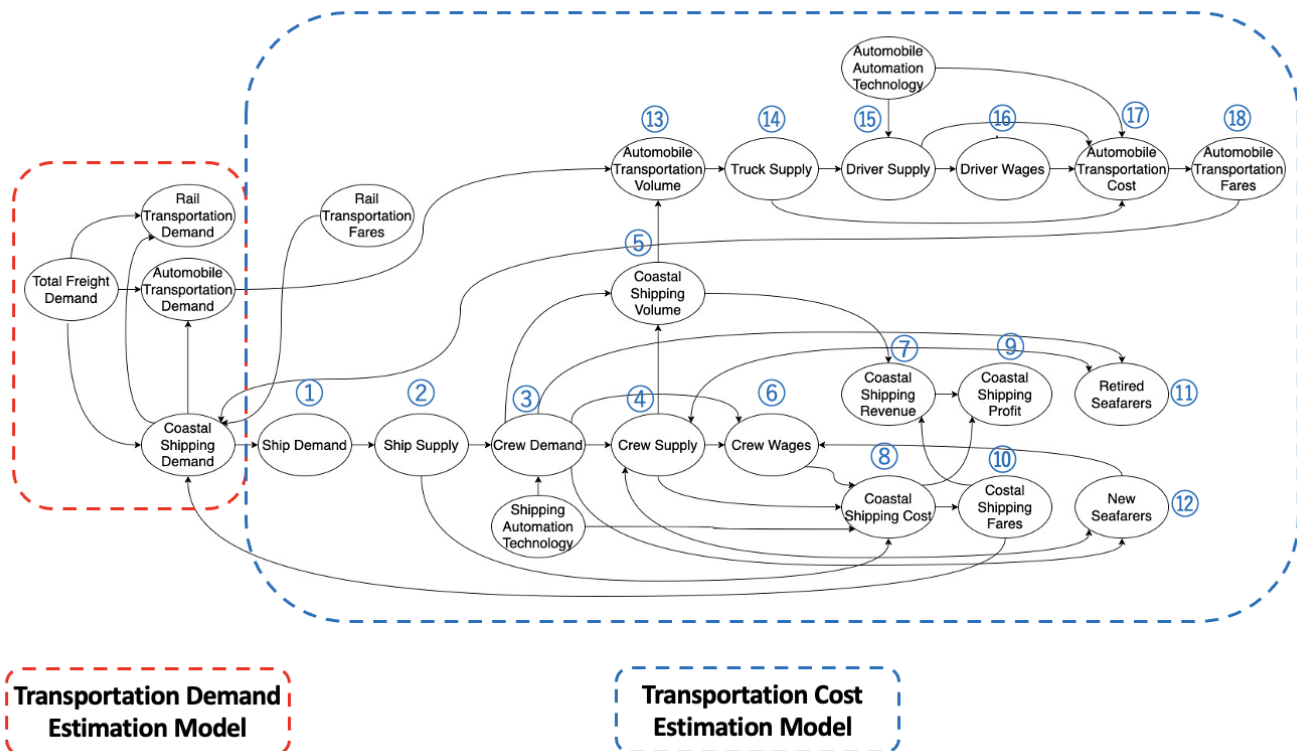

Figure 3: The relationships among variables in one loop. Source: Prepared by the authors from (Shinke, 2007), (Kretschmann, 2017) and (Lee, 2023)

### Simulation model variables

Air transportation was not treated in this study because its share of transportation is small (less than 1%). In addition, rail transportation was treated with fixed freight rates because the percentage of transportation has been fixed in recent years, although there is a certain amount of transportation (The Japanese Shipowners' Association, 2021). For the variables used, the variables necessary for transportation demand allocation (Shinke, 2007) and for calculating the costs of coastal shipping (Kretschmann, 2017) (Lee, 2023) and automobile transportation were selected (Table 1) with reference to previous studies.

**Table 1: The variables in the simulator**

modes of transportation	variable
Coastal shipping	Transportation demand, number of vessels demanded/supplied, crew demand/supply, crew labor costs, transportation expenditures, fare, and transportation revenues
automobile	Transportation demand, truck demand/supply, truck driver demand/supply, truck driver labor costs, transportation expenditures, freight rates, and transportation revenues
railroad	Transportation demand, freight rates

### Estimation of transportation demand

In this study, 47 prefectures are treated as nodes, and the links connecting these nodes are treated as a domestic freight transportation network. Transportation demand by each mode of transportation is distributed by a multinomial logit model. The calculation of the probability  $P_{m,o,d,t}$  of transportation  $m$  from node  $o$  to node  $d$  at time  $t$  is defined in Equation [1], and the transportation demand  $X_{m,o,d,t}$  is obtained by the expected value using the total transportation demand  $G_{o,d}$  and  $P_{m,o,d,t}$  as shown in Equation [5]. The utility calculated by the logit model  $V_{m,o,d,t}$  is the freight rate per ton-kilometer  $F_{m,t}$  (discussed after) and transport distance  $L_{m,o,d}$  (discussed in Appendix) and time  $T_{m,o,d}$  (discussed in Appendix) based on previous studies and defined in Equations [2] through [4]. The parameters  $\alpha$  used in these equations are described below in Appendix.

$$P_{m,o,d,t} = \frac{\exp(V_{m,o,d,t})}{\sum \exp(V_{m,o,d,t})} \quad [1]$$

$$V_{ship,o,d,t} = \alpha_{time}T_{ship,o,d} + \alpha_{cost}F_{ship,t}L_{ship,o,d} \quad [2]$$

$$V_{rail,o,d,t} = \alpha_{time}T_{rail,o,d} + \alpha_{cost}F_{rail,t}L_{rail,o,d} + \alpha_{rail} \quad [3]$$

$$V_{truck,o,d,t} = \alpha_{time}T_{truck,o,d} + \alpha_{cost}F_{truck,t}L_{truck,o,d} + \alpha_{truck} \quad [4]$$

$$X_{m,o,d,t} = G_{o,d}P_{m,o,d,t} \quad [5]$$

### Shipping

#### Automation progress

Referring to IMO's definition (IMO, 2016) for automation technology and AUTOSHIP's roadmap (Nordahl, 2023), the following stages of automation technology development were established as Table 2.

**Table 2: Automation technology development stage (Nordahl, 2023)**

Automation phase	Description.
AO (Automatic Operation)	Automated technologies such as automatic ship holding and automatic ship release are beginning to be implemented, but decisions are made by the ship's crew.
RC (Remote Control)	Predictive breakdowns of machinery will be possible, and maintenance of machinery will be performed when the vessel makes port calls. The ship will be constantly monitored from shore, and the conventional control system will remain, but decisions will be made remotely from the RCC.
CA (Constrained Autonomy)	The vessel operates autonomously under general conditions, although its autonomy is limited. The vessel no longer requires a crew to be on board and is only operated remotely from a remote-control center (RCC) under complex conditions, such as bad weather.
FA (Full Autonomy)	Full autonomy is achieved, with no crew on board or in the RCC. However, the operator of the RCC must deal with fallback recovery.

#### Fleet configuration

The demand for the number of vessels of each size  $D_{ship,size,t}$  is calculated based on transport demand and defined in Equation [6]. The weekly transport volume  $\beta_{ship}$  per pair of vessels calculated from the past data to calculate the total tonnage required by the vessel. The ship types described in this study are four typical ship types (MLIT, 2021) is

assumed that the ratio of the number of vessels by ship size  $A_{ship,size}$  does not change, we calculate the demand for the number of vessels for each ship size.

$$D_{ship,size,t} = \left\lceil \frac{A_{ship,size}}{\beta_{ship}} \sum_{o,d} X_{ship,o,d,t} L_{ship,o,d} \right\rceil \quad [6]$$

### Number of vessels supply

The shipping company determines the supply of vessels of ship age  $age$ ,  $S_{ship,size,phase,age,t}$  based on the demand  $D_{ship,size,t}$ . In this study, it is assumed that ships are used for 14 years, which is the statutory service life of a ship in Japan, and that they are not scrapped in the middle of their service life. The number of new vessels is determined by the difference between the demand for vessels and the number of existing vessels in the current time step for each vessel type to meet the demand. The number of vessels in each automation phase is defined by Equations [7] and [8] to be allocated to the number of vessels in each automation phase according to the  $C_{phase}$ .

$$S_{ship,size,phase,age+1,t} = S_{ship,size,phase,age,t-1} \text{ if } (0 \leq age \leq 13) \quad [7]$$

$$S_{ship,size,phase,0,t} = \left( D_{ship,size,t} - \sum_{phase} \sum_{age}^{13} S_{ship,size,phase,age,t-1} \right) C_{phase} \quad [8]$$

### Seafarer demand

The demand for seafarers  $D_{crew,t}$  is the supply of number of vessels  $S_{ship,size,phase,t}$  and the demand for seafarers per vessel  $B_{ship,size,phase}$  is calculated using Equation [9]. One of the purposes of introducing automated technology is to solve the shortage of seafarers, and the demand for seafarers is greatly affected by the introduction of automated technology. The factors affecting the demand for seafarers at each stage of automation technology are summarized in Table 3 with reference to AUTOSHIP (Nordahl, 2023). The demand for seafarers for conventional vessels is based on the Ministry of Land, Infrastructure, Transport and Tourism (2021).

**Table 3: Factors influencing the demand for seafarers at each stage (Nordahl, 2023).**

Automation phase	Seafarer services to be reduced
AO	The demand for seafarers on deck will decrease with the introduction of automated technologies such as sensors on the hull, automatic ship holding and automatic ship release.
RC	Machinery maintenance will be performed by the port's machinery mechanics when they call at the port as machine failures can now be predicted MUNIN Project Report. (2015) According to the MUNIN project report (2015) the maintenance that used to be performed during the 216-day voyage is now performed during the 120-day voyage when the vessel is in port. It was assumed that the number of seafarers in the machinery department would effectively increase by a factor of 120/216 as they would be serviced. At the same time, the demand for seafarers in the deck section would be substantially reduced as remote monitoring facilities would provide around-the-clock monitoring and decision making.
CA	Ships will navigate autonomously under all but the most complex conditions, such as bad weather, reducing the number of seafarers required at remote monitoring facilities MUNIN Project Report. (2015) According to the MUNIN project report (2015), the MUNIN project envisions a single remote monitoring facility to monitor 90 autonomous vessels with a crew of 112.
FA	If no abnormalities occur on the vessel, it will operate autonomously, further reducing the number of crew members required at the remote monitoring facility.

$$D_{crew,t} = \sum_{i,j} S_{ship,size,phase,t} B_{ship,size,phase} \quad [9]$$

### Seafarer supply

Seafarers are divided into two categories: staff and departmental staff. Staff members are required to obtain national certification by graduating from a seafarer training school, but they are indispensable to the operation of a ship. Therefore, in this study, it is assumed that new seafarers are hired at the age of 20, when licenses can be issued, and retire at the age of 70 defined by Equation [10]. New Seafarers  $S_{crew,20,t}$  is the new potential seafarer  $N_{crew,t}$  and is calculated as the minimum of the gap between seafarer supply and demand, defined by Equation [11]. New potential seafarers  $N_{crew,t}$  is calculated using Equation [12], assuming that the number of potential new seafarers will decrease by 1% each year from the current number of 900, which is the number of new seafarers in Japan, taking into account the decline in Japan's population.  $E(= 0.01)$  is the seafarer retirement rate for each year. In this study, based on the number of seafarers in 2010, the initial values for seafarers are used, separated by age groups by one year of age. Equation [13] and [14] defines the actions of shipping companies with respect to the dismissal of seafarers. In this model, shipping companies are assumed that they lay off seafarers when the number of seafarers exceeds a certain ratio  $\kappa(= 1.1)$  of the current demand for seafarers. The model is set up so that when dismissing a seafarer, the older seafarers would be dismissed first.

$$S_{crew,age,t} = (1 - E)S_{crew,age-1,t-1} - I_{crew,age,t} \text{ if } (21 \leq age \leq 70) \quad [10]$$

$$S_{crew,20,t} = \min\{N_{crew,t}, (D_{crew,t} - S_{crew,t})\} \quad [11]$$

$$N_{crew,t} = 900 * \{1 - 0.01 * (t - 2010)\} \quad [12]$$

$$I_{crew,t} = \sum_{age} (S_{crew,age,t}) - \kappa D_{crew,t} \quad [13]$$

$$I_{crew,age,t} = \max\left(0, I_{crew,t} - \sum_{i=0}^{70-age} S_{crew,70-i,t}\right) \quad [14]$$

### Worker labor costs

The wage of workers is calculated as defined in Equations [15] and [16] from the effective job openings ratio (the gap between supply and demand for seafarers divided by the number of potential new seafarers) with reference to the Bank of Japan's past analysis (2017).

$$Q_t = 1 + 0.5 \left( \frac{D_{crew,t} - S_{crew,t}}{N_{crew,t}} - 1 \right) \quad [15]$$

$$W_{crew,t} = W_{crew,t-1} \left( 1 + \frac{Q_t}{100} \right) \quad [16]$$

### Vessel transportation expenditures

The multiple subcontracting structure of the Japanese transportation industry has become a problem because it leads to lower profit margins. In this study, we assume a "time-charter contract" as one of these employment types. In this type of employment, the shipowner pays operating costs such as crew costs and ship repair costs, as well as capital costs such as depreciation, and earns charter fees by leasing the ship to an operator who actually carries the cargo. The operator, on the other hand, rents the people and equipment necessary to operate the ship from the shipowner, and in addition pays voyage expenses such as fuel to actually transport the cargo. The operator's source of income is the freight charges from the shipper.

Figure 4: The market structure of Japanese coastal shipping (MLIT, 2020)

In this study, the cost to the owner was calculated with reference to the Maritime Industry Research Institute (2004). The operator's costs were calculated based on a survey by the Ministry of Land, Infrastructure, Transport and Tourism (2010). The following are the costs for each of the conventional sizes. Since only data for 199 GT, 499 GT, and 699 GT were available for the owner's costs, data for 799 GT and 5000 GT were prepared assuming that all costs except crew costs are proportional to the size of the vessel.

**Table 5: The change of cost in each phase (MUNIN, 2015), (Dantas, 2023)**

	existing ship	admission office	reinforced concrete reactor	CA	FA
capital cost	0	+7.5%	+15%	+10%	
freight costs	0				
fuel expenses	0	-5%			
harbor charges	0	+20%			
remote facility	0	Construction costs are \$2,100 thousand. Maintenance costs are \$874 thousand.			

There are also several possible costs that will increase or decrease with the autonomous vessels. Below is a summary of equipment costs that will vary with the introduction of autonomous vessels. The MUNIN report (2015) analyzes the costs associated with remote monitoring facilities to monitor autonomous vessels. It also points out the increased costs associated with port employees performing berthing tasks that would traditionally be performed by the crew. The cost of vessel construction is also expected to change. Various methods have been proposed in the past to estimate the cost of building a conventional ship (Caprace, 2009). Based on these methods, MUNIN (2015) and Dantas et al (2023) have estimated costs. Based on the above, this study has determined that the cost of transportation by ship is shown in the following Table 5.

#### Marine transportation revenues

Revenues from shipping  $R_{ship,t}$  are calculate by freight rates  $F_{ship,o,d,t}$ . In this study, freight rates are calculated as in Equation [17] in a way that is consistent with the actual situation.

$$R_{ship,t} = F_{ship,t} \sum_{o,d} F_{ship,o,d,t} X_{ship,o,d,t} L_{ship,o,d} \quad [17]$$

#### Maritime transportation profit

Profit from shipping  $H_{ship,t}$  is calculated as in Equation [18] from the difference between income  $R_{ship,t}$  and expenditure  $C_{ship,t}$ .

$$H_{ship,t} = R_{ship,t} - C_{ship,t} \quad [18]$$

#### Shipping freight rates

In this study, shipping companies try to keep profit margins. In other words, freight rates fluctuate according to the shipping companies' costs. Using historical data (Maritime Industry Research Institute, 2004), the shipping company was set to maintain a 2% profit margin. Overall freight rates and standard overall freight rates calculated from  $J_{ship}$  and standard freight rates for each link  $E_{m,o,d}$  (discussed below in Appendix), as shown in Equation [19].

$$F_{ship,o,d,t+1} = \frac{C_{ship,t} E_{m,o,d}}{J_{ship} \sum_{o,d} X_{ship,o,d,t} L_{ship,o,d}} \quad [19]$$

## Automobile transport

#### Automation progress

Automation is being promoted not only in coastal shipping, but also in the automobile industry. Already in 2023, there have been demonstrations of Level 4 automated trucks on highways (unmanned operation under certain conditions) (LNEWS, 2023). In addition, the Japanese government's roadmap sets the goal of social implementation of Level 4 automated trucks at 2026 (MLIT, 2023a). Automated driving outside of expressways will be available after 2026, but in terms of modal shift to and from marine transportation, the modal shift in automobile transportation is mainly for long-distance transportation, and

many of them use expressways. Therefore, we assumed that the demand for transportation will change with shipping due to automation on highways, and that the introduction rate of automated trucks will increase linearly between 2026 and 2060.

#### Number of trucks

Truck demand at time  $t$   $D_{truck,t}$  is calculated from the ton-kilometer-based transportation demand calculated and weekly transport volume per vehicle  $\beta_{truck}$  (All Japan Trucking Association, 2010) as defined in Equation [20].

$$D_{truck,t} = \left\lceil \frac{\sum_{o,d} X_{truck,o,d,t} d_{truck,o,d}}{\beta_{truck}} \right\rceil \quad [20]$$

In addition, the supply of trucks  $S_{truck,t}$  The supply of trucks is assumed to be equal to the demand as shown in Equation [21] because the number of trucks produced is large and the lead time of production is small, so the supply can be changed flexibly in response to fluctuations in demand.

$$S_{truck,t} = D_{truck,t} \quad [21]$$

#### Number of truck drivers

In this study, we assumed that the proportion of trucks  $S_{truck,t}$  and the number of drivers is not likely to change. In addition, the results of a comparison of the number of trucks and drivers using historical data (All Japan Trucking Association, 2022) are shown that the number of drivers per vehicle has not changed significantly over the last eight years. Therefore, as shown in Equation [22],  $B_{driver}$  drivers are needed per vehicle ( $B_{driver} = 0.60$ ).

$$D_{driver,t} = S_{truck,t} B_{driver} \quad [22]$$

In addition, there are fewer barriers for people to obtain a license to drive trucks. Although a license is certainly required to transport medium-sized or larger trucks, the demand for small truck drivers is also high, so we assumed that supply and demand would almost balance, as in the case of the number of trucks, as in Equation [23], and that demand and supply  $S_{driver,t}$ , as in the case of the number of trucks.

$$S_{driver,t} = D_{driver,t} \quad [23]$$

#### Trucking expenditures

Trucking expenditures are calculated from the number of trucks and the number of drivers. In this study, per-vehicle costs were calculated based on data from the All Japan Trucking Association (2022), and costs were divided into four major categories: labor, fuel, insurance, and other vehicle-related costs. In addition, the variation in transportation costs when automated technology is implemented. Lee et al. (2023) conducted a cost analysis of the implementation of automation technology in 1-ton trucks. With reference to those analyses, this study established the costs of automobile transportation as shown in Table 6.

**Table 6: The change of cost of trucking**

	Conventional (thousand yen)	Autonomous (thousand yen)
personnel expenses	1.25 Wages	0.125 Wages
fuel expenses	246	196.8
insurance premium	41	36.9
Other expenses related to the vehicle	775	775

#### Trucking fare

Trucking freight rates  $F_{truck,o,d,t}$  is the cost to maintain a profit margin similar to that of shipping companies. In this study, the formula was set up as shown in Equation [24], assuming that the profit margin is kept at 2% with reference to past data (All Japan Trucking Association, 2022).

$$F_{truck,o,d,t+1} = \frac{C_{truck,t} E_{truck,o,d}}{J_{truck} \sum_{o,d} X_{truck,o,d,t} L_{truck,o,d}} \quad [24]$$

### 3. CASE STUDY

#### Case study subject

The purpose of this study is to analyze how coastal shipping can introduce automation technology that is desirable from the perspective of employment and economics while maintaining shipping capacity in a market that includes complex interactions between freight rates, transportation demand, and other factors. Therefore, the case study will focus on which stage of automation to choose when building a ship.

#### Case study settings

With regard to the strategy for introducing automation technology, the roadmap created by AUTOSHIP, as mentioned earlier in Section 2, aims to develop automation technology in four phases. In this study, assuming that the development of automation technology will proceed according to the roadmap, whether or not shipping companies will start introducing automation technology when vessels in each phase are ready for introduction is defined in Figure 5 divided into Strategy 1 to 16. as follows. Furthermore, these strategies are divided into Group 1 through Group 4 based on the introduction of CA and FA.

	Group 1 (With CA and FA)				Group 2 (With CA and no FA)			
	Strategy 1	Strategy 2	Strategy 3	Strategy 4	Strategy 5	Strategy 6	Strategy 7	Strategy 8
AO	✓	✓			✓	✓		
RC	✓		✓		✓		✓	
CA	✓	✓	✓	✓	✓	✓	✓	✓
FA	✓	✓	✓	✓				

	Group 3 (With FA and no CA)				Group 4 (Without CA and FA)			
	Strategy 9	Strategy 10	Strategy 11	Strategy 12	Strategy 13	Strategy 14	Strategy 15	Strategy 16
AO	✓	✓			✓	✓		
RC	✓		✓		✓		✓	
CA								
FA	✓	✓	✓	✓				

**Figure 5: The strategy of deploying automated technology**

In addition, three scenarios of future demand for freight transportation were considered: "demand will increase," "demand will remain unchanged," and "demand will decrease". The three scenarios were developed as shown in Table 7.

**Table 7: Total transportation demand assumptions for each scenario**

scenario	Description.
Scenario A	Total transport demand increases by 0.5% per year
Scenario B	Aggregate demand for transportation does not change
Scenario C	Total transport demand decreases by 0.5% per year

#### Results and Discussions

The results of the case study described in the previous part are presented below. The scatter plot shows the cumulative percentage of seafarers who retired early due to the oversupply of seafarers [%] on the horizontal axis, the percentage of lost transportation opportunities [%] due to the shortage of seafarers on the vertical axis. The lower right of the graph is the preferred result because the cumulative percentage of seafarers who retire early is smaller, and the cumulative transportation opportunity loss percentage is also smaller. Also, the bar plot shows the cumulative cost [yen/ton-kilometer] on a ton-kilometer basis for shipping companies calculated using a discount rate of 3% in the marker color for simulation results for 2025 to 2070 when automated technologies can be introduced.

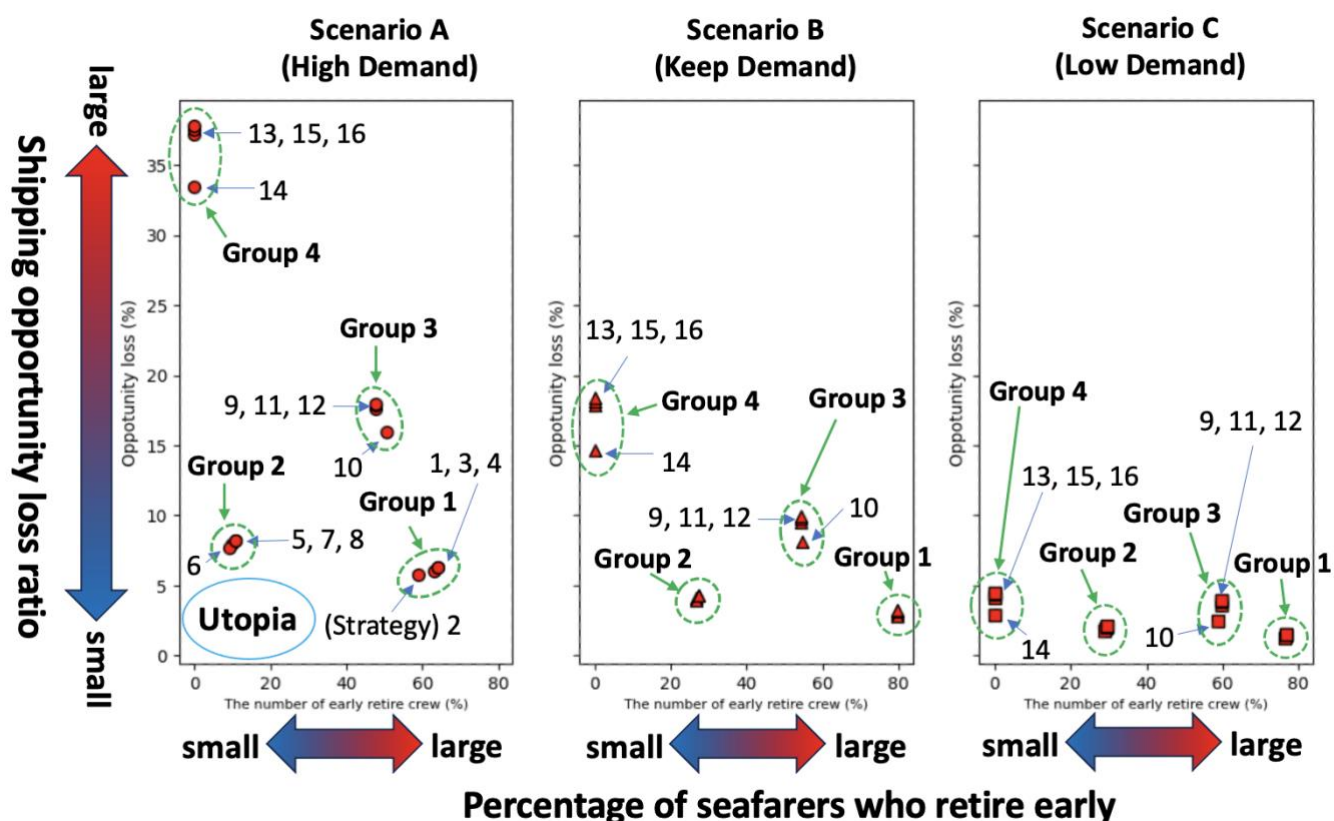

Figure 6: The results by case in Model A

Figure 7: The results by case in Model A

Table 8: The influence of each technology

	Retirement of seafarers	Opportunity loss	Shipping cost
AO	+ (in most cases)	+	+
RC	almost zero	almost zero	—
CA	— —	++	++
FA	— — (when used with CA, —)	++ (when used with CA, +)	++ (when used with CA, +)

- "+" means positive influence and "—" means negative influence.
- The number of icons represents the size of influence.

From the assumptions of this research, these results can be divided into four Groups, and it can be read that the impact of the introduction of CA and FA is significant. A comparison of each of these groups shows that Group 3 is completely inferior to

Group 2, while Group 1, 2, and 4, are in a trade-off relationship, with no strategy superior to the other strategies in all indicators, indicating that the decision to introduce automation technology is difficult. The overall result of the three indicators shows that as the total demand for transportation increases, the strategy that does not introduce autonomous ships significantly increases “Shipping opportunity loss ratio” and “NPV cost per ton kilometer”, indicating the superiority of Group 2 that only introduces CA in these scenarios, while in the scenario where the total demand for transportation decreases, the strategy that only introduces autonomous ships is superior to Group 2. In the scenario where the total demand for transportation decreases, Group 4, which does not introduce autonomous vessels, shows a smaller difference in the two indicators, indicating that the demand for introducing autonomous vessels in this scenario is small.

In the following parts, we will discuss in detail the impact of the introduction of automation on each of these indicators.

### Retirement of seafarers

- 1) The impact of deploying CA and FA is larger than that of deploying AO and RC, and these results are divided into four groups.
- 2) The ratio of early retired seafarers increases with the introduction of CA and FA regardless of the scenario of the transport demand, while the introduction of AO has reduced the percentage of early retired seafarers in most cases.
- 3) The number of early retired seafarers fluctuates with changes in total transportation demand, but not monotonically.

In discussing these results, we use Figure 8, a graph on the supply-demand gap for seafarers, with positive values on the y-axis indicating a shortage of seafarers and negative values indicating a surplus of seafarers. At the same time, the x-axis represents the year. In Figure 8, Strategy 1 is used to represent Group 1, Strategies 6, 7 and 8 to represent Group 2, Strategy 12 to represent Group 3, and Strategy 16 to represent Group 4. And to evaluate the impact of the introduction of AO, and Strategy 7 to evaluate the impact of the introduction of RC by comparing Strategy 7 and Strategy 8. It is clear from these comparisons that the introduction of CA and FA has significantly changed the supply and demand for seafarers, indicating the magnitude of the impact of the introduction of CA and FA as described in 1).

Regarding 2), the introduction of CA and FA has caused an excess of seafarers. Figure 8 shows that the introduction of FA without CA has caused a temporary large overcrowding of seafarers due to the rapid alleviation of the seafarer shortage. Comparing Strategy 6 and Strategy 8 for the introduction of AO, the number of seafarer shortages during the period when a seafarer shortage is occurring is mitigated by a decrease in the demand for seafarers per vessel. At the same time, the reduction in the number of seafarers employed in the cases where AO was introduced due to the reduction in the seafarer shortage also alleviated the seafarer surplus during the period after the seafarer shortage was resolved.

With regard to 3), the percentage of early retired seafarers is expected to decrease as the demand for transport increases because the demand for seafarers also increases, but no significant change was observed between Scenario B, where the demand for transport is maintained, and Scenario C, where the demand for transport decreases (Figure 6). The simulation results indicate that when transport demand declines, shipping companies hire fewer new seafarers, which reduces the supply of seafarers, and as a result, the number of seafarers who retire early also declines. However, there is a slight difference in the trend between policies, suggesting that changes in transport demand affect the environment of seafarers' employment.

**Figure 8: The difference between the supply and demand of seafarers in each case**

### Opportunity loss

- 1) Under different total transportation demand scenarios, the opportunity loss rate increases with an increase in total transportation demand.
- 2) Groups 1, 2, and 3 with autonomous technology successfully reduce the impact of the increasing total transportation demand compared to Group 4 without autonomous technology.

- 3) With respect to the introduction of AO and RC, both reduced “Opportunity loss”, but the impact was less than that of CA and FA. The reduction in Opportunity loss due to AO implementation can be read from the Figure 6 in most cases, while the reduction due to RC implementation was very small.

Figures 9 and 10 are used to discuss these results. In both graphs, the horizontal axis represents years and shows the results for each scenario in Strategy 1. The left graph in Figure 9 shows the volume transported by coastal shipping, while the middle graph shows the difference between supply and demand for seafarers, as discussed in Figure 8. Finally, Figure 10 shows the number of seafarers in each age group.

As can be read from the middle graph in Figure 8, before the introduction of autonomous vessels such as CA and FA, the shortage of seafarers accelerated as total transport demand increased. This is due to the aging of seafarers in Japan's coastal shipping industry, which is resulting in the retirement of currently elderly seafarers on a large scale (Figure 9). This shortage of seafarers is causing the drop in coastal shipping volumes seen through the second half of 2020, as seen in the left graph in Figure 8, and leads to the result in 1), "As total transportation demand increases, the proportion of lost transportation opportunities due to the shortage of seafarers increases.

In addition, as described in 1), the shortage of seafarers accelerates in line with the increase in total transportation demand before the introduction of CA and FA autonomous vessels, while the supply-demand balance for seafarers after the introduction of CA and FA does not differ significantly between scenarios (Figure 8), indicating the benefits of introducing autonomous vessels, especially in a scenario where total transportation demand increases, as described in 2).

**Figure 9: Shipping volume, crew gap, and shipping costs of Strategy 1 under each scenario.**

**Figure 10: Change in the number of seafarers in Strategy 1 under each scenario.**

### Shipping cost

- 1) Except AO and RC, the deployment of autonomous technology helps shipping companies to reduce their shipping cost.
- 2) Under different total transportation demand scenarios, the transportation cost increase with an increase in total transportation demand.
- 3) As opportunity loss, Groups 1, 2, and 3 with autonomous technology successfully mitigate the impact of the increase compared to Group 4 without autonomous technology.

Firstly, 1): the impact of each strategy on costs is discussed. Figure 11 shows the costs for each of all transportation demand scenarios. The results show that for all transport demand scenarios, the impact of automation technologies other than FA on pure costs was not significant. However, the introduction of AO and RC increases costs, while the introduction of CA slightly decreases costs, and the introduction of FA significantly decreases costs. However, the difference between Strategies when comparing costs based on the volume of transportation activity is due to the increase in the volume of transportation due to

the introduction of automation technology, which will alleviate the labor shortage. This effect for AO results in the cost increase due to the introduction of AO almost offsetting the increase in transport volume, while for CA and FA, the increase in transport volume results in a significant decrease in cost per transport volume on a ton-kilometer basis.

As for 2), as can be read from Figure 8, the greater the scenario of aggregate demand for transport, the more the shortage of seafarers accelerates, resulting in higher wages for seafarers. Figure 6 shows that this effect raises the labor cost of seafarer wages, resulting in higher costs. However, even in scenarios where demand increases, the introduction of autonomously operated vessels has succeeded in mitigating the adverse effects, as mentioned in 3) and like “Opportunity loss” 2).

**Figure 11: Transportation costs in each case.**

#### 4. SUMMARY

The following findings were obtained from Section 3 in the assumption of this research.

- While the introduction of autonomous vessels reduced transportation costs and lost transportation opportunities, the number of early retired seafarers increased significantly with their introduction. At the same time, the introduction of automation technology to support navigation has had a positive impact in many cases, and there are advantages to early deployment even in this model, which does not consider the experimental introduction of new technology to promote technology maturity.
- In the case where automation technology was introduced, a case with RC (Remote Control) was inferior to strategy without RC in all three indicators and in the transportation demand scenario. However, the other policies had a trade-off relationship with each other on one of the indicators, so it was not possible to conclude which strategy was better.
- The current Japanese domestic logistics transportation mode choice has low sensitivity to freight rates, and the decrease in transportation demand due to higher freight rates is smaller than the increase in freight rates, making higher freight rates one effective means for shipping companies to pursue profits.

#### 5. CONCLUSION

In this study, we developed a simulator based on a Japanese cargo transport model and proposed a method to evaluate the impact of introducing automation technology. The results of the simulation showed changes in the impact of several policies on the economics and employment of seafarers and provided decision-making support for shipping companies on the introduction of desirable automation technology.

#### ACKNOWLEDGEMENT

This research was made possible by the support of many people, and I would like to take this section to thank them. First, I would like to thank the Ph.D., M.S., and undergraduate students of this laboratory for their various advice in my research activities. Thank you very much. Second, I would like to thank the technical specialists and secretaries of this laboratory for their generous support in the procurement of research equipment, administrative procedures, schedule coordination, and so on. I would like to express my sincere gratitude to them.

#### AUTHOR CONTRIBUTION

## A. Appendix

### Transportation choice model

Various models of transportation mode choice have been studied. Typical examples include the logit model and the sacrifice quantity model. In this study, the logit model was employed to express the interaction between each transportation mode and the equilibrium that results from the interaction. In addition, many studies on modal shifts take a wide area as the target region or limit the routes to be covered, however, we wanted to create a model that covered the entire country. Therefore, this study calculates utility based on time and cost with reference to the study by Shinke et al (2007). In this study, 47 prefectures are considered as nodes, and the links connecting these nodes are treated as a transportation network.

### Transportation distance for each transportation agency

Regarding transport distances, the transport distances for coastal shipping are listed in the domestic shipping distance table published by the Nippon Kaiun Syukaijyo (2013). The distance between representative ports in each prefecture was used as a shipping distance. For automobiles and railroads, Google Map was used, and distances between prefectural offices were used. Transportation distances within the same prefecture were calculated from transportation time and average speed using the average speed described below. For links for which transport time data was not available, the average transport distance within the same prefecture was used. Also, National Freight Forwarding Survey (MLIT, 2022) and the distances collected in the above method were used to calculate transport volume on a ton-kilometer basis, and the transport volume calculated by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT, 2023b). A discrepancy was observed when two statistics were compared. Therefore, we adjusted the transport distances for each transportation mode by multiplying them by a constant in order to match the latter transport volume. The following are the transport distances for each transport mode. Inland shipping links with no ports are indicated by 0.

### Transportation time for each transportation agency

Comparing transport times in 2005, 2010, and 2015 collected from the Logistics Census (MLIT, 2022) with the transport distances, there is a proportional relationship between transport distance and transport time for coastal shipping and rail transport, while transport time for automobile transport increases slowly as the distance increases. Therefore, in this study, the transport  $m$  from node  $o$  to node  $d$ ,  $T_{m,o,d}$  is calculated using the following Equations [A1] ~ [A3]. They are calculated using  $L_{m,o,d}$  and average transport speed  $v_m$  for ocean and rail transport, and the square root of transport distance and parameters  $\gamma_{truck}$  and  $\delta_{truck}$  for automobile transport. For auto transport, we used the minimum transport time in the 2005, 2010, and 2015 data because in some cases the transport distances were small, and the time was negative.

$$T_{ship,o,d} = \frac{L_{ship,o,d}}{v_{ship}} \quad [A1]$$

$$T_{rail,o,d} = \frac{L_{rail,o,d}}{v_{rail}} \quad [A2]$$

$$T_{truck,o,d} = \gamma_{truck} \sqrt{L_{truck,o,d}} + \delta_{truck} \quad [A3]$$

### Fares for each mode of transportation

Comparing freight rates per ton-kilometer for 2005, 2010, and 2015 obtained from the Logistics Census (MLIT, 2022) and the transport distance, it can be said that freight rates per unit ton-kilometer decrease with increasing transport distance for all transport modes. Therefore, as well as the transport time, the fare of transport  $m$  from node  $o$  to node  $d$ ,  $E_{sm,o,d}$  is calculated by the following Equations [A4] ~ [A6], respectively  $L_{m,o,d}$  and the parameters  $\varepsilon_m$ ,  $\theta_m$ . Note that when calculating freight rates, negative values may be obtained due to long transport distances, in which case the lowest freight rates from the 2005, 2010, and 2015 data were used.

$$E_{ship,o,d} = \varepsilon_{ship} \sqrt{L_{ship,o,d}} + \theta_{ship} \quad [A4]$$

$$E_{rail,o,d} = \varepsilon_{rail} \sqrt{L_{rail,o,d}} + \theta_{rail} \quad [A5]$$

$$E_{truck,o,d} = \varepsilon_{truck} \sqrt{L_{truck,o,d}} + \theta_{truck} \quad [A6]$$

## Parameter optimization of logit model

When optimizing the parameters, in the National Net Freight Flow Survey (MLIT, 2023b), there were some routes that did not have any transportation performance. Since this study focuses on the variation in transportation demand among transportation agencies, the parameters are divided among the cases of "routes with a track record of transportation by coastal shipping and a track record of transportation by rail or trucks", "coastal shipping & automobiles & rail". In this case, the amount of transportation may be biased toward one mode of transportation on a particular route, and modal shift is unlikely to occur on that route due to the large dominance of that particular transportation agency. Therefore, the case classification of routes is defined as follows.

- Coastal & Automobile & Rail": Ratio of coastal shipping, automobile, and rail transportation to all transportation is 0.1 or more.
- Coastal & Automobile": Ratio of coastal shipping and automobile transportation is more than 0.1 and that of rail transportation is less than 0.1.
- Coastal & Automobile": Ratio of coastal shipping and automobile transportation is more than 0.1 and that of rail transportation is less than 0.1.
- "Coastal & Rail": characteristics of each link based on the definition of a transport ratio of more than 0.1 between coastal and rail transport and less than 0.1 between car transport.

Freight and Passenger Regional Flow Surveys (MLIT, 2023b) in 2005, 2010 and 2015 were used to determine the characteristics of each link. For parameter optimization, the 2005, 2010, and 2015 national freight net flow surveys (MLIT, 2022). freight hours, fare per ton-kilometer were used. The results are shown in Table A-1 below.

**Table A-1 Parameters of the logit model in each case**

\parameter case	$\alpha_{time}$	$\alpha_{cost}$	$\alpha_{rail}$	$\alpha_{truck}$
Coastal & Automobile & Railroad	$-1.02 * 10^{-2}$	$-1.24 * 10^{-5}$	$-6.87 * 10^{-1}$	$-7.34 * 10^{-1}$
Coastal & automobile	$3.27 * 10^{-3}$	$-2.00 * 10^{-6}$	$-5.12 * 10^{-1}$	0
Coastal Shipping & Railroad	$4.95 * 10^{-3}$	$-2.20 * 10^{-6}$	0	$1.27 * 10^{-2}$

Using the parameters obtained, the 2010 Freight and Passenger Regional Flow Survey (MLIT, 2023b) to predict the data. The obtained ton-kilometer-based transport volumes are shown in Table A-2 shows that 15~30% of the total transport volume is subject to modal shift.

**Table A-2 Comparison of predicted and measured values on a ton-kilometer basis**

		coastal shipping	automobile	railroad
Measured value		179,898	20,398	246,175
Predicted value	whole	162,122	22,750	271,231
	fixed content	114,504	15,617	231,417

## Model with greater impact by transportation cost (Model B)

The previous part discussed the impact of automation technology on shipping companies. However, in the freight transportation demand estimation model within the simulator, the impact of the cost term was small, and transportation demand did not change much in response to changes in freight transportation costs and associated changes in freight rates. This may be due to a lack of explanatory variables, the limited impact of freight rates on the Japanese freight market, or other factors. The model reflects the impact of freight rate changes on transportation demand by setting the parameters in the cost term to the same order as the parameters in the constant term. This new model is called Model B and the previous one is called Model A thereafter.

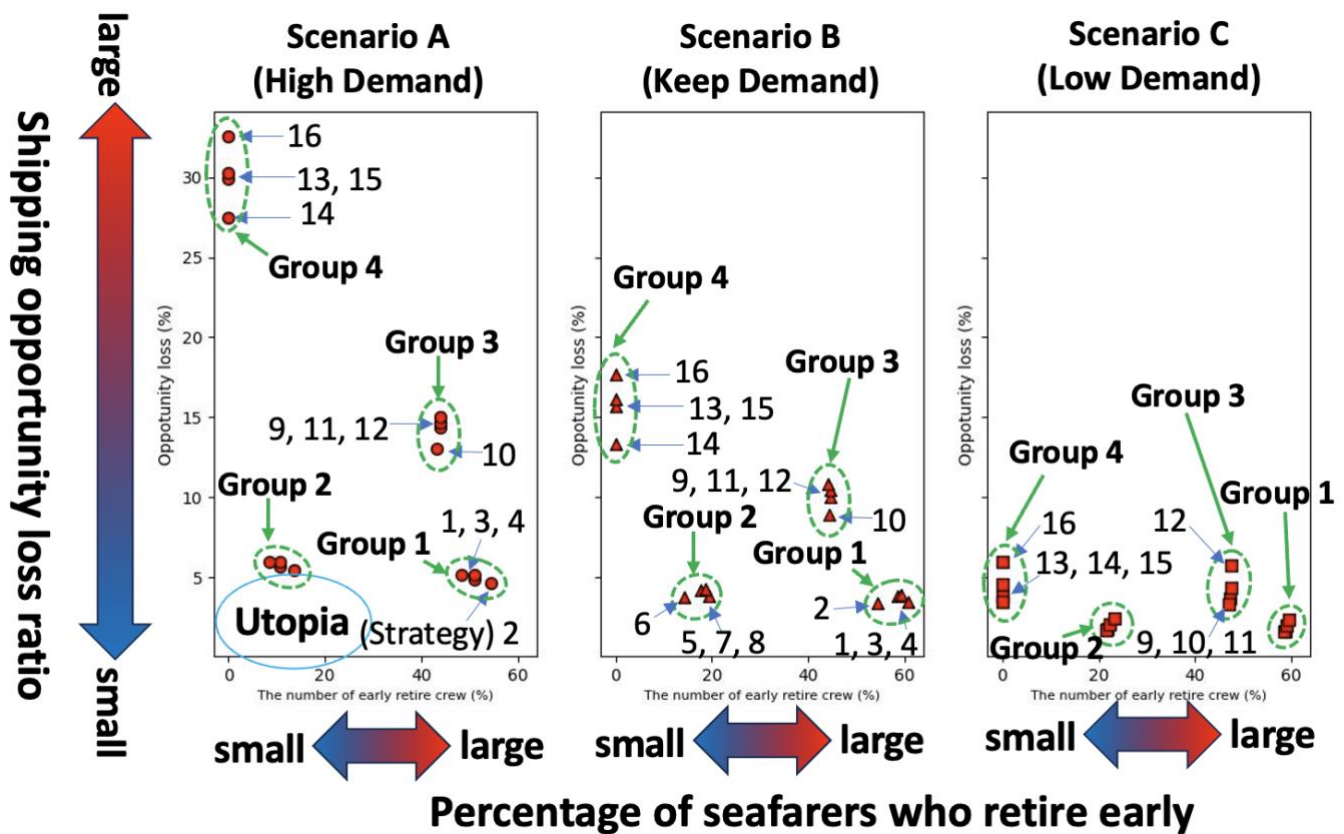

Figure 12: The results by case in Model B

Figure 13: The results by case in Model B

The general shape of the results for Model B (Figure 12, 13) was similar to Model A (Figure 6, 7). However, some differences were observed. In Groups 1, 2, and 3 with CA or FA, Scenario B, where transport demand is maintained, and Scenario C, where it decreases, the case with AO only has smaller values for all three indicators than the cases with both AO and RC. In comparison with the case with neither AO nor RC, the case with only AO showed smaller values for the loss of transport opportunities and the ratio of early retired seafarers, but only for the NPV of transport costs in the case with neither AO nor RC. On the other hand, in Scenario A, where total transportation demand increased, the case with AO only, the case with both AO and RC, and the case with RC only were compared, and the case with AO only showed smaller transportation cost and opportunity loss ratio, but the case with AO only showed smaller NPV in the ratio of early retired crews. However, the percentage of seafarers who retired early was higher in the AO-only case.

These results show that when total transport demand is maintained or decreases, AO implementation benefits shipping companies in all three indicators, but when total transport demand increases, AO implementation adversely affects shipping companies only in terms of seafarer employment.

Initially, as a consideration of the improvement in transportation costs due to the introduction of AO that was seen in the results of Model B but not seen in the results of Model A. This phenomenon is caused by a decrease in demand for marine transportation and seafarers is triggered by the increase in costs due to the introduction of AO (Figure 14). This is a decrease not seen much in the Model A due to the smaller impact of the cost term (Figure 15). The timing of this decline coincides with the retirement of seafarers currently aged 60 and over, as discussed before, causing a shortage of seafarers, which combined with the effect of the reduction in seafarer demand per vessel due to the introduction of AO, alleviates the seafarer shortage. This, in turn, is thought to have reduced the cost of shipping per ton-kilometer by reducing the rising labor costs of seafarers.

**Figure 14: Result of shipping demand in Model B.**

**Figure 15: Result of shipping demand in Model A.**

The next part discusses the cases in Model B where the introduction of AO has a positive impact on seafarer employment in scenarios where aggregate transport demand is maintained (Scenario B) or reduced (Scenario C), and where the introduction of AO has a negative impact in scenarios where aggregate transport demand is increased (Scenario A). In Model A, the introduction of AO had a positive impact on seafarer employment in all scenarios. This is one of the advantages of phasing in automation technology. Furthermore, as discussed in the previous part, the percentage of early retired seafarers decreased when aggregate transport demand increased, but there was no significant difference in the percentage of Scenario B and C. In Model B, the latter phenomenon is confirmed, but the former phenomenon, in which the ratio of early retired seafarers improves as aggregate demand increases, is not observed in the case where AO is introduced.

One factor contributing to this is that the recruitment of seafarers is done on an annual basis rather than in one time step. As a result, in Model A, the seafarer shortage is eliminated one year earlier in the case where AO were introduced (left graph in Figure 16). On the other hand, in Model B, the seafarer shortage was eliminated in the same year regardless of introduction of AO (right graph in Figure 16). This means that in Model A, where the seafarer shortage was solved a year earlier by the introduction of AO, the working environment for seafarers improved, while in Model B, where the seafarer shortage was solved in the same year regardless of the introduction of AO, the working environment for seafarers worsened in Strategy 1, which employed the same number of seafarers in both cases but introduced more automation through the introduction of AO. This suggests that even a one-year delay in eliminating the seafarer shortage by introducing automated technology can have a significant impact on the employment environment for seafarers, and that it is necessary to introduce automated technology with caution.

**Figure 16: Result of crew gap (Left is Model A. Right is Model B).**

## **Part 7:**

# **DIGITAL TRANSITION**

# Exploring the Opportunities of Generative Artificial Intelligence in Concept Ship Design

Grech La Rosa Andrea<sup>1,\*</sup>, Simpson Peter<sup>1</sup> and Zammit Ryan<sup>2</sup>

## ABSTRACT

*Designing vessels is a complex process requiring the consideration of numerous aspects to develop a successful design. Ship and submarine design often requires the designer to approximate, make assumptions, consider scenarios and imagine how the vessel may be used in operation. Having the ability to consult for feedback or request additional information may be a welcome aid.*

*The onset of Generative AI (GENAI) presents a new opportunity to integrate this resource into the workflows of the concept ship design process. Augmenting the design process could have a positive impact on the outcome of the design, further improving various qualities such as performance, sustainability, equality, diversity and inclusion. Aspects associated with weight groups, payload catalogues, technical analysis and layout set out will be explored to investigate whether GENAI could add value to the design process. A case study will be used to facilitate this investigation, taking note of GENAI's content throughout the process.*

## KEY WORDS

Generative Artificial Intelligence, concept ship design. text to text, text to image, Chat GPT, Gemini, Dal E

## BACKGROUND

### Generative Artificial Intelligence (GENAI)

Generative AI (GENAI) refers to a class of artificial intelligence systems that can generate new content, such as images, text, video, voice, or even music, often indistinguishable from content generated by humans. These systems are based on generative models, which are trained on large datasets to learn patterns and relationships within the data. GENAI has made significant strides in recent years, leading to advancements in creative content generation, data augmentation, and problem-solving across various domains (Fui-Hoon Nah et al., 2023).

In contrast to internet search engines, GENAI is designed to create novel content by learning patterns from datasets. It generates completely new and possibly realistic images, text, or other forms of media as opposed to finding existing media like in traditional search. Jason Allen famously won an art competition in 2022 by submitting a digital art piece to the Colorado State Fair's annual art competition, won an award, and only then did the submitters announce that it was created using GENAI (Kevin Roose, 2022).

Search engines such as Google, are focused on retrieving and presenting existing content from the web in response to user queries. They index and rank pre-existing information rather than generating new content, making their functionality distinct from that of GENAI. From a practical perspective, AI query data sources and generate answers based on the prompt, whilst with search engines, the user is expected to manually go through the results, assess applicability and apply the results.

The models produce these outputs based on a prompt or a series of prompts. This is a specific input or instruction given to the model to generate output. The prompt serves as a guide for the model to produce content based on the provided input, and if it's a follow-up prompt, previous prompts, and answers will be taken into consideration as context. The format and content of the prompt depend on the type of generative AI model and the desired output. Different types of models exist, mostly

specialising in one format such as text to text or text to image. The specificity and clarity of the prompt play a crucial role in influencing the quality and relevance of the generated content however it is important to note that the same prompt will not necessarily generate the same exact results.

A new field of specialisation is emerging that is not limited to computer engineering called “prompt engineering”. The term prompt engineering can refer to the process of crafting effective prompts or inputs for generative AI models, to receive optimal outputs (MsKinsey&Company, 2023). Prompt engineering involves understanding the capabilities and limitations of the model and designing prompts that elicit the desired responses or outputs. Individuals may specialize in prompt engineering as part of their broader roles in machine learning engineering, data science, or AI research, however we speculate that in the near future most jobs aided by AI will require a basic understanding of prompt engineering.

Generative AI has applications in various fields, including:

1. **Image Generation:** Creating images that may resemble photographs, sketches, drawings, etc.
2. **Text Generation:** Writing coherent and contextually relevant text, which has applications in natural language processing, content creation and technical writing.
3. **Code Generation:** Writing computer code in a specified language to fulfill a design brief.
4. **Video Generation:** Creating video, including accompanying audio, based on user input prompts (OpenAI, 2024).

There is a large selection of commercially available GENAI tools available. Chat Generative Pre-Trained Transformer (ChatGPT) by OpenAI has arguably brought GENAI to the public limelight. The current GENAI tools are built on fields of research that pre-exist the current technology. Fields such as Machine Learning, genetic algorithms, sentiment analysis, data mining, etc. have been around for years. However, it was only fairly recently that the interest in GENAI has boomed. Competition is heating up with Google quickly attempting to catch-up by hastily launching Bard, only to rebrand to Gemini within a few months (Ortiz, 2024). It is well-accepted that OpenAI is the leading model with Chat-GPT, a text-text algorithm and Dall-E, a text-image algorithm, and now having demoed Sora, a text-to-video generating algorithm.

### ***Challenges with AI***

When new technologies and processes are introduced to an established industry, new challenges, risks and uncertainties become apparent. GENAI is no different, with several industries becoming increasingly concerned about how this technology can be improperly utilised in applications that may not be suitable for it yet. For example, the education industry is concerned of generative AI’s negative influence on learning (Michel-Villarreal et al., 2023) and the creative industry is aware of the impact it will have as algorithms are improved (Amankwah-Amoah et al., 2024).

While the potential of GENAI is undisputable, there are inherent risks associated with using such a platform. Some of the more noteworthy points for technical industries include:

1. Hallucinations (Alkaissi et al., 2023):
  - AI models, including generative ones, can sometimes produce erroneous or factually incorrect responses, but are presented by the model in a convincing manner. These “hallucinations” occur due to their reliance, and possible limitations, on training data and algorithms used to build the model.
  - Users may encounter misleading or blatantly wrong answers, especially when relying on AI chatbots for information. It is always recommended to check the response, which means the human using GENAI ultimately requires some field-knowledge to be able to check the response.
  - Detecting these biases or inaccuracies can be challenging as AI solutions become increasingly believable, especially to novice or inexperienced users.
2. Cybersecurity Risks (Gupta et al., 2023):
  - GENAI can inadvertently expose sensitive and proprietary enterprise data.
  - Interactions with AI chatbots may inadvertently leak confidential information, posing cybersecurity threats.
  - GENAI could be used by malicious actors (e.g. cyber criminals) to try and circumvent current security protocols or practices (Stanham, 2023)
3. Copyright Issues (Ren et al., 2024):
  - As GENAI is built on existing content to learn and train the model, there are ethical and legal copyright considerations on permission of using this data to generate new content (Appel et al., 2023)
  - As GENAI produces content, questions arise about intellectual property rights and copyright infringement.
  - Ensuring that AI-generated works respect existing copyrights is crucial to avoiding legal disputes.
4. Computational Power (Crawford, 2024):

- GENAI uses large amounts of computational power to train the model, keep it running, and to produce results to prompts. In a world where we are seeking to reduce our power consumption, there is an argument that the increased use of GenAI will increase the need of using more power.

### Industry Specific GENAI platforms

As stated earlier, the performance of an AI model is heavily influenced by the data used to train and develop it. Platforms like Chat-GPT have been trained on a myriad of data, and is able to provide answers about most generic questions. However, if there is a lack of specific information in its training model, it wouldn't be able to provide a specific answer to the prompt. One way of mitigating such risks is to develop and implement customized models for specific industries. These models are tailored to address the unique challenges and requirements of specific industries, domains, or applications, offering specialized capabilities and domain-specific knowledge. Some examples of how different industries can benefit from GENAI are:

1. **Engineering** (Kar et al., 2023)
  - GENAI models can aid in product design, optimization, and simulation across various manufacturing processes, such as additive manufacturing, CNC machining, and supply chain management.
  - Natural language processing models can generate technical documentation, automate parts cataloging, assist in troubleshooting and maintenance tasks as well as support project management tasks.
2. **Architecture** (Liao et al., 2024; van Hooijdonk, 2023)
  - GENAI can be used to streamline design processes, explore innovative solutions, and optimize complex systems and support technical designs.
  - Conduct parametric design, urban planning, spatial analysis and facilitate brainstorming sessions.
  - Natural language processing models can generate technical documentation, automating construction sequences and assist in project management.
3. **Healthcare** (Lan et al., 2023)
  - Generative models trained on medical imaging data can assist in tasks such as image reconstruction, disease detection, and medical image synthesis.
  - Natural language processing models can generate clinical notes, summarize medical records, or assist in medical literature review.
4. **Finance** (Cao, 2022)
  - GENAI can generate synthetic financial data that mimics real-world patterns without compromising privacy or security to help train models. It could also process large volumes of financial data, generate reports, and perform analyses and learn from historical fraud cases and identify suspicious patterns.
  - Natural language processing models can generate financial reports, summarize market trends, and analyze financial news articles

### Ship Design Procedure

Ship design is a complex iterative process used to design vessels needing to fulfill a role. Figure 1 illustrates a summary of the design method, showing the multitude of relationships between the different aspects needed to design a vessel. The aspects illustrated are technical and administrative that vary based on the scenarios being considered (UCL, 2024).

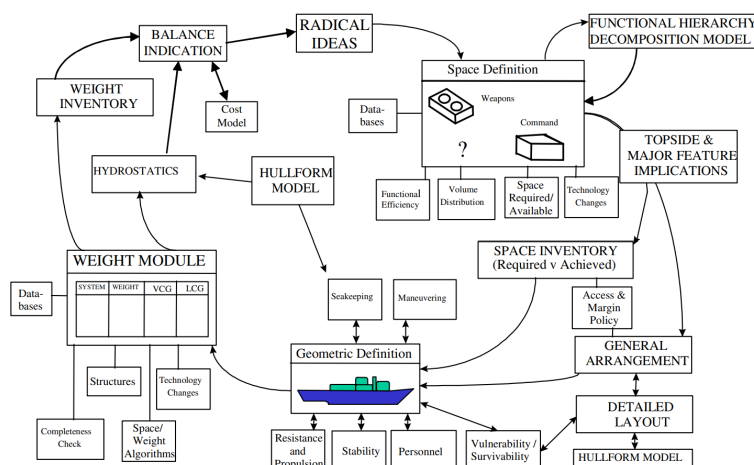

Figure 1 – Illustration of the Design Building Block Methodology applied to Surface Ships (Andrews et al., 2008)

The major milestones in the ship design process are setting the requirements, the initial sizing, conducting a cost capability trade off, payload selection, parametric survey and finally the design refinement (UCL, 2024). Each of these milestones require different skills and resources to complete however they all entail diligent project management to ensure the project is successful. The naval architect must also carry out supplementary analysis to determine what capabilities are essential and where compromises can be incorporated to create a vessel that is able to fulfill its role.

New maritime regulations, conflicting requirements and tight budgets are some of the reasons why ship designers must constantly keep up-to-date with the latest technologies and procedures to identify the best compromise for the design to be successful. As Figure 1 shows, radical ideas may also be required to satisfy some requirements however the consideration and/or implementation of such ideas typically requires the knowledge of a team of naval architects and marine engineers having experiences. While there isn't a standard procedure to follow when considering and implementing radical ideas, typical approaches include brainstorming, research and consultations with third parties who may have had to consider such options for other projects.

## **GENAI and Ship Design**

The ship design process presents a number of opportunities to explore the use of GENAI. While limited literature is available to show examples of how this has been done so far, models such as Chat GPT suggest that they would be able to conduct:

- Conceptual design exploration
- Feasibility analysis
- Performance Optimisation
- Material selection and Sustainability
- Risk assessment and Safety Analysis
- Integration of advanced technologies
- Documentation and Reporting.

No publicly available resource was found saying that GENAI was used in full or in part to design a vessel, but there is no doubt that it is being explored. Although such algorithms have been in existence for some time, their integration in company processes is limited. This new technology is pushing boundaries in a similar way to how the introduction of the internet in 1993 led to radical change to facilitate communication, knowledge transfer, collaboration and much more. In this instance, ship designers were not immediately drawn to this service. However, as technology evolved, the marine industry recognized the potential benefits of integrating the internet into ship design and operations. They now recognize its potential to create smarter, more connected vessels that benefit shipowners, crew, and passengers alike.

Direct evidence to demonstrate how each of these points were determined was not found however Khan S et al (Khan et al., 2023) conducted an analysis showing a Hullform parametric study using a customised genetic algorithm called ShipHullGAN, that was trained using 52,591 validated designs differing in features. The algorithm successfully generated valid designs that were deemed feasible however future work will involve integrating CFD solvers to continue building on the tool's capabilities (Khan et al., 2023).

## **SCOPE OF WORK**

The literature review highlights the need to explore how GENAI, particularly commercially available software, can help facilitate the ship design procedure. Different aspects of the concept design were investigated using commercially available text to text and text to image GENAI tools. The research aims to identify whether some examples of commercially available tools can add value to the ship design process by supporting, conducting or improving it.

## **METHOD**

A range of commercially available text-to-text and text-to image GENAI platforms were queried with questions relating to ship design. In addition to general questions that aim to establish the GENAI's confidence in conducting such analysis, the prompts were used to explore the early concept design aspects of potential designs. The latter was focused on two vessel types, a regular fishing boat for text-to-text and a cruise liner that pushes boundaries of the status quo for text-to-image. A summary of the requirements of each vessel can be found in Table 1.

**Table 1 – Requirements for the 2 vessels being considered in this study**

	<b>Fishing Boat</b>	<b>Cruise Liner</b>
Role	Utilitarian fishing vessel to operate in Indonesian waters to catch tuna	Extravagant Cruise Liner for young families to operate in the Mediterranean Sea having a floating zoo and entertainment.
Primary Tasks	Making new technology accessible to Indonesian communities	Embrace green technology
		Full of activities
Area of Operation	Indonesian Coast	Mediterranean Sea
Duration of Mission	4 days	10 days
Passengers	20	600
Accommodation	basic	luxury
Environmental	Net Zero	Net Zero
In Service Date	2030	2040

Each text-to-text GENAI model was provided with the same initial data associated with the requirement of each respective vessel. The current study was linear in its approach where only one GENAI model was considered at a time. Further studies exploring how responses one model could be linked to another GENAI model for increased utility and analysis.

The GENAI model was then asked a range of questions becoming more specific based on the responses received. The text-to-image models on the other hand were utilized to generate visualisations of the vessel or particular features. The outcomes of each respective query were recorded, and additional refinement was requested when needed.

## RESULTS

A selection of the results recorded in the study will be presented below showing the prompt and response. In those cases where the responses consisted of a series of bullet point outputs, up to 3 list levels are published..

### Text-to-Text

#### *Chat GPT 3.5*

*How does an AI machine such as Chat GPT think it can support the Ship design process?*

As an AI language model, I can indeed provide assistance in the ship design process by offering guidance, generating ideas, and answering questions related to various aspects of ship design. Here's how I can support the ship design, knowledge base, idea generation, problem solving, simulation and modelling, regulatory compliance, collaboration and communication and continuous learning and adaptation

While I cannot replace the expertise and experience of human naval architects, engineers, and designers, I can complement their skills and knowledge by offering valuable insights, information, and support throughout the ship design process. Ultimately, the combination of human creativity, expertise, and AI assistance can lead to innovative and successful ship designs that meet the needs of the maritime industry

*You are a naval architect tasked to design the fishing vessel in Table 1, what are your thoughts?*

Designing a fishing boat for Indonesian waters with a focus on catching tuna and incorporating new technology while ensuring environmental sustainability presents both challenges and opportunities. Here are some initial thoughts:

Size and Stability, Efficient Tuna Fishing Equipment, Accessibility of Technology, Environmental sustainability, accommodation and amenities, Safety features, local regulations, durability and maintenance. By integrating these considerations into the design process, the fishing boat can effectively fulfill its role while contributing to sustainable fishing practices and technology accessibility in Indonesian communities.

*How should this vessel be sized?*

The size of the fishing boat for tuna fishing in Indonesian waters should be determined by several factors including the number of passengers, the duration of the mission, the type of fishing equipment onboard, and the intended area of operation. Here are some considerations for determining the size of the vessel passenger capacity, cargo capacity, deck space, stability and seaworthiness, maneuverability and fuel efficiency. Considering these factors, the fishing boat should be sized to strike a balance between accommodating passengers and crew, providing adequate storage and deck space for fishing operations, ensuring stability and seaworthiness, and optimizing fuel efficiency. The specific size and dimensions will depend on the

detailed requirements of the mission and the preferences of the operators. Working closely with naval architects and marine engineers can help determine the optimal size of the vessel based on these considerations.

#### *How should the calculations be carried out*

Calculating the dimensions and specifications of a fishing boat involves several technical considerations and calculations. Here's an overview of the key aspects to be taken into account: hydrostatics and stability analysis, weight estimation, hull design, propulsion system sizing, structural design, systems engineering, regulatory compliance and cost estimation. These calculations and analyses are typically carried out by naval architects, marine engineers, and other specialized professionals using advanced software tools, mathematical models, and engineering principles. Collaboration between various disciplines is essential to ensure that the vessel meets its performance, safety, environmental, and operational objectives.

#### *What are the big ticket payload items that should be considered?*

In the context of designing a fishing boat, "big ticket payload items" refer to significant components or equipment that directly contribute to the vessel's functionality, operational capabilities, and mission objectives. These items are crucial for the vessel's primary task of catching tuna and ensuring operational efficiency. Here are some of the big ticket payload items that should be considered: fishing gear and equipment, fish storage and holding facilities, navigation and communication systems, safety and survival equipment, fuel and propulsion systems and deck machinery and handling equipment. These big ticket payload items constitute essential components of a fishing boat designed for tuna fishing in Indonesian waters. Each item plays a crucial role in the vessel's operational effectiveness, safety, and ability to fulfill its mission objectives. Integrating these payload items into the vessel's design requires careful consideration of space, weight distribution, operational requirements, and regulatory compliance.

#### *Can you give me a weight estimate in kg for Longline fishing equipment for a vessel like this?*

Estimating the weight of longline fishing equipment for a vessel depends on several factors, including the vessel's size, the fishing method employed, the target species (in this case, tuna), and the operational requirements. While it's challenging to provide an exact weight without specific details, I can offer a rough estimate based on common components and considerations. Here's a breakdown of the typical longline fishing equipment and their approximate weights:

- **Mainline** The mainline is the primary line that extends from the vessel and supports the branch lines and hooks. Depending on the length and diameter, a mainline can weigh anywhere from 1 kg to 5 kg per 100 meters
- **Branch Lines** Branch lines are attached to the mainline and hold the baited hooks. The weight of branch lines varies depending on their length, diameter, and the number of hooks per line. On average, branch lines can weigh between 0.5 kg to 2 kg per 100 meters.
- **Hooks** Hooks are essential components of the longline setup. The weight of hooks depends on their size, material, and design. On average, a hook can weigh between 20 grams to 100 grams, depending on the type and size of the target species
- **Buoys and Floats** Buoys and floats are used to mark the position of the mainline and provide buoyancy. The weight of buoys and floats varies depending on their size and material. A typical buoy or float can weigh between 0.5 kg to 5 kg each
- **Weights and sinkers** Weights or sinkers are used to keep the mainline and branch lines submerged at the desired depth. The weight of weights and sinkers depends on their size and material. They can range from 50 grams to 500 grams each

#### *What propulsion system should be considered for this design?*

Selecting the appropriate propulsion system for a fishing boat designed to operate in Indonesian waters and catch tuna involves considering factors such as efficiency, reliability, maneuverability, environmental impact, and operational requirements. Here are several propulsion options to consider: Diesel propulsions, Hybrid propulsion, outboard motors, pod propulsions, stern drives and waterjet propulsion. The choice of propulsion system should be based on a comprehensive evaluation of the vessel's size, intended use, operating conditions, budget constraints, and environmental considerations. Collaborating with marine engineers, naval architects, and propulsion system manufacturers can help identify the most suitable propulsion solution for the fishing boat design, ensuring optimal performance, efficiency, and sustainability throughout its service life.

#### *Are these options appropriate for Net Zero?*

Achieving a "Net Zero" designation for a fishing boat involves minimizing or offsetting the vessel's greenhouse gas emissions and environmental impact over its operational lifecycle. While some propulsion options inherently produce fewer emissions or can be optimized for reduced environmental impact, others may require additional measures to achieve Net Zero status. Here's how each propulsion option mentioned previously aligns with Net Zero goals and considerations. Diesel propulsion, hybrid propulsion, outboard motor, pod propulsions, stern drives and waterjets

*Should alternative options like wind propulsion or electric drive be considered*

Yes, alternative propulsion options such as wind propulsion and electric drive should definitely be considered, especially in the context of designing a fishing boat with a Net Zero objective. Here's a closer look at these alternative options and their potential benefits:

- Wind propulsion,
  - Wind propulsion systems, such as sails or wind-assist technologies like Flettner rotors or kite sails, harness the power of the wind to supplement or replace traditional propulsion methods
  - Benefits include reduced fuel consumption, lower emissions, and increased energy efficiency, particularly during favorable wind conditions
  - Wind propulsion can be especially effective for vessels engaged in long-range voyages or coastal navigation where wind patterns are favorable
  - Integrating wind propulsion systems requires careful consideration of vessel design, stability, and operational requirements, but they can significantly contribute to reducing the vessel's carbon footprint and achieving Net Zero goals
- Electric drive
  - Electric propulsion systems, powered by batteries or fuel cells, offer a clean and efficient alternative to traditional diesel engines
  - Benefits include zero emissions at the point of use, reduced noise and vibration, and potential cost savings over the vessel's lifecycle
  - Electric drive systems are well-suited for short-range operations, harbor maneuvering, and low-speed cruising, making them ideal for fishing boats operating in coastal waters or protected areas
  - Charging infrastructure, battery capacity, and range limitations are important considerations when integrating electric drive systems, but advancements in battery technology and charging infrastructure are making electric propulsion increasingly viable for marine applications

*How achievable would it be to integrate wind propulsion on this fishing vessel being designed?*

Integrating wind propulsion on a fishing vessel designed for tuna fishing in Indonesian waters can be achievable, but it requires careful consideration of various factors including vessel design, operational requirements, cost-effectiveness, and regulatory compliance. Here are some key points to consider when evaluating the feasibility of wind propulsion integration:

1. Vessel Design and Compatibility
  - The fishing vessel's hull design, size, and stability characteristics must be compatible with the installation of wind propulsion systems such as sails, Flettner rotors, or kite sails.
  - Modifications to the vessel's superstructure and deck layout may be necessary to accommodate the additional equipment and rigging associated with wind propulsion.
2. Operational Profile
  - The vessel's operational profile, including typical routes, wind patterns, and sailing conditions, will influence the effectiveness of wind propulsion systems.
  - Wind propulsion may be more suitable for vessels engaged in coastal navigation or longer voyages where favorable wind conditions are more prevalent.
3. Performance and Efficiency
  - Wind propulsion systems can enhance the vessel's overall performance and fuel efficiency by harnessing wind power to supplement or replace traditional propulsion methods.
  - Computational fluid dynamics (CFD) simulations and performance modeling can help assess the potential impact of wind propulsion on the vessel's speed, maneuverability, and fuel consumption.
4. Costs and Return on Investment (ROI)
  - a. The initial investment and ongoing maintenance costs associated with integrating wind propulsion systems must be carefully evaluated against potential fuel savings and operational benefits.
  - b. Factors such as equipment costs, installation expenses, and crew training should be considered when assessing the economic viability of wind propulsion.
5. Regulatory Considerations
  - Compliance with maritime regulations and classification society standards is essential when integrating wind propulsion systems into the vessel's design.
  - Safety, stability, and seaworthiness requirements must be met to ensure the safe operation of the vessel and its crew.
6. Technology Readiness and Support
  - Availability of reliable and proven wind propulsion technologies, as well as access to technical expertise and support, are critical considerations during the integration process.
  - Collaborating with experienced wind propulsion providers and naval architects can help mitigate risks and ensure successful implementation.

*What design features do Indonesian fishers desire on their vessels?*

Indonesian fishers typically desire fishing vessels that are well-suited to the local maritime environment, meet their operational needs, and enhance their productivity and safety at sea. Here are some design features that are commonly sought after by Indonesian fishers for their vessels: seaworthiness, maneuverability, deck space and layout and storage and seaworthiness, maneuverability, deck space and layout and storage and fish handling facilities, safety equipment and features, comfort and accommodation, fuel

*What budget would an Indonesian fisher have to purchase a vessel like this?*

The budget required for an Indonesian fisher to purchase a fishing vessel can vary widely depending on several factors, including the vessel's size, age, condition, equipment, and specifications. Additionally, market conditions, availability of financing, and regional differences in pricing can also influence the cost of acquiring a fishing vessel in Indonesia. Generally, fishing vessels range in price from tens of thousands to several million dollars, with smaller vessels typically being more affordable than larger ones.

## ***Gemini***

*How does an AI machine such as Gemini think it can support the Ship design process?*

My approach to supporting the ship design process differs slightly from other large language models like ChatGPT due to my specific capabilities and the ongoing advancements in the field of GENAI. Here's how I envision contributing:

1. Enhanced Information Access and Deeper Analysis:
  - Similar to other language models, I can access and process vast amounts of ship design data, including regulations, technical specifications, and case studies.
  - However, leveraging my advanced natural language processing (NLP) capabilities, I can go beyond simple information retrieval. I can analyze this data to identify trends, correlations, and potential design implications not readily apparent through basic summaries.
2. Collaborative Design Exploration and Iteration:
  - I can assist with design exploration by generating variations based on your initial specifications, similar to other models.
  - However, my ability to understand and respond to natural language prompts and feedback allows for collaborative design iteration. You can provide feedback on my generated concepts, and I can then refine them based on your input, iteratively leading towards the optimal design solution.
3. Advanced Optimization and Generative Design:
  - Beyond basic calculations, I am capable of utilizing machine learning algorithms to perform more complex optimization tasks. This could involve optimizing hull shapes for fuel efficiency or analyzing various configurations to maximize stability and payload capacity.
  - Additionally, I can leverage generative design techniques to explore entirely new design solutions by learning from existing successful models and identifying innovative layouts and structures.
4. Integration with Design Tools and Automation:
  - My ability to understand and generate code allows for potential integration with existing ship design software. This could involve automating repetitive tasks, extracting data from various sources into the design software, or even generating code to perform specific design calculations.
5. Evolving Capabilities and Adaptation:
  - As the field of generative AI continues to evolve, my capabilities will continue to improve and expand. This includes ongoing advancements in NLP, knowledge representation, and reasoning, allowing me to better understand the intricacies of ship design and provide even more comprehensive support.

### **Limitations:**

Similar to other AI models, I cannot replace the expertise of human ship designers or engineers. My role is to augment their capabilities by providing efficient information access, facilitating design exploration, performing advanced optimization, and potentially supporting automation. Ultimately, the responsibility for creating a safe, functional, and compliant vessel lies with qualified professionals.

In conclusion, while other language models can offer valuable support in the ship design process, I believe my unique capabilities in information analysis, collaborative design exploration, advanced optimization, and potential integration with design tools offer a more comprehensive and evolving approach for the future of AI-assisted ship design.

*You are a naval architect tasked to design the fishing vessel in Table 1, what are your thoughts?*

I think this initial design concept for a tuna fishing vessel in Indonesia has great potential! As a large language model, I can't fully design the vessel myself, but I can offer some key considerations and suggestions based on the information you provided:

**Strengths and Objectives:**

- Utilitarian: Focusing on functionality for tuna fishing is a good starting point.
- Technology Accessibility: Integrating new technologies to benefit Indonesian communities aligns with a noble goal.
- Net Zero: Aiming for zero emissions is commendable and aligns with future sustainability goals.

**Considerations and Suggestions:**

- Vessel Size and Type: Based on the 4-day mission duration, 20 passengers, and basic accommodation, a medium-sized vessel (around 20 meters) could be suitable. Depending on the chosen technology, explore options like purse seiners, longliners, or even innovative designs like electric or hybrid fishing vessels.
- New Technologies: Identify specific technologies that address local needs. This could include:
  - Fuel-efficient engines or alternative fuel sources (e.g., biofuels) for net-zero emissions.
  - Advanced fish detection and tracking systems for sustainable fishing practices.
  - On-board pre-processing facilities to improve catch quality and value.
- Local Context:
  - Regulations: Ensure the vessel design complies with Indonesian maritime regulations.
  - Infrastructure: Consider local infrastructure like available ports and fuel supplies for the chosen technology.
  - Community Needs: Engage with local fishing communities to understand their specific needs and challenges to incorporate them into the design.
- Cost and Feasibility:
  - Net-zero technology is still under development and might be expensive.
  - Analyze the cost-effectiveness and long-term sustainability of implementing such technology.

**Next Steps:**

1. Conduct further research on specific technologies and their feasibility in this context.
2. Consult with naval architects, marine engineers, and local stakeholders to refine the design based on technical expertise and community needs.
3. Create detailed plans and cost estimates for building and operating the vessel.

With proper research, design, and collaboration, this project has the potential to be an innovative and impactful contribution to the Indonesian fishing industry.

*How should this vessel be sized?*

Determining the optimal size for your fishing vessel involves several factors, but based on the information provided, here are some considerations to guide you:

**Key factors influencing size:**

1. Mission duration (4 days): This suggests the need for sufficient fuel storage and provisions for the crew, but doesn't necessarily require a massive vessel exclamation
2. Number of passengers (20): This translates to basic accommodation needs explanation. Bunk beds and shared spaces can be employed efficiently on smaller vessels.
3. Catch target (tuna): Tuna fishing techniques like longlining or purse seining require varying degrees of space for equipment and catch handling.
4. Net-zero goal: Depending on the chosen technology (e.g., batteries for electric propulsion), you might need space for additional equipment, potentially impacting size.

**Considering these factors:**

- A medium-sized vessel (around 20 meters) could be a good starting point. This size offers a balance between accommodating basic needs, maneuverability, and potentially adhering to net-zero goals with advancements in technology.
- However, it's important not to solely rely on estimations.

**Next steps for determining size:**

1. Refine your understanding of the chosen technology: Different net-zero technologies like electric or biofuel engines might have varying space requirements.
2. Consult with a naval architect: They can provide expertise in calculating the necessary space for crew, equipment, fuel, and catch based on specific chosen technologies and fishing practices.
3. Consider regulations and local context: Indonesian maritime regulations might define minimum or maximum size limitations for specific fishing vessel types.

**Additional points:**

- Smaller vessels generally offer increased maneuverability and might be more fuel-efficient (excluding the potential impact of net-zero technology).
- Larger vessels can offer more space for catch processing, which might be relevant depending on your goals and chosen technology.

Ultimately, the optimal size will be a result of careful consideration of all these factors and collaboration with professionals like naval architects and local stakeholders.

#### *How should the calculations be carried out?*

While I cannot perform the specific calculations myself, I can guide you through the general process of determining the optimal size for your fishing vessel. Here's how it might unfold:

1. Gather detailed information:
  - Specific net-zero technology: Finalize the type of technology you plan to implement (e.g., battery capacity for electric propulsion, biofuel storage tanks). Each technology has specific space requirements.
  - Fishing practices: Determine the exact fishing technique you'll utilize (e.g., longlining, purse seining) as it dictates the space needed for equipment and catch handling.
  - Regulations: Research any size limitations or regulations set by Indonesian maritime authorities for your chosen fishing vessel type and technology.
2. Consult a naval architect:
 

With the gathered information, collaborate with a professional naval architect. They can perform the following:

  - Space estimation: Based on your chosen technology, fishing practices, crew size, and basic accommodation needs, the architect can estimate the required space for various onboard elements.
  - Weight and stability calculations: They can perform crucial calculations to ensure the vessel maintains proper stability and buoyancy while accommodating the planned weight of passengers, equipment, fuel, and catch.
  - Regulations compliance: The architect can verify if the proposed size adheres to Indonesian maritime regulations for the chosen vessel type and technology.
3. Software tools for visualization and optimization:

Naval architects often utilize specialized software to:

- Create 3D models: These models help visualize the vessel layout, ensuring efficient use of space and optimal placement of equipment.
- Perform simulations: Software can simulate the vessel's performance with different sizes and equipment configurations, providing valuable insights into fuel efficiency, stability, and maneuverability.

4. Iteration and refinement:

The initial size estimate from the architect might not be the final solution. Based on the calculations, simulations, and potential regulatory limitations, you might need to:

- Adjust the chosen technology: If space constraints arise due to the initial net-zero technology choice, explore alternative options that might offer a smaller footprint.
- Optimize the layout: The architect can work with you to refine the internal layout to maximize space utilization and ensure efficient workflow.
- Remember, this is a collaborative process. By providing detailed information, working closely with a naval architect, and utilizing specialized software, you can arrive at the optimal size for your fishing vessel, ensuring it meets your operational needs, adheres to regulations, and adheres to your net-zero goal.

#### *What are the big ticket payload items that should be considered?*

For your utilitarian tuna fishing vessel aiming for net-zero operation, several "big ticket" payload items need careful consideration:

1. Net-Zero Propulsion System:
  - This is likely the most significant investment and will depend on the chosen technology:
    - Electric: High-capacity batteries will be needed for extended operation. Their size and weight significantly impact available space and overall vessel size.
    - Biofuels: Requires storage tanks for the chosen biofuel, with capacity considerations based on mission duration and fuel efficiency of the engine.
    - Hybrid: Combines elements of both, requiring space for both traditional fuel tanks and the chosen net-zero technology (e.g., batteries).
2. Fishing Gear:
  - The specific equipment varies based on the chosen fishing technique:
    - Longlining: Requires longlines, reels, hooks, and bait storage.
    - Purse seining: Needs purse seines, winches, and potentially fish sorting and processing equipment.
3. Catch Handling and Processing (Optional):

- Depending on your goals, you might consider:
  - Refrigeration units: To preserve catch quality, especially for longer missions.
  - Processing equipment: If you plan to pre-process the catch onboard for increased value.
- 4. Navigation and Communication Equipment:
  - Essential for safety and efficient operation:
    - GPS and navigation systems: For accurate positioning and course plotting.
    - Communication equipment: Radios and satellite communication devices for emergency situations and staying connected.
- 5. Safety Equipment:

Mandatory and crucial for crew safety:

- Life rafts and life jackets: For emergency situations.
- Firefighting equipment: To address potential onboard fires.
- First-aid kits: To provide basic medical care for crew members.

Additional Considerations:

- Spare parts: Carrying essential spare parts for critical equipment minimizes downtime and ensures operational continuity.
- Freshwater and provisions: Enough freshwater and food supplies are essential for the crew's well-being during the 4-day mission.

Remember, the final selection and cost of these big-ticket items will depend on the chosen net-zero technology, fishing technique, and specific functionalities you prioritize. Carefully analyzing your needs and conducting thorough research on each item is crucial for making informed decisions within budgetary constraints.

*Can you give me a weight estimate in kg for Longline fishing equipment for a vessel like this?*

Providing a precise weight estimate for longline fishing equipment for a vessel intended for your project is challenging due to several factors:

- Specificity of equipment: The weight can vary significantly depending on the specific longline configuration chosen. Factors like:
  - Mainline length: Longer mainlines require more weight.
  - Number of hooks: More hooks contribute to increased weight.
  - Hook size and material: Larger and heavier-duty hooks weigh more.
  - Buoy type and number: The type and quantity of buoys used to mark the mainline can impact weight.
- Fishing vessel size: While your project outlines a medium-sized vessel (around 20 meters), slight size variations can still influence the amount of equipment typically carried.
- However, to provide a rough estimate, a vessel of this size engaged in longline fishing in Indonesia might typically carry longline equipment weighing between 1,000 and 3,000 kg. This includes:
  - Mainline: 5,000 to 10,000 meters, typically made of synthetic materials like nylon or Dyneema, weighing around 0.2-0.3 kg per 100 meters.
  - Hooks: 1,000 to 3,000 depending on the target species and spacing, with individual hook weights varying based on size and material (typically 50-200 grams each).
  - Swivels and clips: Used to connect the mainline to leaders and hooks, contributing a relatively small overall weight.
  - Buoys: Several dozen buoys might be used, with varying weights depending on size and material (typically 1-5 kg each).

Important Note:

This is just a general estimate, and the actual weight of your longline equipment will depend on the specific choices you make regarding the factors mentioned above. It's crucial to consult with experienced longline fishermen and fishing gear suppliers in Indonesia to get a more accurate estimate based on your specific needs and local practices.

*What propulsion system should be considered for this design?*

Choosing the most suitable propulsion system for your net-zero fishing vessel in Indonesia involves careful consideration of several factors:

1. Net-Zero Goal:
  - Electric:
    - Pros: Zero emissions, quiet operation, potential for efficiency improvements.
    - Cons: High initial cost of batteries, limited range based on current battery technology, requires access to charging infrastructure.

- Biofuels:
    - Pros: Reduced emissions compared to traditional fuels, potentially aligns with local sustainability initiatives if using regionally produced biofuels.
    - Cons: Emissions still present, engine modifications might be needed, availability and cost of suitable biofuels in Indonesia need evaluation.
  - Hybrid:
    - Pros: Combines the benefits of electric and traditional fuel sources, offering extended range and flexibility.
    - Cons: Increased complexity, potentially higher maintenance costs.
2. Operational Needs:
- Mission duration (4 days): This suggests needing sufficient range or the ability to recharge/refuel efficiently.
  - Area of operation (Indonesian Coast): Accessibility of charging infrastructure (for electric) or biofuel availability needs evaluation.
3. Local Context:
- Regulations: Indonesian regulations on net-zero technologies and emissions might influence your choice.
  - Infrastructure: Availability of charging stations (electric) or biofuel suppliers is crucial for operational feasibility.

Considering these factors:

- Hybrid systems might be a good initial option. They offer the flexibility of using a combination of electric and traditional fuels, providing extended range while reducing emissions compared to solely relying on traditional fuels. This might be suitable until battery technology and charging infrastructure in Indonesia advance significantly.
- Biofuels could be a future alternative. If sustainable and cost-effective biofuel production and distribution become established in Indonesia, biofuels could become a viable option for achieving net-zero goals.

Additional Considerations:

- Emerging technologies: Explore advancements in hydrogen fuel cells or other promising net-zero options, keeping in mind their current feasibility and long-term potential.
- Consult with experts: Collaborate with naval architects, marine engineers, and local stakeholders to understand the best fit for your project based on technical expertise and the evolving landscape of net-zero technologies in Indonesia.

Remember, there is no single "perfect" solution at this stage. Carefully evaluating the factors mentioned above and staying updated on technological advancements will guide you towards choosing the most suitable and sustainable propulsion system for your innovative fishing vessel.

*Are these options appropriate for Net Zero?*

The appropriateness of the proposed propulsion systems (electric, biofuels, and hybrid) for achieving net-zero emissions for your fishing vessel project depends on a nuanced understanding of the concept of "net-zero" and the specific context of your project:

Understanding Net-Zero:

- Net-zero emissions: This doesn't necessarily mean zero emissions during operation. It signifies that any emitted greenhouse gasses are balanced by removing equivalent amounts from the atmosphere elsewhere in the lifecycle of the vessel and its operation.

Evaluating the Options:

- Electric:
  - Pros: During operation, electric propulsion produces zero emissions directly.
  - Cons: Emissions are potentially generated during electricity generation if the source isn't renewable. Additionally, battery production and disposal might have environmental impacts.
- Biofuels:
  - Pros: Some biofuels, like sustainably produced biodiesels or advanced biofuels, can offer significant emissions reduction compared to traditional fossil fuels.
  - Cons: Even "cleaner" biofuels still generate emissions during operation. Additionally, sustainability concerns exist regarding potential land-use change and potential indirect emissions associated with biofuel production.
- Hybrid:
  - Net-zero potential: Hybrid systems can be considered partially net-zero if they combine electric propulsion with renewable energy sources (e.g., solar panels for battery charging) and biofuels with extremely low lifecycle emissions.

Contextual Considerations:

- Indonesian energy mix: If Indonesia's electricity grid relies heavily on fossil fuels, electric propulsion might not be truly net-zero due to indirect emissions during electricity generation.

- Biofuel sustainability: If the chosen biofuel isn't demonstrably sustainable, it might not contribute meaningfully to net-zero goals.

Therefore:

- None of the options might be fully "net-zero" in the strictest sense, considering the current limitations and potential upstream emissions. However, they represent steps towards achieving net-zero by reducing direct emissions compared to traditional fossil fuels.

Recommendations:

Focus on maximizing the use of renewable energy sources whenever possible, regardless of the chosen propulsion system.

This could involve:

- Onboard solar panels for partially charging batteries in an electric or hybrid system.
- Investing in renewable energy sources for charging infrastructure if opting for electric propulsion.
- Prioritize biofuels with demonstrably low lifecycle emissions if biofuels are considered.
- Continuously monitor and refine your approach as technology advances and the understanding of "net-zero" becomes more comprehensive.

Ultimately, achieving true net-zero requires a holistic approach that extends beyond the vessel itself, encompassing the entire lifecycle, energy sources, and potential environmental impacts of all involved elements.

*Should alternative options like wind propulsion or electric drive be considered?*

- While your initial options (electric, biofuels, and hybrid) offer promising paths towards reduced emissions, including alternative options like wind propulsion and electric drives in your evaluation is definitely worthwhile. Here's a breakdown of their potential:

Wind Propulsion:

- Pros:
  - Harnessing natural wind power can significantly reduce reliance on fossil fuels and associated emissions.
  - Simple and low-maintenance technology compared to some other options.
  - Environmentally friendly and aligns with net-zero goals.
- Cons:
  - Highly dependent on wind conditions, making them unreliable for consistent operation and requiring a backup propulsion system like a diesel engine.
  - Limited effectiveness in calm winds and might not be suitable for all fishing activities.
  - Potentially lower maneuverability compared to traditional engines.
- Electric Drive (assuming you meant electric motors powered by on-board batteries or other renewable sources):
- Pros:
  - Zero emissions during operation if the electricity source is renewable (e.g., solar panels on board).
  - Quiet operation compared to traditional engines, potentially reducing underwater noise pollution.
  - High potential for efficiency improvements as battery technology advances.
- Cons:
  - Limited range due to current battery limitations, potentially requiring frequent recharging.
  - High initial cost of batteries and charging infrastructure.
  - Weight and space constraints associated with batteries might require careful design considerations.

Considering your project's specific context:

- Indonesian Coast: While wind patterns might be favorable in some regions, relying solely on wind propulsion might not be feasible due to potential calm periods.
- Mission duration (4 days): Current battery technology might limit the range of an electric drive system for a 4-day mission without recharging options.

Therefore:

- Wind propulsion can be considered as a supplementary option. In conjunction with another propulsion system (e.g., hybrid with a diesel engine), it could be used in favorable wind conditions to reduce fuel consumption and emissions.
- Electric drive has potential but requires further investigation. Evaluating advancements in battery technology, potential for onboard solar charging, and exploring hybrid configurations with a smaller battery pack for limited electric operation are recommended.

Additionally:

- Emerging technologies like hydrogen fuel cells might offer future possibilities for net-zero operation, but their current stage of development needs to be factored in.
- Seek expert advice from naval architects, marine engineers, and wind propulsion specialists to understand the feasibility and practical applications of these alternative options in your specific context.

- By exploring various options and conducting thorough research, you can choose the most suitable and sustainable propulsion system for your innovative fishing vessel, contributing to advancements in net-zero fishing practices in Indonesia.

#### *How achievable would it be to integrate wind propulsion on this fishing vessel being designed?*

Integrating wind propulsion into your fishing vessel design has potential but comes with challenges and considerations for achieving practical and operational success. Here's an assessment of its feasibility:

##### Feasibility factors:

- **Technical feasibility:** Integrating wind propulsion systems onto vessels is technically possible. Different configurations exist, such as rigid sails, soft kites, or Flettner rotors.
- **Partial emissions reduction:** Wind power can significantly reduce reliance on fossil fuels and associated emissions when conditions are favorable.

##### Challenges and limitations:

- **Dependence on wind:** Wind is unreliable and unpredictable. Calm periods or unfavorable wind directions would require a backup propulsion system like a diesel engine, negating some environmental benefits during those times.
- **Limited effectiveness:** Wind propulsion is less effective in calm conditions and might not be suitable for all fishing activities requiring precise maneuvering or maintaining specific speeds.
- **Maneuverability concerns:** Depending on the chosen wind propulsion system, vessel maneuverability might be impacted, potentially affecting fishing operations and safety.
- **Design considerations:** Integrating wind propulsion requires careful design integration with the existing vessel structure and other equipment, potentially impacting layout and functionality.
- **Safety and operational training:** Crew members need training on operating and maintaining the wind propulsion system and adapting fishing practices to variable wind conditions.

##### Considering your project's specific context:

- **Indonesian Coast:** While wind patterns are generally favorable in some regions, relying solely on wind propulsion might not be feasible due to potential calm periods.
- **Mission duration (4 days):** A backup propulsion system is highly recommended for completing the mission in case of unfavorable wind conditions.

Therefore, integrating wind propulsion on this vessel is achievable but with limitations. Here are some recommendations:

- **Treat wind propulsion as a supplementary system.** Combine it with another, more reliable propulsion system (e.g., hybrid) to provide flexibility and ensure operational continuity when wind is insufficient.
- **Carefully evaluate the chosen wind propulsion system's impact on maneuverability** and ensure it aligns with the intended fishing practices.
- **Consult with naval architects and wind propulsion specialists** to design the system effectively and integrate it seamlessly into the vessel's design.
- **Remember, achieving true net-zero requires a multifaceted approach.** While wind propulsion offers potential, it's crucial to consider its limitations and combine it with other sustainable solutions for a comprehensive and practical net-zero fishing vessel design.

#### *What design features do Indonesian fishers desire on their vessels?*

Understanding the specific needs and desires of Indonesian fishers is crucial for designing a truly useful and sustainable fishing vessel. While specific preferences might vary based on factors like location, fishing techniques, and target species, here are some general design features often desired by Indonesian fishers:

##### Efficiency and Functionality:

- **Fuel efficiency:** Reducing fuel costs is a significant concern, so features like efficient hull design, optimized engine selection, and potential for alternative fuels (e.g., biofuels) are often desired.
- **Ease of operation:** Simple and intuitive controls, user-friendly layouts, and minimal maintenance requirements are valued, especially for smaller-scale or less experienced operators.
- **Durability and reliability:** Vessels operating in potentially harsh marine environments need robust construction materials and reliable equipment to minimize downtime and ensure safety.

##### Safety and Comfort:

- **Safety features:** Adequate life-saving equipment, proper navigation and communication systems, and adherence to safety regulations are essential for ensuring crew well-being at sea.
- **Basic comfort:** While space might be limited on smaller vessels, providing comfortable sleeping quarters, designated cooking areas, and basic sanitation facilities is crucial for longer missions.

##### Storage and Processing:

- Adequate storage space: Sufficient space for fishing gear, catch, provisions, and other equipment is essential for efficient operation.
- Basic processing capabilities: Depending on the target catch and market demands, on-board processing facilities like sorting, icing, or refrigeration might be desired to improve catch quality and value.

Additional Considerations:

- Cultural and religious considerations: Incorporating design elements that respect the cultural and religious beliefs of Indonesian fishers can foster a sense of ownership and comfort onboard.
- Environmental sustainability: While the project aims for net-zero emissions, features that minimize waste generation, promote fuel efficiency, and encourage responsible fishing practices are generally appreciated by environmentally conscious fishers.

It's crucial to emphasize that these are general considerations. To gain a deeper understanding of the specific needs and preferences of Indonesian fishers in your target region and fishing practices, it's highly recommended to:

- Conduct interviews and focus groups with local fishers and fishing communities.
- Engage with local boat builders and maritime experts familiar with the regional context.
- Research existing literature and studies on the needs and challenges faced by Indonesian fishers.

By involving the intended users in the design process and understanding their specific needs, you can create a fishing vessel that is not only technologically innovative and environmentally friendly but also practically useful and well-received by the Indonesian fishing community.

*What budget would an Indonesian fisher have to purchase a vessel like this?*

Unfortunately, it's impossible to provide a definitive budget for a vessel like the one you're conceptualizing without more specific details. Several factors significantly influence the cost:

- Net-zero technology: The chosen net-zero propulsion system (electric, biofuels, hybrid) has a substantial impact on the overall cost. Currently, electric propulsion systems with sufficiently powerful batteries are still expensive, while the cost of biofuels and their infrastructure can vary significantly.
- Final design and size: The finalized size and complexity of the vessel design directly impact the cost of construction materials, equipment, and labor.
- Local market and regulations: Costs of materials, labor, and permits can vary depending on the specific location in Indonesia where the vessel is built.

However, considering the features and target functionalities mentioned, here's a general range to provide context:

- A medium-sized (around 20 meters) fishing vessel with basic accommodation, designed for longlining in Indonesian waters, and utilizing traditional fuel sources might cost between US\$200,000 and US\$500,000.
- Integrating net-zero technologies like electric propulsion or biofuels can significantly increase the cost, potentially doubling or tripling the base price depending on the chosen technology and its current market state.

It's important to remember:

- This is just a rough estimate based on general market trends and might not accurately reflect the actual cost.
- Obtaining accurate pricing requires consulting professional naval architects and shipbuilding companies in Indonesia. They can provide cost estimates based on your specific design, chosen technologies, and local market factors.

Additionally:

- Consider exploring available government subsidies or financing options for sustainable fishing vessels in Indonesia. Some initiatives might offer financial support to encourage the adoption of net-zero technologies in the fishing industry.
- Collaborate with local communities: Partnering with fishing communities and organizations might offer opportunities for collective investment or innovative financing models to make these types of vessels more accessible to Indonesian fishers.

Remember, the primary goal is to design a sustainable and affordable solution for Indonesian fishers. By carefully considering their needs, exploring cost-effective options, and seeking potential financial support mechanisms, your project can contribute to a positive transformation in the Indonesian fishing industry.

## Text to Image

A sample of the images created using the requirements for the cruise liner will be presented below.

### *Microsoft Copilot with Dal-E (OpenAI tech)*

Microsoft Copilot generates 4 images for each prompt submitted. The GENAI's initial response to the requirements set can be seen in Figure 2 to Figure 5.

**Figure 2 – AI Generated cruiser liner 1**

**Figure 3 - AI Generated cruiser liner 2**

**Figure 4 - AI Generated cruiser liner 3**

**Figure 5 - AI Generated cruiser liner 4**

Additional prompts were then implemented to coerce the GENAI model to add different features. Similarly, four images per updated prompt were generated however only the best outcome each of the updates is being reproduced here in Figure 6 to Figure 9.

**Figure 6 – Add wind propulsion**

**Figure 7 – Add Flettner Rotors**

**Figure 8- Add solar panels**

**Figure 9 – Interior shot of dinning lounge**

Additional results recorded from this explorative study can be found in Figure 10 and Figure 11.

**Figure 10 - AI Generated energy efficient Cruise liner 1**

**Figure 11 – AI Generated energy efficient Cruise liner 2**

### *Deep AI*

The fantasy Deep AI model was prompted to create images of cruise liners meeting the design requirements. A sample of the results can be seen in Figure 12 and Figure 13.

**Figure 12 – AI generated fantasy cruiseliner**

**Figure 13 - Interior of fantasy cruise liner**

## DISCUSSION

The results presented showcase the outcomes of the investigative study into using text to text and text to image GENAI models for concept ship design. A total of four models were used independently from each other utilizing similar prompts depending on the type of GENAI model throughout the process. The study yielded some interesting results that will be expanded upon to ultimately determine whether ship designers should consider using such tools and who stands to benefit the most from them.

When using either of the text to text GENAI models, plausible results were recorded that would be suitable to consider at an early stage of the design. When reflecting on whether the responses were elevating the ship design process or returning elementary aspects that should already be known by the designer, it was concluded that this is highly dependent on the experience of the designer and on the past portfolio of the studio. This means that design studios that have designed a particular vessel type for many years stand to gain far less than those exploring new business and design opportunities in the particular sector.

Naturally, when one lacks experience, there is a greater chance of acting on incorrect, incomplete or false knowledge. While the same argument could be put forward when utilizing open source non peer reviewed material, the GENAI algorithms are able to frame responses in a convincing and well framed manner. To counter this risk, studios should consider carrying out a risk assessment on the utilization of such algorithms for each respective project and confining the scope of the GENAI exploration. Such an approach would enable safer use of while acknowledging the embedded risk is the design process.

Both text to text GENAI algorithms recognized their limitations and suggested contacting naval architects and marine engineers despite having told the algorithm that they are that capacity. This outcome is reassuring as it sobers the user to acknowledge the uncertainty in response and provides them with good direction with what to do next.

This study also showed the importance of generating prompts well to try and tap in to useful information that be included in the design process. Users must be aware of the language used to generate responses and make use of action words to empower the algorithm to divulge data that would be otherwise time consuming to determine. As with any numerical or analytical model, verification and validation should be conducted to try and quantify the error and uncertainty in the predicted results. Since ship design is a heavily iterative process, it is commonly known that the initial parameters considered for a design don't need to have high accuracy or confidence as they are sure to change as the design evolves. The GENAI models can add value by accelerating this process and empowering the designer to continue advancing. A GENAI register should be created to complement the assumptions register to help trace and troubleshoot any parameters formally established by a GENAI machine.

The responses from the current study didn't suggest or recommend novel technologies despite having set the algorithm design requirements to do that. When emphasizing this and even suggesting some possible options such as wind or electrical propulsion, the algorithm didn't dispute them but it is clear that they weren't the first option of choice for it to recommend. A potential reason for this is that the data used to form these models is heavily biased by technologies that claim to be reach net zero but isn't able to verify that using technical knowhow. In light of this, it is unlikely for the algorithm to produce something new in way of technology.

The legal aspects of acting on the advice of such models that could later be traced to misinformation generated by GENAI are interesting and valid to be aware of. The maritime industry is heavily regulated and already has rigorous regulations, procedures and protocols to safeguard all parties, irrespective of how the vessel was designed. Prescriptive regulations may limit the use of such models but goal based regulations are already heavily scrutinized, irrespective of whether the proposals were generated by AI. It would be interesting to investigate whether GENAI models could be used to assist in scrutinizing designs or narratives before they are submitted for assessment. Similarly, regulating bodies could consider developing dedicated models to aid them in processing requests. Such an approach would leave more resources to instances or cases in the regulating body that require more attention.

An interesting outcome of this study was becoming aware of the potential information overload produced by the GENAI models. The study presented in this paper took longer than expected due to the volume of information and data returned by the models. Although this was not initially expected, design studios should be conscious of this and introduce measures to limit the breadth of direction and time sunk into a project through AI. The barrier to access knowledge and data is so minimal that it encourages further prompting in areas that may not necessarily add value to the project.

The results from the study conducted with text to image GENAI models produced a range of images that were refined with further prompts through the same GENAI algorithms. The ship design process rarely uses images to facilitate design but they can be helpful to start conversations and get ideas of layout and payload integration on similar vessels.

The images created by the GENAI models have minimal value from a technical perspective but do present the opportunity of visualizing radical ideas. Although none of the images are suitable for construction, they could be useful to demonstrate to clients requiring bespoke aesthetic statement features on a particular vessel. Figure 12 is a good example of this where despite the vessel not being practical to construct in that format does have a visual appeal that may be appropriate for the target end user it was trying to attract. The fantasy elements of the vessels produced did offer the opportunity to have some interesting discussions with no effort needed to create them in the first place. In particular, the visualization of a zoo on a cruise ship could be seen as a useful output to the client requesting it to understand the extent the zoo would dominate the vessel. This could have been used to help facilitate a conversation with the client to reel back the design requirement to something more manageable or determine a constructive way of how the radical idea may be implemented.

Similar to text-text models, text to image models also generated incorrect responses that are not even physically possible to create. Interestingly, Gemini took more of an initiative with the design process. In some instances, the output was unquestionable, even to a non-technical person such as in Figure 10. Other AI generated images with irregular proposals may not necessarily be as clear to non-technical people such as Figure 11 where water jets were fitted to the proposed cruise liner.

Nonetheless, there is no doubt that these GENAI models are powerful and increasingly becoming more capable. Should a dedicated GENAI tool be developed specifically for ship design that is coupled with physics models to introduce technical rigor, it is fair to assume that more sensible outputs would be created. Although not available yet, new GENAI models that would do text to CAD or IMAGE to CAD would enable quicker transitions between formats. Software such as Autodesk Fusion already makes use of generative design as part of its offering where products being designed are modified according to different constraints and criteria. Similar approaches can be found in literature for different hull form analysis models but they require substantial training and expertise to use.

## CONCLUSIONS

The study undertaken successfully explored the utilisation of text to text and text to image GENAI models for concept ship design. Two differing case studies were considered to explore the type of content that the GENAI models could generate to determine whether they would be an added asset to the ship design process.

GenAI is very easy to engage with, breaking the barrier between thoughts and actions. The experience is similar to talking with a colleague when asking questions. This differs to search engines what require selecting key words for the speech. The models are also able to remember the previous responses and use this to understand the context of the questions and influence the next prompts.

The results and analysis recorded suggest that overall, GENAI would help the ship design process but should only be used in an assistive role. Until the design studio is confident with how to use it and gain confidence in the results, greater care should be implemented to minimise risk of acting on invalid recommendations. It is evident that not having the relevant technical background and understanding in both ship design and AI could result in poor decision making.

The GENAI models used for this study were trained and modelled against an existing catalogue of items that are not topic specific. A ship design studio could build their own version of an AI tool by inputting appropriate research papers, past designs and relevant content that could be a useful source of information to influence future designs. Such models could be tailored for initial sizing, parametric modelling or other ship design milestones.

Based on the study conducted, GENAI models can be a useful addition to the ship design process but their use should be limited to an assistive role. The text-text GENAI models were able to produce more useful results than the text-image models however the benefits of being able to cycle through new images to facilitate brainstorming did not go unnoticed. The models utilized were unable to propose new ideas, methods or technologies for the ship design process. Coupling such models with a physics model or numerical analysis may yield more complex but plausible results. Other possibilities to explore include the linking of different GENAI models to determine whether there exists a benefit of having them work together.

A genuine opportunity exists to develop tailored GENAI models for the ship design process. Future work should explore this option further and work closer with ship designers to record their feedback when using this technology.

## DECLARATION OF GENERATIVE AI AND AI-ASSISTED TECHNOLOGIES IN WRITING

Statement: During the preparation of this work the author(s) used [CHAT GPT 3.5, Microsoft CoPilot, Dal E and Deep AI] in order to conduct the research and support the report writing process. After using this tool/service, the author(s) reviewed and edited the content as needed and take(s) full responsibility for the content of the publication.

## CONTRIBUTION STATEMENT

**Author 1:** Conceptualization; data curation, methodology; writing – original draft.

**Author 2:** Conceptualization; supervision; writing – review and editing.

**Author 3:** Conceptualization; – review and editing.

# A Novel Application of Tensor Networks for the Investigation of Design Optimization Tools in the Marine Domain

Connor W. Arrigan<sup>1,\*</sup>, Alexander D. Manohar<sup>1</sup>, Matthew D. Collette<sup>1</sup>, and David J. Singer<sup>1</sup>

## ABSTRACT

*Traditional optimization methods often struggle to map the unique interactions between design variables, operational constraints, and performance objectives. Tensor networks, a mathematical framework rooted in quantum physics, address this challenge by providing a tool to model state relationships within multidimensional data structures. In the context of bulk carrier synthesis and optimization, tensor networks enable the simultaneous analysis of multiple constraints and their interactions via a state space representation. A state space representation offers a holistic understanding of the optimization landscapes by providing insights that add to traditional optimization analysis techniques. This paper presents a methodology for converting the optimization problem into multiple tensor network representations, details the implementation of tensor network algorithms, and showcases implementation results. The findings underscore the capacity of tensor networks to provide a deep, data-driven understanding of complex optimization landscapes, thus enabling novel decision-making opportunities.*

## KEY WORDS

Tensor Networks, Early-Stage Design, Optimization, Concept Design Tools, Informed Decision Making

## INTRODUCTION

In recent years, optimization techniques have emerged as indispensable tools in the pursuit of efficient, autonomous, eco-friendly, and high-performance marine solutions. This conference paper delves into the multifaceted challenges faced when applying optimization methodologies in the nascent stages of marine design. From the intricate dance between hydrodynamics and structural integrity to the intricacies of incorporating sustainability criteria, this paper illuminates the complexities that must be navigated by designers and engineers in this dynamic and evolving field.

The maritime industry stands at the precipice of transformation, driven by the demands for greater efficiency, sustainability, autonomy, and performance in marine vessels. As designers and engineers embark on the challenge of designing the next generation of vessels, they are increasingly turning to optimization techniques to guide their decisions from the very inception of a project. However, this endeavor is not without its challenges, as optimizing marine designs at the early stages presents a unique set of challenges. Engineers and designers, driven by the promise of improved efficiency, cost-effectiveness, and innovation, often embrace optimization results with unwavering trust. However, this “blind faith” in optimization outcomes may have unintended consequences that warrant careful consideration.

Traditional optimization methods and optimization analysis methods often struggle to comprehensively map the complex interactions between design variables, operational constraints, and performance objectives Papalambros and Wilde (2000) Marler and Arora (2004). No current methods exist for mapping populations of solutions in relation to design variables, objectives, or constraint activation across a solution space. The case study presented in this manuscript aims to help provide a framework for understanding how to better formulate and understand the results of optimization in early-stage design. The methodology and framework presented in this manuscript employ tensor networks and concepts from ontological commitment.

There has been limited research utilizing the philosophy-based side of ontologies within engineering, but there can be crucial implications for marine design. One concept that is of great interest in this domain is ontological commitment. Ontological commitment is a concept from philosophy that pertains to assertions of existence and entities of kinds of entities Juben (1998). In the context of engineering and design, ontological commitment refers to the assumptions and pre-conditions about the fundamental nature of the design variables, objects, functions, and relationships that comprise the design. Ontological commitment in this context yields the possibility to enable the understanding of potential design implications associated with the integration of the multiple contextual views of design artifacts within a singular framework. To enable the use of ontologies and ontological commitment in the marine domain, tensor networks show promising capability as a framework. Tensor networks, a mathematical framework rooted in quantum physics, have found promising utility in diverse domains due to their ability to capture intricate patterns and correlations within large, highly entangled datasets, such as those seen in the marine domain Klishin (2020). The main question addressed by this research is how one understands a-priori the encoded and non-encoded relations and inter-dependencies that exist within design tools from an ontological lens. In the case of this research, an encoded relation is one captured by a direct relation of input variables or objectives in relation to constraints or intermediate functions. A non-encoded relation is a relation that may exist between variables, constraints, intermediate functions, or objectives that is not directly codified in the formulation of a problem. A tensor network framework is able to capture the impact of non-encoded and encoded relations by having the ability to investigate all possible couplings in n-dimensions.

While networks and network science have proven to be invaluable tools, in most cases researchers are simply analyzing networks that already exist with some innovative modifications and representations. However, within the naval design domain, standard networks (e.g., social networks) do not exist. For this reason, naval design researchers have been forced to create unique novel network frameworks and associated novel network metrics, tailored to specific naval design problems. As with other naval design research, a critical step is the proper abstraction and creation of not only a ship-centric ontological framework but also the methods needed to populate the network. How one structures the nodes, edges, layers, and population will determine the framework's ability to uncover the desired insights. Based on the challenges presented by the problem, tensor networks show promise in their ability to provide insights. Tensor networks address the challenge of investigating optimization tools by providing a powerful framework to unravel intricate relationships within multidimensional data structures.

This manuscript presents a novel tensor network framework for investigating optimization codes, which is used in the presented case study. The case study presented in this manuscript is based on the Sen and Yang Bulk Carrier multi-objective optimization problem Sen and Yang (1998). The problem is well studied and provides a simple example to investigate the capabilities of tensor networks while providing novel insights. The Sen and Yang Bulk Carrier Optimization is governed by three objectives, six design variables, 13 constraints, and 34 intermediate functions. In the performed case study, both optimization-based data and Monte Carlo-based data from the model were analyzed using the novel tensor network framework. The novel framework developed provided several insights detailed later in this paper. These insights included the ability to investigate constraint activation, the nature of constraints and regions of binding, and the ability to identify regions of viability within the solution space.

The investigation completed in this case study provides a few important insights for the marine domain. First, as engineers and designers, one must recognize that one's design tool predicts the resulting trade space. The way one defines inputs and objectives directly impacts and commits the resulting solution space of the problem. Second, one must investigate what assumptions or constraints bind a design space. This will help ensure that the solutions from an early-stage design optimization tool have a meaningful impact on the designs made and prevent later design re-work. Third, the case study shows that it is critical to investigate whether one's inputs and their ranges and constraints are reasonable. Fourth, it is essential to

know if the preferred solution is valid and robust. Finally, the case study presented provides a framework to evaluate the crucial question of can a design tool give the designer what they want relative to a specified objective.

## BACKGROUND

The following sections detail the necessary background for the case study presented in this manuscript.

### Ontological Commitment

The notion of ontological commitment stemming from the realm of metaphysics has not found widespread application within the field of engineering design, especially not directly or overtly. In metaphysics, ontological commitment refers to the necessity of positing certain entities for a theory or system to be deemed valid or true Rayo (2007). In the context of engineering design, ontological commitment holds relevance concerning the presumptions and prerequisites that underlie a design. This concept is formally defined as “a relation that holds between persons or existence assertions, on the one hand, and specific entities or kinds of entities, on the other” Jubien (1998). This implies that “assertions of the existence of specific entities or kinds of entities are the intuitive source of the notion of an ontological commitment” Jubien (1998).

In simpler terms, ontological commitment signifies the recognition that one assigns significance to something by inferring belief within an established domain or context, and its validity hinges on its connection to some notion of prior existence. There are numerous instances illustrating ontological commitments. For instance, within the realm of physics, the field is ontologically committed to the existence of entities such as atoms, quarks, and space-time. To expand on this, physics theory is ontologically committed to the concept of electrons, meaning that the authenticity of physics demands the existence of electrons, adhering to specific behavioral patterns.

Another perspective on ontological commitment is that it discloses the “demands imposed on the world” Rayo (2007). Nevertheless, despite extensive discussions in philosophy, the term “ontological commitment” is not commonly utilized in engineering design as a technical term or framework. Engineering primarily concerns itself with practicality and concrete outcomes, prioritizing tangible requirements over abstract metaphysical considerations.

However, the notion of ontological commitment does hold relevance in engineering design in the sense that the design process often entails decisions regarding which types of entities should be included or excluded from a design. In certain instances, engineers or designers may need to make assumptions or commitments about the nature of reality or the existence of specific entities to develop a functional design. For instance, in the field of software engineering, choices about the inclusion of particular data structures or classes in a program may carry ontological implications. Similarly, in the design of complex systems, decisions about the incorporation of various components or subsystems may involve ontological commitments. Nonetheless, in both scenarios, the language and concepts employed to address these matters typically belong to the engineering domain, rather than being derived from metaphysics.

Two critical concepts within ontological commitment are explicit and implicit ontological commitment. The concepts are directly a bi-product of the modern efforts to try to quantify all entities involved in a commitment and were originally presented by Peacock and Krämer and expanded upon by Österblom Peacock (2011) Krämer (2014) Österblom (2017). Explicit ontological commitments are defined by the entities that are claimed to exist that are directly stated in the statement of a theory or statement Peacock (2011) Österblom (2017). Put simply, “a theory is explicitly ontologically committed [to an entity] if it contains some sentence that means there are X” Krämer (2014) Österblom (2017). Explicit ontological commitment is a pretty clear notion and covers any direct statement of existence. To cover the commitments that are not directly stated or directly related to a theory or statement, there is implicit ontological commitment. Implicit ontological commitment is defined by two criteria. The first of the criteria for determining implicit ontological commitments is “the theory could not be true unless X existed,” and the second is “the theory is committed to X and not explicitly committed to X” Peacock (2011) Österblom (2017). One important aspect to note about ontological commitments is that they are an

“unavoidably modal notion” Österblom (2017). Specifically, this means with implicit ontological commitment, it is not necessarily always clear whether an entity is involved in the commitment of a statement or theory or not. A more in-depth discussion of the use of ontological commitment in the marine domain can be found in a previous conference paper written by the author Arrigan et al. (2022).

Within the domain of naval architecture, there is a multitude of ontological commitments that go into a ship’s design. For example, one can explore the ontological commitment to ship stability, which is inherently acknowledged as a paramount design principle. This is exemplified by the explicit prioritization of a positive, non-zero metacentric height (GM), which serves as a fundamental criterion for a vessel’s ability to right itself after being heeled by external forces. The acceptance of this constraint reveals a naturally embedded ontological commitment to ensuring the stability of a ship, a necessity for operational safety and seaworthiness. Consequently, the solution space for ship design is inherently limited to configurations that yield a positive, non-zero GM. In this case, there is an explicit commitment to ships with positive, non-zero GMs and an implicit commitment to their stability. Digging deeper into the components that contribute to the calculation of GM, which includes the distance from the keel to the center of buoyancy (KB), the distance between the metacenter and center of buoyancy (BM), and the distance from the keel to the center of gravity (KG), one stumbles upon a series of implicit commitments. These pertain to the various elements and design choices that influence KG, such as weight distribution, onboard systems, and cargo loading protocols, which themselves are circumscribed by a myriad of other constraints and linguistic stipulations. Simultaneously, KB and BM are predominantly dictated by the engineered geometry of the hull. Thus, there are clearly ontological commitments in ship design regarding stability. In this context, they can be classified as high-order commitments due to the layering of explicit and implicit first-order commitments that make up the ontological commitment of stability.

## STATISTICAL PHYSICS

Statistical physics is a branch of quantum physics concerned with understanding the behavior of large-scale systems based on the interactions between their individual components largely via tensor networks Huang (2009). Tensor networks are networks of  $n$ -dimensional arrays, referred to as tensors. Tensor networks can be utilized as a powerful tool for investigating highly correlated and entangled, complex systems. Tensor networks efficiently represent all possible combinations of components’ states and their connections to other components and their respective states. This ability directly allows one to rapidly query the state space and obtain probability distributions across different components and their respective states through performing contractions and studying the statistical properties of their collective behavior. In the marine domain, tensor networks have just started to be used and are in the nascent stages of being introduced to their many use cases. Currently, within the marine domain, tensor networks have been used to shed new light on the problem of ship arrangements and routing Klishin (2020) Klishin et al. (2019). Additionally, tensor networks are being used for decoupling diagnostic decision-making from the scale of the state space to enable self-adaptive health monitoring Manohar and Singer (2022).

In the view of the authors, tensor networks enable a strong framework for investigating optimization codes as one can easily investigate the impact of individual or multiple components across certain or changing states. Traditional optimization analysis methods, design of experiments, and sensitivity analysis struggle to comprehensively map the complex interactions between design variables, operational constraints, and performance objectives. Tensor networks provide a powerful tool to unravel intricate relationships within multidimensional data structures since it is native for data to be represented as high-dimensional tensors in the tensor network. Tensor networks enable the simultaneous analysis of multiple constraints, design variables, and their interactions simultaneously and offer a holistic understanding of the optimization landscape. Furthermore, tensor networks allow for the identification of constraint activation regions, shedding light on the conditions under which specific constraints come into play. This ability directly provides the design process with insights that would otherwise remain hidden. To fully understand the results presented from the case study detailed in this manuscript, it is critical to lay out the technical details of a few important statistical physics and tensor network-based concepts.

Statistical physics largely utilizes the Variation Principle of Maximum Entropy Cimini et al. (2019). This principle states that the probability distribution best representing the current state of (knowledge on) a system maximizes Shannon entropy subject to the context of any prior information on the system itself. In more common terms this means that the lowest en-

energy is the most probable. In quantum mechanics, the ground state of a system is the state in which the quantum mechanical Hamiltonian operator has its lowest eigenvalue Klishin (2020). The wave function corresponding to the ground state contains information about the probability distribution of finding a particle in various positions and momentum states. This same idea applies to tensor networks where one can obtain position and state probability information from a given network. Within statistical physics there are two primary information structures: partition functions and tensor networks Klishin (2020). The partition functions describe the statistical properties of a system and can be manipulated to obtain statistical properties, such as probability distributions, about the system Klishin et al. (2019). The partition function directly provides a connection between the microscopic properties of individual particles and the macroscopic properties of the entire system. It is defined as the sum of the Boltzmann factors (meant to obtain the Boltzmann Distribution), which are exponential functions of the system's energy at each state. In work done by Klishin et al., they developed a method for integrating a partition function into a tensor network such that the tensor network can be modified and contracted to evaluate the partition function and learn statistical information about the system Klishin et al. (2019) Klishin (2020). The partition function  $\mathcal{Z}$  sums over all possible system state configurations  $\alpha$ . The energy of the system in configuration  $\alpha$  is given by the objective function  $\mathcal{O}_i(\alpha)$ . The partition function is defined below.

$$\mathcal{Z} = \sum_{\alpha} e^{-\sum_i \lambda_i \mathcal{O}_i(\alpha)} \quad (1)$$

From this partition function, the probability of specific configurations can be derived. By taking the specific configuration  $\alpha$ , it can be extracted from the equation and normalized as in Eq. 2. This gives the probability of the system being in configuration  $\alpha$ .

$$p_{\alpha} = \frac{1}{\mathcal{Z}} e^{-\lambda \mathcal{O}(\alpha)} \quad (2)$$

In the above formulation  $\lambda$  is  $\frac{1}{T_{Critical}}$ . In statistical physics, the critical temperature of the system represents when phase transition occurs. The value selected for the critical temperature, or in this case  $\lambda$ , is essential. A lower value of  $\lambda$  suggests that the behavior of a system is more random. A higher value of  $\lambda$  suggests that the behavior of a system is more known. A value around the transition point suggests the behavior of the system is largely unknown. In terms of a probability distribution, a lower  $\lambda$  suggests a more uniform distribution, and a higher  $\lambda$  suggests a centered or skewed distribution. A second important component of the partition function is the objective function  $\mathcal{O}_i(\alpha)$ . The objective function  $\mathcal{O}_i(\alpha)$  returns the system's energy while at state configuration  $\alpha$ .  $\mathcal{O}(\alpha)$  is equivalent to the system's Hamiltonian at configuration  $\alpha$ . The objective function can be configured for varying goals. For the case study presented in this manuscript, the objective function was configured to favor extreme high or low displacements.  $\lambda$  could also be thought of as a configuration pressure, favoring more random or known behavior of the system. Fundamentally, the objective function defines state-to-state relationships via the energy between states. This is the point where the Principle of Maximum Entropy comes into play since the lowest objective state will have the highest probability.

The second information structure of statistical physics is tensor networks. Tensor networks are networks of tensors where the edges between tensors represent contractions, which are summations over a shared index Ran et al. (2022). The first important concept to understand in relation to tensor networks is the concept of rank. Rank refers to the order of the tensor. A rank zero tensor is a scalar, a rank one tensor is a vector, a rank two tensor is a matrix, and so on. Since contractions represent a summation over a shared index between two tensors, a tensor network represents a series of mathematical operations. Therefore, by encoding a partition function into a tensor network, contracting the tensor network evaluates the partition function Klishin (2020). As an example, consider the contraction between two two-rank tensors  $A_{ij}$  and  $B_{jk}$  over a shared index  $j$ . The result of the contraction is a new two-rank tensor,  $C_{ik}$ .

$$A_{ij}B_{jk} = A_{i1}B_{1k} + A_{i2}B_{2k} + \dots + A_{in}B_{nk} = C_{ik} \quad (3)$$

Within this partition-encoded tensor network, there are two types of tensors. The first type of tensors are those which represent particles in the system and their states. The second type of tensor is a coupling tensor which represents all state-to-state energy combinations between two particles in the system. In the tensor network, particle tensors are connected to other particle tensors via an intermediary coupling tensor if those two particles directly impact one another. The states represented within the particle tensors and the energy represented within the coupling tensors are determined by their use case. The values utilized in these tensors will be detailed in the later sections of this manuscript.

When the tensor network is contracted, the result is a probability distribution over that system's state space. There are two other critical concepts related to contractions that should also be mentioned. To obtain statistical information about a system via a tensor network, there are two critical concepts related to contractions that need to be presented. These are the concepts of external legs and anchors. In addition to being able to perform contractions of the tensor network, to aid querying one can add external legs and or anchors. An external leg artificially adds a rank to a tensor to prevent it from being fully summed in the partition function. If there are no external legs on a tensor network, a contraction of the tensor network yields a single number. Multiple external legs can be added to a network. A single external leg will yield a marginal probability relative to the node it was placed and multiple external legs will result in a joint probability relative to the respective nodes. Similar to external legs, none, one, or multiple anchors can be added to a tensor network. Anchors condition the system on being in a specific state. Thus, the specified configuration is held constant over partition function summation. This in turn yields a conditional probability for the system conditioned on a specific state or multiple states.

To wrap up this brief introduction to statistical physics and tensor networks, it should be noted that tensor networks require three pieces of information to be constructed. The first is a logical network of nodes of a system. The second is the state space of these nodes. Finally, there needs to be an objective function that describes the cost or energy of the system being in specific configurations.

## Sen and Yang Bulk Carrier Problem Formulation

The following section details the formulation of the Sen and Yang Bulk Carrier optimization. Sen and Yang (1998). Additional information may also be found in Yang et al. (1990) and Yang and Sen (1996).

### *Inputs and Intermediate Functions*

The model defines six inputs: length ( $L$ ), beam ( $B$ ), draft ( $T$ ), depth ( $D$ ), speed ( $V$ ), and block coefficient ( $C_B$ ).

Using these inputs, the model defines a host of intermediate functions:

$$\begin{aligned} \text{annual cost} &= \text{capital charges} + \text{running cost} \\ &\quad + \text{voyage cost} + \text{RTPA} \end{aligned} \quad (4)$$

$$\text{capital charges} = 0.2 \times \text{ship cost} \quad (5)$$

$$\begin{aligned} \text{ship cost} &= 1.3 \times (\text{steel mass})^{0.85} \\ &\quad + 3500 \times \text{outfit mass} + 2400 \times P^{0.8} \end{aligned} \quad (6)$$

$$\text{steel mass} = 0.034 \times L^{1.7} \times B^{0.7} \times D^{0.4} \times C_B^{0.5} \quad (7)$$

$$\text{outfit mass} = L^{0.8} \times B^{0.6} \times D^{0.3} \times C_B^{0.1} \quad (8)$$

$$\text{machinery mass} = 0.17 \times P^{0.9} \quad (9)$$

$$P = \Delta^{2/3} \times V^3 \times \frac{1}{b(C_B) \times \frac{V}{(g \times L)^{0.5}} + a(C_B)} \quad (10)$$

$$\Delta = 1.025 \times L \times B \times T \times C_B \quad (11)$$

$$\text{running cost} = 40000 \times DW^{0.3} \quad (12)$$

$$DW = \Delta - \text{light ship mass} \quad (13)$$

$$(14)$$

$$\begin{aligned}
\text{voyage cost} &= \text{fuel cost} + \text{port cost} & (15) \\
\text{fuel cost} &= 1.05 \times \text{daily consumption} \times \text{sea days} \times \text{fuel price} & (16) \\
\text{daily consumption} &= P \times 0.19 \times 0.024 + 0.2 & (17) \\
\text{sea days} &= \frac{\text{round trip miles}}{24 \times V} & (18) \\
\text{round trip miles} &= 5000 \text{ (nautical miles)} & (19) \\
\text{fuel price} &= 100 \text{ (pounds/ton)} & (20) \\
\text{port cost} &= 6.3 \times DW^{0.8} & (21) \\
RTPA &= \frac{350}{\text{sea days} + \text{port days}} & (22) \\
\text{port days} &= 2 \times \left( \frac{\text{cargo deadweight}}{\text{cargo handling rate}} + 0.5 \right) & (23) \\
\text{cargo deadweight} &= DW - \text{fuel carried} - \text{crew, stores, and water} & (24) \\
\text{fuel carried} &= \text{daily consumption} \times (\text{sea days} + 5) & (25) \\
\text{crew, stores, and water} &= 2.0 \times DW^{0.5} & (26) \\
\text{cargo handling rate} &= 8000 \text{ (tons/day)} & (27)
\end{aligned}$$

where  $RTPA$  is round trips per annum,  $DW$  is deadweight, and  $g$  is the gravitational constant ( $g = 9.8065 \text{ m/s}^2$ ). The functions  $a(C_B)$  and  $b(C_B)$  are regression equations based on Froude Number and a coefficient referred to as the *Admiralty Coefficient*, detailed in the original paper. Functions  $a(C_B)$  and  $b(C_B)$  are defined as follows:

$$a(C_b) = \eta_1 \times C_B^2 + \eta_2 \times C_B + \eta_3 \quad (28)$$

$$b(C_b) = \zeta_1 \times C_B^2 + \zeta_2 \times C_B + \zeta_3 \quad (29)$$

$$\eta = [4977.06, -8105.61, 4456.51] \quad (30)$$

$$\zeta = [-10847.2, 12817, -6960.32] \quad (31)$$

## Objectives

The model defines three objectives:

$$\text{transportation cost} = \frac{\text{annual cost}}{\text{annual cargo}} \quad (32)$$

$$\text{light ship mass} = \text{steel mass} + \text{outfit mass} + \text{machinery mass} \quad (33)$$

$$\text{annual cargo} = \text{cargo deadweight} \times RTPA \quad (34)$$

$$\Omega_1 = \min(\text{transportation cost}) \quad (35)$$

$$\Omega_2 = \min(\text{light ship mass}) \quad (36)$$

$$\Omega_3 = \max(\text{annual cargo}) \quad (37)$$

## Constraints

The model defines dimensional and displacement constraints:

$$L/B \geq 6 \quad (38)$$

$$L/D \leq 15 \quad (39)$$

$$L/T \leq 19 \quad (40)$$

$$T \leq 0.45 \times DW^{0.31} \quad (41)$$

$$T \leq 0.7 \times D + 0.7 \quad (42)$$

$$DW \geq 3000 \quad (43)$$

$$DW \leq 500000 \quad (44)$$

Powering constraints:

$$C_B \geq 0.63 \quad (45)$$

$$C_B \leq 0.75 \quad (46)$$

$$V \geq 14 \quad (47)$$

$$V \leq 18 \quad (48)$$

$$\frac{V}{(g \times L)^{0.5}} \leq 0.32 \quad (49)$$

Stability constraint:

$$GM \geq 0.07 \times B \quad (50)$$

where

$$GM = KB + BM - KG \quad (51)$$

$$KB = 0.53 \times T \quad (52)$$

$$BM = \frac{(0.085 \times C_B - 0.002) \times B^2}{T \times C_B} \quad (53)$$

$$KG = 1.0 + 0.52 \times D \quad (54)$$

## CASE STUDY DATA

The following sections detail the data collected and used for the case study presented in this manuscript. Included in the table below are the selected limits that were used with the Sen and Yang Bulk Carrier problem for this study.

**Table 1: Lower and Upper Bounds Defined for Case Study**

Design Variable	Lower Bound	Upper Bound
Length (m)	195	500
Draft (m)	10	27
Depth (m)	13	46
Block Coefficient	0.63	0.75
Beam (m)	24	80
Speed (kts)	14	18

In the case study presented in this manuscript, the states of the tensor network were determined to be a change in the dimension of a meter, a change in speed of a meter per second, and a change in the block coefficient of one hundredth. Some cases were run for the case study where each of the design variables was given 100 different possible states over the range of the lower and upper bound.

In this work, point-wise mutual information was utilized in the creation of the tensor networks for the case study presented. The point-wise mutual information takes the form as shown below.

$$PMI(a, b) = \log\left(\frac{P(a, b)}{P(a) * P(b)}\right) \quad (55)$$

The point-wise mutual information represents comparing the joint probability of  $P(a, b)$  occurring to the marginals of  $P(a)$  and  $P(b)$ . In this case study, the point-wise mutual information was used as a surrogate for the energy needed in tensor building and contracting the tensor networks. For the investigated case, the objective function was defined following the formulation below.

$$\mathcal{O}(\alpha) = e^{PMI(\alpha) \times Cost(\alpha)} \quad (56)$$

$$Cost(\alpha) = e^{-\frac{Displacement(\alpha)}{1,000,000}} \quad (57)$$

$$Displacement(\alpha) = L(\alpha) \times B(\alpha) \times T(\alpha) \times C_b(\alpha) \quad (58)$$

In the above equations,  $\alpha$  represents a given state configuration. The displacement is averaged based on the data points in each respective state configuration. The state configurations are determined by the number of states for each node. In this case, the states are as defined earlier in this section.

Two methods for developing data for this case study were used. The first approach used was to output the iterations of a multi-objective optimization of the Sen and Yang bulk carrier. The optimization was formulated using the equations detailed in this manuscript and using MATLAB's built-in fminimax optimizer. The algorithm for the optimizer is gradient-based. The data from the optimizer is comprised of multiple runs from multiple initial starting conditions, some including those mentioned in the original formulation. The other data set developed for this case study was a Monte Carlo simulation of the Sen and Yang Bulk Carrier Optimization. The Monte Carlo simulation was run with the upper and lower bounds detailed in this manuscript. These were also used as the upper and lower bounds for the optimization. The Monte Carlo simulation was run for 1,000,000 iterations. The data sets are comprised of the values of the inputs, output, constraints, and every intermediate function value for each iteration of the optimization or the Monte Carlo. In both data sets only the feasible solutions were considered for this initial case study. It was noted from looking at the results including the in-feasible solutions that the trends seen did not largely vary from those seen in the feasible solutions.

## DEVELOPED CASE STUDY NETWORKS FOR INVESTIGATING RELATIONS

To investigate a priori the encoded and non-encoded relations and inter-dependencies that exist within the Sen and Yang Bulk carrier design tool multiple tensor networks were formulated. The formulation used for the case study presented in this manuscript is similar to some of the work done by Klishin et al (2019). In this case study, each variable or node in the tensor networks presented later in this manuscript represents a rank one tensor acting as a possible state vector. The tensor networks formulated were developed to be able to easily place external legs and anchors on important variables within the tool. Based on the input tensor network to the framework, the data was populated for the network to enable necessary calculations and queries. The following sections delve into the four networks developed and their states.

## Input to Output Network

The first of the four networks developed sought to investigate one of the most fundamental relations that exist, the relation of the input variable to the output final objective values. In the developed bipartite network, the input variables are on the left and each is connected to each of the relevant output objectives that they impact. In this case, each input is connected to each of the outputs. This can be seen in the developed network below.

**Figure 1:** Developed Tensor Network for Investigating Input Output Relations

In the developed network above, the states for each of the nodes were defined as a change in the value of the input variable or the output objective.

## Input to Constraint Status Network

The second network developed sought to begin to capture some of the more hidden relations in the tool. The bipartite network consists of the input variables on the left and three nodes on the right indicating a constraint status of non-binding, near binding, or binding. In this case, the values of each constraint in the data were pre-processed to determine the associated node to which each belonged. In this case study near binding was defined to be a value of  $\epsilon$  away from the binding value. Each constraint was re-arranged so that when the constraint was bound or violated the value would become zero or greater than zero. For the presented data,  $\epsilon$  was determined using best judgment as an engineer. In this case,  $\epsilon$  was defined to be 0.5 for when a constraint was near binding.

**Figure 2:** Developed Tensor Network for Investigating Constraint Status (Non-Binding, Near Binding, Binding)

In the developed network above, the states for each of the input nodes were defined as a change in the value of the input variable. For the status nodes of non-binding, near binding, or binding, the states were determined to be the number of constraints falling under non-binding, near binding, or binding for each data point.

## Input to Solution Status Network

The third network developed again sought to capture some of the relations that are not typically apparent in a tool. The bipartite network consists of the input variables and the output objectives on the left and one node on the right for the solution status.

**Figure 3:** Developed Tensor Network for Investigating Solution Status (Non-Pareto, Near Pareto, Pareto)

In the developed network above, the states for each of the input and output objective nodes were defined as a change in the value of the variable. For the solution status node, only three possible states were defined, non-Pareto, near Pareto, or Pareto referring to the optimality of the solution. In this case, the values of output objectives in the data were pre-processed to determine if a solution was non-Pareto, near Pareto, or Pareto. In this case study, near Pareto was defined to be a value of  $\epsilon$  away from the Pareto front. For the presented data,  $\epsilon$  was determined using best judgment as an engineer.

## Input to Constraint Network

The final network developed sought to capture some of the relations in terms of constraint activation that are not typically apparent in a tool. The bipartite network consists of the input variable nodes on the left and constraint nodes on the right. Each of the input nodes is connected to each of the relevant constraints that they impact.

**Figure 4:** Developed Tensor Network for Investigating Constraint Activation over the Solution Space

In the developed network above, the states for each of the input nodes were defined as a change in the value of the variable. For the constraint nodes, each of the nodes had the possible states of non-binding, near binding, or binding. In this case, the values of each constraint in the data were pre-processed to determine the associated state for each of the constraint nodes. As stated above, near binding was defined to be a value of  $\epsilon$  away from the binding value. For the presented data,  $\epsilon$  was determined using best judgment as an engineer.

## RESULTS

The following section details the results from performing queries in the developed networks with different external legs. Numerous more contractions were performed, not detailed in this manuscript, to further validate the findings. The contraction results presented in this manuscript are intended to provide insight into the tool and to demonstrate the capabilities of tensor networks in relation to optimization.

One of the first sets of contractions performed was done to help begin to understand the results of a tensor network contraction and to be able to easily check the result against one's instincts as a naval architect. The contraction was done on the input to output relation network and an external leg was placed on length. In evaluating the contraction, the tensor network objective was defined to maximize or minimize displacement. As a naval architect, with a simple ship like a bulk carrier, one would expect if one minimizes displacement, they would get a very short ship close to the minimum, and if one maximizes displacement, they would get a long ship close to the maximum. Included below are the contraction results for the queries. In this case, a higher probability indicates a higher likelihood of a ship with that given length.

**Figure 5:** Input Output Tensor Network Contraction Result from Gradient-Based Optimization Data with Objective of Minimizing Displacement with External Leg on Length

As expected, the results from performing the contraction indicate that the smallest ship is the most probable. The contraction from the Monte Carlo data set shows some interesting dynamics. The reason for the lack of a single line as in the above figure is due to the Monte Carlo data set having a more limited number of feasible solutions in the shorter length range. However, it can be noted that the trends and behavior between the data are the same and that the Monte Carlo data has a higher level of fidelity due to the increased number and range of coverage of the points. This behavior can be seen in the figure below.

**Figure 6:** Input Output Tensor Network Contraction Result from Monte Carlo Data with Objective of Minimizing Displacement with External Leg on Length

Further, one can investigate the results of maximizing the displacement instead of minimizing it. Included below again are

figures of the same contraction from the optimization data set and the Monte Carlo data set.

**Figure 7:** Input Output Tensor Network Contraction Result from Gradient-Based Optimization Data with Objective of Maximizing Displacement with External Leg on Length (Left) and Input Output Tensor Network Contraction Result from Monte Carlo Data with Objective of Maximizing Displacement with External Leg on Length (Right)

One can see from these contractions that the trends and behavior between the data are the same and that the Monte Carlo data has a higher level of fidelity. Additionally, one interesting behavior can be noted. As a naval architect, one would expect if one maximizes displacement they would get a long ship close to the maximum length. However, this is not the case in either of the contractions. In both, the most probable lies approximately 50 meters shorter than the maximum length. This result does not logically make sense. To investigate the reasoning for this, several other contractions using the other developed tensor networks were performed.

The next set of contractions performed to investigate the findings from maximizing the displacement was looking at the constraint activation across the solution space. One would naturally think that based on the behavior seen above one of the constraints is probably binding. Included below is a sample contraction of the constraint activation network with multiple external legs. The contraction shows the relation of the constraint state of non-binding, near binding, or binding to the entire state space. In the following contractions, the color bar on the right of the plot indicates the probability value for the contraction. In this case, the displacement was maximized and again similar behavior to the previous set of contractions can be seen. The constraint referred to in the contraction is the length-to-beam constraint detailed in Eq. 38.

**Figure 8:** Constraint Activation Tensor Network Contraction Result from Monte Carlo Data with Objective of Maximizing Displacement with External Legs on Constraint 1 and Length

From the figure above, it can be noted that over the majority of the state space, the constraint is non or near binding but not binding. While the above figure supports the conclusions, it does not provide insight into the behavior of solutions when maximizing displacement. To provide insight, more contractions were performed. Some interesting results were found from the draft constraints over the solution space. The following contractions are of the same contraction of the constraint activation network just with different external legs. The constraint referred to in the contraction is the draft constraint detailed in Eq. 41.

**Figure 9:** Constraint Activation Tensor Network Contraction Result from Monte Carlo Data with Objective of Maximizing Displacement with External Legs on Constraint 4 and Length with  $\lambda = 1$

In the above contraction, one can notice the behavior of interest. In the contraction's result, it looks like a barcode for each of the states of the constraints. To investigate the meaning of the result, the value of  $\lambda$  was increased to see if the critical temperature had an impact. The figure below demonstrates the results.

**Figure 10:** Constraint Activation Tensor Network Contraction Result from Monte Carlo Data with Objective of Maximizing Displacement with External Legs on Constraint 4 and Length with  $\lambda = 3$

From the figure above it can be seen that the lower probability values become more muted and the same behavior of the near binding and binding states can be observed. Largely, a higher value of  $\lambda$  suggests that the behavior of a system is more known. In terms of the probability distribution seen, the higher  $\lambda$  highlights the underlying or grounding behavior of the contraction. In addition to performing the contraction with an external leg on length, the same contraction was performed with an external leg on draft.

**Figure 11:** Constraint Activation Tensor Network Contraction Result from Monte Carlo Data with Objective of Maximizing Displacement with External Legs on Constraint 4 and Draft with  $\lambda = 1$

The results from the contraction in the figure above can largely be seen showing the same behavior as that from the contraction of the same constraint but in relation to the length. Upon further investigation, one can notice that at each small range of states for the length and the draft, the constraint is going from non-binding to near binding and then to binding. This is the reason for not being able to achieve large vessels with the tool. What is happening is that as the design tool tries to increase the size of the vessel, the deadweight increases and causes the draft constraint to bind. This in turn forces smaller vessels and is exaggerated at that upper limit. It can also be noted that a second draft constraint also exists in the code seen in Eq. 42. However, this constraint is not dominant and does not impact the solutions in the same way as in Eq. 41. The origins of this constraint are largely unknown and it is assumed that it is most likely from older regression data of bulk carriers when the code was developed. In the Sen and Yang bulk carrier tool, deadweight is known to be the main driving variable, and as a result, directly impacts the allowable size of the vessel through the draft constraint. To check this, the deadweight limit was increased to see if the solution space changed. To see the change, a Monte Carlo data set was created for the increased deadweight limit. A contraction was then performed on the input to output relation network and an external leg was placed on length. The following figure can directly be compared to Fig. 7.

**Figure 12:** Input Output Tensor Network Contraction Result from Monte Carlo Data with Objective of Maximizing Displacement with External Leg on Length with Deadweight Constraint Upper Limit Increased to 800,000

From performing the contraction above and increasing the deadweight constraint upper limit to 800,000 tons, it can be seen that the peak shifted to the right. The peak value sits around 473 m in length which is a large increase from that of the contraction with the deadweight constraint upper limit set to 500,000 tons. This shows that it is a combination of the deadweight and the draft constraint that is limiting the size of the vessel. In other words, the model is ontologically committed to deadweight and the draft constraint in Eq. 41. Without tensor networks, discovering this behavior and the reasoning would be extremely difficult and time-consuming, whereas with tensor networks, performing the contractions only takes seconds.

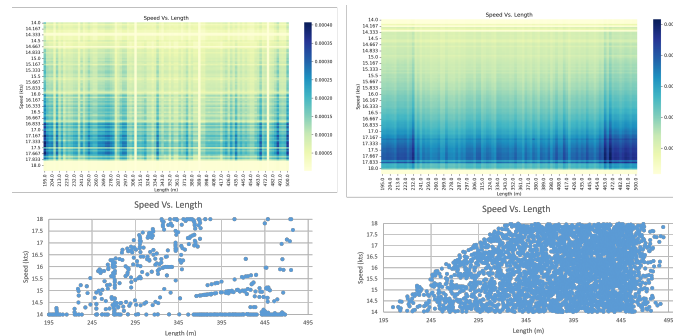

## DISCUSSION

The following section provides a discussion of the results presented above. To verify the results in Fig. 7 the Sen and Yang bulk carrier model was run as a single objective optimization with each of the three objectives in the formulation presented in this manuscript having equal weighting. The optimization was run five times using multiple different optimization algorithms in MATLAB. The results are included in the figure below. The red lines indicate the solution from the optimizer plotted in Fig. 7 or in the case of the genetic algorithm the range of optimal solutions found.

**Figure 13:** Feasible Length from Running fmincon Equal Weighting Single Objective Sen and Yang Bulk Carrier Optimization (Left) and Feasible Length Range from Running GA Equal Weighting Single Objective Sen and Yang Bulk Carrier Optimization (Right)

In both of the cases presented above, the single objective optimization with the objective of maximizing displacement provided solutions close to that found from the tensor network contractions. These results from running the tool as a single objective optimization support the findings in the result section and validate the peak value found. In the results presented in the section above most of the contractions were performed on the data set from the Monte Carlo simulation instead of the optimization data. It was found that both data sets had the same behavior and that the Monte Carlo just provided higher fidelity. The figure below shows this between the two data sets.

**Figure 14:** Comparison of Tensor Network Contraction Result and Data from Monte Carlo and Gradient-Based Optimization Data with Objective of Maximizing Displacement with External Legs on Length and Speed

From the figure above it is clear that the Monte Carlo data set provides a better picture of the solution space. Many of the gaps seen in the optimization data are filled from the Monte Carlo data. Another interesting point to note is that when looking at the data plotted on its own, the trends seen in the data support the conclusions derived from the tensor network contractions.

**Figure 15:** Population of Feasible Solutions Plotted Over Length Solutions Overlaid by Draft

**Figure 16:** Draft Constraint Eq. 41 Versus Deadweight Overlaid by Draft (Left) and Deadweight Versus Length Grouped by Beam Overlaid by Draft (Right)

From the three figures included above, very distinct populations of solutions can be seen in relation to the length, draft, and deadweight. This suggests constraint or function is heavily impacting feasible solutions. This result can especially be seen in Fig. 16 where there is almost no mixing of different draft populations. One would largely expect there to be mixing in the solutions. These plots support the conclusions found from the contractions presented in the results section of this manuscript.

Through the results found and detailed from the presented case study some interesting insights can be made when looking at the case study from an ontological lens. From the presented results, one can directly see that the optimization model for the bulk carriers is highly committed to deadweight and the identified draft constraint. What this means is that the solutions of the model are predicated on these commitments. This was directly shown by how the set of solutions changed when the deadweight was increased. In the case of the draft constraint discussed earlier in this manuscript, there is an explicit commitment to the constraint from its inclusion in the model, but there is also an implicit commitment to the unknown origin or meaning of the constraint. These simple commitments to the deadweight and the discussed draft constraint significantly impact the optimization and the results that are possible to be obtained from the optimization. The insights from this analysis are more than what one could get from a Design of Experiments analysis and it is much more efficient in terms of finding the information necessary to be able to make similar conclusions.

## CONCLUSIONS

In conclusion, the application of tensor networks to the Sen and Yang bulk carrier model has shed light on the intricate relationships between design variables, operational constraints, and performance objectives that are often challenging for traditional optimization methods to capture. The results from the case study highlight the unique capabilities of tensor networks, rooted in quantum physics, to effectively model state relationships within multidimensional data structures.

The analysis of the bulk carrier synthesis and optimization through tensor networks has allowed for the simultaneous examination of multiple constraints and their interactions using the state space representation. This holistic approach has proven invaluable in unraveling hidden relations within the Sen and Yang model, particularly when attempting to maximize displacement while navigating the complex behavior of the draft constraint.

The presented methodology, which involves converting the optimization problem into multiple tensor network representations and implementing tensor network algorithms, demonstrates the practical efficacy of this approach. The implementation results not only showcase the capacity of tensor networks to provide a deep, data-driven understanding of complex optimization landscapes but also emphasize their potential to uncover novel decision-making opportunities.

As one reflects on the outcomes of this study, it becomes evident that tensor networks offer a promising avenue for addressing the challenges posed by intricate and interconnected optimization parameters in the maritime industry. By providing insights that complement traditional optimization analysis techniques, tensor networks contribute to a richer understanding of optimization landscapes. The findings presented in this paper serve as a catalyst for further exploration of tensor network methodologies in tackling complex optimization challenges across diverse domains. Ultimately, this research opens new horizons for innovative decision-making support processes and underscores the transformative potential of tensor networks in the realm of optimization. There are many opportunities for future work in creating general, easily applicable frameworks for diverse optimizations and engineering design tools.

# C-ShipGen: A Conditional Guided Diffusion Model for Parametric Ship Hull Design

Noah J. Bagazinski<sup>1\*</sup> and Faez Ahmed<sup>2</sup>

## ABSTRACT

Ship design is a complex design process that may take a team of naval architects many years to complete. Improving the ship design process can lead to significant cost savings, while still delivering high-quality designs to customers. A new technology for ship hull design is diffusion models, a type of generative artificial intelligence. Prior work with diffusion models for ship hull design created high-quality ship hulls with reduced drag and larger displaced volumes. However, the work could not generate hulls that meet specific design constraints. This paper proposes a conditional diffusion model that generates hull designs given specific constraints, such as the desired principal dimensions of the hull. In addition, this diffusion model leverages the gradients from a total resistance regression model to create low-resistance designs. Five design test cases compared the diffusion model to a design optimization algorithm to create hull designs with low resistance. In all five test cases, the diffusion model was shown to create diverse designs with a total resistance less than the optimized hull, having resistance reductions over 25%. The diffusion model also generated these designs without retraining. This work can significantly reduce the design cycle time of ships by creating high-quality hulls that meet user requirements with a data-driven approach.

## KEY WORDS

Hull Design   Generative Artificial Intelligence   Diffusion Model   Design Constraint Satisfaction   Drag Reduction

## INTRODUCTION

Generative artificial intelligence has shown to be a promising tool for engineering design. By training models on engineering datasets, generative models have created designs with high performance. These tools are particularly useful in ship design, as the complexity of balancing competing trade-offs in a ship requires long design cycles for human design teams. A hull's shape affects several key aspects of a ship's performance, including buoyancy, upright stability, hydrodynamics, and general arrangements. A generative model specifically trained to generate ship hulls can improve this workflow by creating high-quality designs quickly and inexpensively. The availability of open-source datasets on ship hull designs enables the use of generative artificial intelligence for design. This work builds on prior work, a guided diffusion model called *Ship-Gen* (Bagazinski and Ahmed, 2023a).

Hull design was chosen as the application for this work as hulls have a direct impact on over 70% of the cost of a ship (Lin and Shaw, 2017) and they are the first step in the traditional workflow for ship design (Evans, 1959). Ship hulls can exist

across many length scales, ranging from a few meters to over three hundred fifty meters in length. In addition, hulls can exhibit large ranges in relative dimensions such as the beam, draft, depth, and volume displacement. A well-designed generative model for hull design should consider the scale and diversity of ship hulls in its training. This would allow the generative model to create ship hulls based on a designer's needs.

This work proposes a model called C-ShipGen, which generates early-stage hull designs considering a designer's inputs: length, beam, draft, depth, volume displacement, and intended velocity. C-ShipGen is a conditional diffusion model that implements guidance algorithms to create ship hull designs with low resistance while constraining to a user's desired principal characteristics. Figure 1 shows an overview of C-ShipGen, highlighting how the model utilizes a combination of input conditioning and guidance algorithms during the design sampling process. The following sections detail prior research on generative artificial intelligence for engineering design and computational ship design; the methods for training and sampling hull designs with C-ShipGen; the evaluation of hulls generated by C-ShipGen; and a discussion on the work. C-ShipGen generates ship hulls with low resistance for future design analysis. These generated hulls do not necessarily resemble real-world ship hulls as many other factors influence the design of hulls in addition to total resistance. Through the development of C-ShipGen, the contributions of this paper are:

1. The use of a conditional diffusion model to generate diverse ship hulls within a 5% volume error tolerance given desired principal characteristics across the full spectrum of hull sizes and relative dimensions found in real-world hull designs.
2. The use of guidance in a conditional diffusion model to generate hulls with lower total resistance than optimized hulls, having resistance reductions greater than 25% while maintaining the displaced volume within 5% of a target.

**Figure 1:** C-ShipGen is a guided conditional diffusion model that generates hull designs with low resistance while maintaining the principal dimensions provided by the user during sampling. The model leverages guidance gradients from pre-trained regression models to improve the performance of the hulls.

## PRIOR WORK

Computational ship design refers to the application of computer-based modeling, simulation, and optimization techniques in the design and analysis of marine vessels. This facilitates more efficient, innovative, and integrated design solutions. Historically, computational ship design can be divided into three categories: design representation, forward modeling which includes surrogate regression models, and inverse design or synthesis, which includes optimization methods. Recently, generative artificial intelligence methods have emerged as a powerful technique, which has been used to represent and synthesize ship hull designs.

In order to computationally design a product, a design representation is needed that allows a computer to manipulate the design. For ship design, the two most popular modes to represent the design of a ship hull are parameterized vectors (Brown and Salcedo, 2003; Feng et al., 2022; Read, 2009; Zhang et al., 2018; Chrismianto and Kim, 2014; Lu et al., 2016; Knight et al., 2014, 2015; Hodges et al., 2022; Bagazinski and Ahmed, 2023a) and free form deformation techniques (Wang et al., 2022; Ao et al., 2021, 2022; Peri et al., 2001; Demo et al., 2021; Abbas et al., 2023). With a design representation, a dataset of designs can be created by calculating or simulating performance metrics for each design. With the dataset, data-driven models can be trained to make inferences on new designs. For ship design specifically, the works of Khan et al. (Khan et al., 2022b,a, 2023), Shaeffer et al. (Shaeffer, 2023; Shaeffer et al., 2020), and Bagazinski et al. (Bagazinski and Ahmed, 2023a) have looked at various methods to create diverse design spaces and datasets for ship hull design.

With a dataset of designs and performance metrics of a hull as inputs, data-driven surrogate models, using methods such as neural networks, provide a computationally inexpensive way to predict performance. Significant research has been done on predicting the hydrodynamics of hulls with neural network-based surrogates due to the high cost of performing computational fluid dynamics simulations (Ao et al., 2021, 2022; Khan et al., 2022a,b; Peri et al., 2001; Read, 2009; Lu et al., 2016; Feng et al., 2022; Wang et al., 2022; Marantes and Maki, 2021; Silva and Maki, 2023).

Generative artificial intelligence models are designed to create new content or data that resemble the input they were trained on. These models can produce a wide range of outputs, from text to images, and even complex design structures. In the context of ship design, datasets facilitate quick performance predictions and serve as a foundation for training generative artificial intelligence models to innovate in hull design. Prior work has explored various generative approaches, including variational autoencoders (Hodges et al., 2022), generative adversarial networks (Yonekura et al., 2023; Khan et al., 2023), and diffusion models (Bagazinski and Ahmed, 2023b), each contributing uniquely to the field.

Diffusion models, in particular, iteratively modify a noisy data vector over many specified steps. This transforms random data to mirror the statistics of training data (Ho et al., 2020). The development of diffusion models has shown that they can generate complex data and already have applications for engineering design. For example, diffusion models were shown to create higher quality images compared to generative adversarial networks (Ho et al., 2020). Subsequent advancements in diffusion models introduced guidance, where gradients from a classifier neural network guide image synthesis to match a specific image classification label (Dhariwal and Nichol, 2021). This evolution enabled text-to-image diffusion models that employ text-based guidance to craft custom, lifelike images (Ramesh et al., 2022; Rombach et al., 2022). Guided diffusion models have found applications in generating 3D shapes from image data (Liu et al., 2023). In addition, guided diffusion can be applied to engineering design generation. For example, guided diffusion has been used to create two-dimensional structures (Mazé and Ahmed, 2023; Giannone et al., 2023b,a), room layouts (Ploennigs and Berger, 2023), thermometers (Yang et al., 2023), architected materials (Lew and Buehler, 2023), and vehicles (Arechiga et al., 2023). A notable advantage of diffusion models is their adaptability, allowing the incorporation of new design constraints or objectives without necessitating retraining the entire model. This attribute is particularly beneficial for iterative design processes, where continuous adjustments are essential for optimizing performance.

The work presented in this paper builds on the prior work in training diffusion models for hull design. A prior model called *ShipGen* can generate parametric ship hull designs that have 91.4% lower wave drag and 47.9x higher internal volume on average compared to the original training data (Bagazinski and Ahmed, 2023b). *ShipGen* implements seven different guidance models to create these designs. A major shortcoming of this model is that there is no control to generate desired principal characteristics in a hull design, such as length, beam, draft, depth, and displacement. All hull designs generated by *Ship-*

*Gen* are purely influenced by the guidance models and not by a human designer. This makes *ShipGen* impractical for some real-world design applications, where designers may seek more freedom in imposing constraints. To address this gap, we propose a model that utilizes an additional feature called conditioning, where the diffusion model is given a hull design's principal characteristics during training. This way, the diffusion model will generate designs that satisfy the principal characteristics provided by a designer during sampling. The following subsections detail this improvement and showcase a few design applications with this diffusion model.

## METHODS

This section outlines the methodology for developing C-ShipGen (Conditional *ShipGen*). The first subsection explores the training dataset of ship hulls, including formulae for geometric and performance measurements of the dataset hulls. The second subsection details the model training for the regression models used in this study. The third subsection details training and sampling with a conditional diffusion model. The fourth subsection details the methodology for analyzing designs generated with the diffusion model.

### Dataset

To train the regression and generative models, a dataset of ship hulls and their respective performance metrics was created. The training dataset consists of 82,168 parametric ship hull designs. These dataset hulls were derived from the following sources:

- 30,000 hulls from the *Ship-D* dataset (Bagazinski and Ahmed, 2023a)
- 41,752 hulls generated using *ShipGen* (Bagazinski and Ahmed, 2023b)
- 10,416 hulls subset from the former *ShipGen* hulls with the addition of randomly parameterized bulbous bows and sterns

These parametric hull designs are represented with a forty-five-parameter scheme that algebraically defines the hull's surface. The *Ship-D* hulls cover the full design space possible with the parametric design scheme. The *Ship-D* hulls do not represent realistic-looking or performing hullforms. The hullforms, however, provide a large diversity of feature combinations that encompass realistic hull designs for machine learning applications (Bagazinski and Ahmed, 2023a). A few examples of the *Ship-D* dataset hulls are shown in Figure 2. Using the initial 30,000 *Ship-D* hulls, a guided tabular diffusion model called *ShipGen* was trained to generate high-performing hull designs. The mean performance of the 41,752 *ShipGen* hulls and the mean performance of the 30,000 *Ship-D* hulls was calculated and non-dimensionalized. Comparatively, the generated *ShipGen* hull designs have a mean wave drag that is 91.4% lower and a mean internal volume that is 47.9x higher than the mean performances found among the *Ship-D* dataset hull designs (Bagazinski and Ahmed, 2023b). A selection of *ShipGen* hulls is shown in Figure 3. The *ShipGen* hulls are much more representative of realistic hull designs compared to the *Ship-D* hulls. Among the *ShipGen* hulls, it was observed that few were generated with bulbous bows and bulbous sterns, a feature that can reduce the drag on hulls when designed well. To increase the presence of bulbs in the training dataset, bulbs were added to 10,416 hulls by randomly sampling the design parameters for bulbs. These bulbs were not tuned for hydrodynamic performance. Only a smaller subset of the *ShipGen* hulls were selected for bulbs as these were the hull designs that allowed for the generation of feasible bulb designs.

The feasibility of hulls is calculated using a set of forty-nine algebraic constraints. These constraints ensure that a parametric hull surface is watertight and non-self-intersecting. These algebraic constraints are solved with the parameter values for a given hull design without generating the hull's surface, reducing the total computation time. Full documentation of the hull design parameters and constraints is provided at <https://decode.mit.edu/projects/ShipGen/>.

**Figure 2:** A selection of hulls from the *Ship-D* dataset, showing the variability possible with the hull parameterization. A random sampling from the dataset may lead to unrealistic hulls, containing combinations of features that do not resemble real-world ships and features that lead to poor performance.

**Figure 3:** A selection of hulls generated with multi-objective guided performance generation. Notice the relative slenderness of the hulls leading to drastically reduced drag coefficients relative to the *Ship-D* dataset hulls.

### Measures of Hull Geometry

In addition to the parametric hull designs, the dataset includes geometric measures for each hull. The displaced volume, wetted surface area, and waterline length were calculated at 100 evenly spaced draft marks across the depth of each hull. To generate designs regardless of scale, these geometric measures are scaled using the first parameter in the hull representation: length overall, or *LOA*. The equations for the normalized volume, surface area, and waterline length are provided in Equations 1, 2, and 3.

$$V_{t*} = \left( \frac{\int_0^{T/D=t*} \delta V(z) \delta z}{LOA^3} \right) \quad (1)$$

$$SA_{t*} = \left( \frac{\int_0^{T/D=t*} \delta SA(z) \delta z}{LOA^2} \right) \quad (2)$$

$$WL_{t*} = \left( \frac{X_{fwd}(t*) - X_{aft}(t*)}{LOA} \right) \quad (3)$$

In each equation, *LOA* scales the value based on its dimensionality:  $LOA^n$ . The other terms,  $t^*$  is ratio of draft,  $T$ , to depth,  $D$ . During model training,  $t^*$  will be used as an additional embedding to hull shape to predict the geometric measures of a hull at a specific draft mark.

### Calculation of Total Hull Resistance

In addition to the geometric measures of each hull, the total resistance of each hull is calculated for many speed and draft conditions. Total resistance,  $R_T$  is estimated to be the sum of wave-making resistance,  $R_w$ , and skin friction resistance,  $R_f$ , as seen in Equation 4. Wave drag calculations were computed using Michell's integral. Michell's integral was chosen as the simulation for this study as it considers the full 3D geometry of a hull in the total resistance prediction while being computationally inexpensive to calculate. In practice, any fluid simulation would work for this study as the methodology of training generative models is the same. For this study, 2.6 million fluid simulations were performed using the Michell integral. The Michell integral balances the need for accurate simulation data with reduced computational cost of performing the simulation. For this study, thirty-two wave drag coefficients for each hull across four different drafts and eight velocity conditions. The four drafts are  $t^* = 0.25, 0.33, 0.50$ , and  $0.67$ . The eight velocity conditions are normalized using Froude

scaling as seen in Equation 5, where  $g$  is gravitational acceleration,  $U$  is the ship's speed, and  $WL_{t*}$  is the non-dimensional waterline length for a given draft. In the denominator,  $WL_{t*}$  is multiplied by  $LOA$  to balance the dimensions of  $U$  and the denominator.

$$R_T = R_w + R_f \quad (4)$$

$$F_n = \frac{U}{\sqrt{gWL_{t*}LOA}} \quad (5)$$

The eight ship speeds are scaled between  $F_n = 0.10$  and  $F_n = 0.45$  in increments of 0.05, corresponding to typical operating conditions of traditional displacement hulls (Zubaly, 1996; Newman, 2018). Given the 3D surface of a hull submerged to  $t^*$  and a velocity,  $U$ , the wave-making resistance is calculated with Equation 6.

$$R_w = \frac{A\rho g^2}{\pi U^2} \int_1^\infty (I^2 + J^2) \frac{\lambda^2}{\sqrt{\lambda^2 - 1}} d\lambda \quad (6)$$

where  $\rho$  is the density of water, and  $A$ ,  $I$ , and  $J$  are integrated terms relating to the surface normal across the hull and the direction of wave propagation. Further insight into these terms is in Michell's paper from 1898 (Michell, 1898). With these thirty-two wave drag measurements, a given hull's wave-making resistance for a given  $t^*$  and  $F_n$  is interpolated between these calculations.

Skin friction resistance is calculated using the ITTC-1957 formula in Equations 7 and 8.

$$C_f = \frac{0.075}{(\log(Re) - 2)^2} \quad (7)$$

$$R_f = \frac{1}{2} C_f \rho U^2 SA_{t*} LOA^2 \quad (8)$$

The Reynolds number of the hull,  $Re$ , scales with forward velocity,  $U$ , and waterline length,  $WL_{t*}$ .  $SA_{t*}$  is the non-dimensionalized wetted surface area of the hull for a given draft. Together,  $R_w$  and  $R_f$  can be used to calculate the coefficient of total resistance,  $C_T$ . To learn with the dataset,  $C_T$  is scaled by  $LOA^2$  as opposed to the more traditional use of wetted surface area. This was done so that a regression model can embed  $LOA$  and  $t^*$  to predict  $C_T$  without explicitly providing  $SA_{t*}$ . Additionally,  $C_T$  is on a logarithmic scale so that the distribution of  $C_T$  is approximately Gaussian for model training. The calculation of  $C_T$  is provided in Equation 9.

$$C_T = \log_{10} \left( \frac{R_w + R_f}{\frac{1}{2} \rho U^2 LOA^2} \right) \quad (9)$$

With this representation,  $C_T$  will be predicted using the 45 design parameters,  $t^*$  for a draft embedding, and  $F_n$  for a speed embedding. The predicted coefficient of total resistance,  $\hat{C}_T$ , can then be scaled to a prediction of total resistance.  $\hat{R}_T$  with Equation 10.

$$\hat{R}_T = 10^{\hat{C}_T} \frac{1}{2} \rho U^2 LOA^2 \quad (10)$$

The following subsection will detail training the regression models and the diffusion model with a dataset made from these equations.

## Regression Modeling with Neural Networks

Using neural networks, four regression models were trained with the dataset: displaced volume, coefficient of total resistance, waterline length, and design feasibility. A trained neural network for regression provides two key benefits for computational design. The first benefit is a fast prediction of performance directly from design parameters. The second benefit is the ability to calculate the gradient of a performance metric with respect to the design parameters. This subsection will detail the process of training the regression models.

Following prior work, the forty-four (not including  $LOA$ ), design parameters are quantile normalized and then scaled between -1 and 1 (Bagazinski and Ahmed, 2023b). Quantile normalization bins values of the design parameters so that the distributions of the design parameters are approximately Gaussian. This parameter scaling improves the diffusion model training. Scaling the parameters for the regression models allows them to work in conjunction with the diffusion model during sampling. This process, called guidance, will be described in the following subsection.

The process for training the coefficient of the total resistance regression model is described in Table 1. In the algorithm, the neural network is represented as  $P_{C_T}$ . The inputs to the regression model are a quantile normalized design vector,  $X_i$ , a draft embedding,  $t_*$ , a speed embedding,  $F_n$ , and a length embedding,  $\log(LOA)$ . The loss function is the mean-squared error loss between the ground truth and the prediction of  $C_T$ . The draft and speed embeddings are restricted to the limits of the range of draft and Froude numbers used in the dataset calculation of wave-making resistance. The length embedding is on a logarithmic scale for hulls with a length between 3 meters and 450 meters. This range of values allows the model to learn the relative influence of skin friction across velocity and length scales. Given the diversity of hull forms in the dataset and the range of length scales, this regression model is trained to predict the coefficient of total resistance on a large diversity of shapes, speeds, and sizes. This model was trained with a batch size of 1024 for 50,000 batches. The resistance prediction model predicts the total resistance coefficient across the full spectrum of the dataset hulls, draft ratios, and Froude numbers. This regression model predicts the total resistance coefficient derived from the simulation with an  $R^2$  of 0.997. Results of the training accuracy relative to the simulation data are shown in Figure 6 and Figure 8.

---

**Table 1:** The training algorithm for the total resistance coefficient regression model. The algorithm randomly samples a Froude number and draft ratio for a hull in each batch so the model is trained on a full spectrum of speeds and drafts for the hulls in the dataset.

The training for the volume regression model,  $P_V$ , and the waterline regression model,  $P_{WL}$ , is similar. The volume regression model was trained to predict  $\log(V_{t_*})$  given  $X_i$  and  $t_*$ . The model was trained to predict the logarithm of volume as this term has an approximate Gaussian distribution across the dataset. Similar to the  $C_T$  regression model, the volume regression is trained to predict the displaced volume for any draft on a large diversity of hullforms. The waterline regression model predicts the waterline length of a given hull at a given draft. This model is used with the coefficient of total resistance regression model when  $WL_{t_*}$  is unknown.

The final regression model is a feasibility classifier,  $f_\phi$ . The feasibility classifier provides guidance gradients to influence the diffusion model to generate parametric designs that satisfy the forty-nine algebraic feasibility constraints (Bagazinski

and Ahmed, 2023b). The only input to the feasibility classifier is a design vector,  $X_i$ . To learn the distinction between feasible and infeasible designs, a set of 82,793 design vectors that violate at least one constraint was generated. The loss function in training was binary cross-entropy loss, which is better for classifier training than mean-squared-error loss.

## Conditional Diffusion Model

A diffusion model is a generative artificial intelligence model that generates new instances of data by denoising random information over many steps. The generated sample will fall within the statistical distribution of the training dataset samples. Conditional diffusion models are similar to the standard diffusion model described by (Ho et al., 2020), however, their structure includes extra layers that embed information in the training and sampling process. This conditional diffusion model is a modified version of the *ShipGen* model, a tabular diffusion model for ship hull design (Bagazinski and Ahmed, 2023b). The conditioning for the model is the principal characteristics of the hull: draft, beam, depth, and displaced volume. The diffusion model and the conditioning use parameters that are scaled by the length overall, which is the first term in the forty-five parameter representation used to generate the hull designs. After sample generation, the parameter terms are re-scaled by *LOA* to measure the scaled design. By training with parameters scaled with respect to *LOA*, the model does not have to learn “length” in addition to the statistical relationships between the parameters to generate a hull design. This reduces the complexity of the learning task. The training algorithm for the conditional diffusion model is stated in Table 2 and illustrated with Figure 4.

**Figure 4:** During training, the diffusion model predicts a denoising step, given a timestep embedding and a partially noised sample design vector. The model is informed by the input conditioning at each denoising step.

The diffusion model is conditioned with the draft,  $t^*$ ; volume,  $V_{t^*}$ ; Beam,  $B$ , and depth,  $D$  of each hull. During training, the original design vector is partially noised to a timestep,  $t$ , and the conditional diffusion model predicts the noise of the sample at that timestep. Conditioning is applied to the diffusion model to influence the denoising process to satisfy input conditioning. To clarify in the algorithm,  $t$  is the timestep embedding of the denoising process, while  $t^*$  is the draft embedding of the hull design in the conditioning vector.

After training, the diffusion model can be sampled to create design vectors that satisfy the input conditioning. While the diffusion model can generate hull designs that satisfy the input conditioning, the sampling process does not consider the total resistance of the hull. To generate hulls with reduced total resistance, the total resistance coefficient regression model is implemented in the sampling process as a guidance algorithm. Guidance leverages the gradients of the regression model

**Table 2:** This is the training algorithm for a conditional diffusion model. The diffusion model is represented by the function  $\epsilon_{\theta}(X_0, \epsilon, t, C)$  in step 8. The conditioning for hull design is the draft,  $t^*$ ; displaced volume,  $\log(V_{t^*})$ ; beam,  $B$ ; and depth,  $D$ , of the hull,  $X_0$

at each timestep to influence the denoising process toward producing designs with reduced total resistance. In addition to resistance guidance, the feasibility classifier and the volume prediction regression models are also used as guidance. The feasibility classifier aims to improve the likelihood that a generated design vector leads to a feasible hull design. The volume guidance assists the diffusion model in generating a design that satisfies the input conditioning for displaced volume. This was implemented to prevent the resistance guidance from over-influencing the sampling process and producing hulls that do not satisfy the input conditioning. Each guidance algorithm is tuned with a hyperparameter:  $\gamma$  tunes the classifier guidance, while  $\lambda_0$  and  $\lambda_1$  tune the performance guidance. The sampling process is illustrated in Figure 1. The sampling algorithm is stated in Table 3.

8:	<b>end for</b>
9:	<b>return</b> $X_0$

---

**Table 3:** This is the sampling algorithm for a guided conditional diffusion model. The diffusion model is represented by the function  $\epsilon_{\theta}(X_t, t, C)$  in step 7.

In the sampling algorithm,  $\gamma$  is equal to 0.2, while  $\lambda_0$  and  $\lambda_1$  are equal to 0.3. The performance guidance hyperparameters are set equal so that no model overpowers the others. The  $\lambda$  values are set low so the guidance models do not overpower the denoising process from the diffusion model. One advantage to leveraging performance guidance is that the diffusion model does not need to be retrained to produce designs when considering different objectives. The guidance model can simply be replaced with a new one. Using an *NVIDIA GeForce RTX 4090*, 512 samples are generated in approximately 2.5 seconds. The feasibility check, total resistance calculation, and geometric measurements are computed on a single *Intel Core i9-13900K* core in approximately 2.5 seconds per sample. After sampling, the parallel CPU process across 32 cores for the 512 samples is less than 30 seconds.

Diffusion models rely on a degree of randomness in the denoising process. Sampling from the guided conditional model will not guarantee that every generated design will be high-quality. Therefore, studies on designs generated from the model evaluate the statistics from a set of generated designs. In addition, high-quality designs will be filtered from a set of generated designs to select potential candidates for further design evaluation. This is distinctly different from other data-driven design approaches, such as optimization, which provides some guarantee of design performance and constraint satisfac-

tion among generated designs. Assuming that intended designs fall within the statistical distribution of the training dataset, conditional diffusion models can produce a large diversity of designs without needing to retrain the model, significantly decreasing the computational effort to create high-quality designs compared to optimization methods.

## Evaluation of Diffusion Model for Low-Drag Design

A baseline comparison is needed to evaluate the ability of the guided conditional model to generate high-quality hull designs. Design optimization for drag reduction was selected as the baseline comparison. To conduct the study, five design test cases compare optimized hull forms to diffusion-generated hull forms. The purpose of this test is twofold:

1. Evaluate the diffusion model’s ability to design low-resistance hulls while meeting specific dimensional properties.
2. Evaluate the accuracy of the total resistance regression model for a wide array of designs, scales, and relative speeds.

The five test cases were selected to create a unique set of dimensional requirements for both the design optimization and the diffusion model to satisfy. The designs of real-world ship classes inspired the dimensions of the five test cases. The design inspirations are a supercarrier <sup>1</sup>, a kayak <sup>2</sup>, a NeoPanamax container ship <sup>3</sup>, a frigate <sup>4</sup>, and a ROPAX ferry <sup>5</sup>. These test cases encompass two military-style ships, two large ship designs, one small hull design, two small block coefficient designs, and one high beam-to-draft ratioed hull. The principal dimensions and design speed of the test cases are provided in Table 4.

Test Case	LOA (m)	BOA (m)	T (m)	D (m)	$\nabla$ (m <sup>3</sup> )	$C_B$ (–)	$U_s$ (m/s)	$U_s$ (knots)
Supercarrier <sup>1</sup>	333.0	42.1	11.3	29.6	97,561	0.617	16.0	31.1
Kayak <sup>2</sup>	3.8	0.787	0.15	0.438	0.166	0.372	1.50	2.92
NeoPanamax <sup>3</sup>	366.0	50.0	15.2	40.0	182,114	0.654	10.3	20.0
Frigate <sup>4</sup>	127.0	16.0	6.90	11.0	4,488	0.320	14.4	28.0
ROPAX Ferry <sup>5</sup>	72.0	20.0	3.2	4.8	3,917	0.850	6.17	12.0

**Table 4:** This table provides the dimensions of hull design test cases inspired by real-world ship designs. These test cases cover a diversity of principal characteristics, hull speeds, and length scales.

It is not expected for the diffusion model nor the optimization algorithm to produce designs that look like real-world ship designs with the same principal characteristics. Real-world hull designs satisfy many additional performance objectives in addition to total resistance; such as seakeeping, upright stability, cargo packing, general arrangements, etc. Since these hulls are generated only considering total resistance and principal dimensions, they are not expected to resemble real-world hull designs. For each design test case, 512 hull designs were generated with the full diffusion model, 512 were generated with the diffusion model and classifier guidance only, and 100 designs were generated using design optimization. In each test case, the diffusion-generated designs will be evaluated on drag, dimensional target satisfaction, and design diversity compared to optimized designs.

The optimization algorithm used for these studies is *NSGA-II* (Deb et al., 2002). *NSGA-II* is a state-of-the-art genetic algorithm for optimizing two or more objectives. Genetic algorithms are a set of optimization algorithms that act similarly to biological evolution to drive the optimization over several “generations”. These tests were performed with a population

of 100 samples for 200 generations. The initial population consisted of randomly selected designs from the dataset. For each test case, the optimization algorithm constrains the design parameters to be within 2% of the beam target, 1% of the depth target, and  $\geq 99\%$  of the volume target, while also constraining the design with the forty-nine feasibility constraints to maintain design feasibility. The target draft is held constant, so  $t^*$  is scaled appropriately for each design at each generation during optimization. This provides a buffer for the optimization algorithm to find low-drag designs around the test case targets. In this study, the two objective functions were the total resistance of a hull and the total resistance coefficient of a hull, which were evaluated using the total resistance coefficient regression model,  $P_{CT}$  at the test case's target speed. By leveraging the same regression model in both optimization and diffusion generation, we can directly compare the ability of each design method to produce low-drag designs. The optimization is expected to exploit the regression model, likely finding local minima and not a true minimum. This will be seen as a significant loss in accuracy when comparing predictions from the regression model to the original total resistance simulation. With the combined use of parallelized CPU computation (*Intel Core i9-13900K*) and GPU (*NVIDIA GeForce RTX 4090*), this optimization is performed in approximately 80 minutes per test case.

## RESULTS

This section contains the results of the studies described in the Methods Section. The first subsection provides error measurements of diffusion-generated samples meeting the principal dimensions from the five test cases. The second subsection provides the results by generating low-resistance designs using the conditional diffusion model and the design optimization algorithm.

### Targeted Design Sampling with Conditional Diffusion Model

For each design test case, 512 samples were generated with the full model, and 512 samples were generated with only feasibility guidance,  $\nabla_{X_t} f_\phi(y|X_t)$ . The feasibility rate and adherence to principal dimensions in each test case are provided in Table 5.

Test Case	Model	Feasibility Rate	Volume Error		Beam Error		Depth Error	
			Mean	Std.	Mean	Std.	Mean	Std.
Supercarrier	Full Model	67.77%	-3.17%	8.83%	2.03%	2.98%	-2.14%	1.82%
	$\nabla_{X_t} f_\phi$ Only	88.28%	2.53%	5.97%	1.46%	4.94%	-1.65%	1.82%
Kayak	Full Model	86.91%	0.05%	4.52%	-0.50%	2.75%	-0.45%	1.77%
	$\nabla_{X_t} f_\phi$ Only	95.70%	0.62%	3.50%	0.40%	3.55%	0.06%	1.63%
NeoPanamax	Full Model	71.09%	-2.89%	5.63%	1.41%	3.60%	-0.44%	1.69%
	$\nabla_{X_t} f_\phi$ Only	92.19%	2.26%	4.66%	0.18%	3.74%	-0.01%	1.70%
Frigate	Full Model	91.99%	-0.87%	6.60%	0.22%	8.06%	-0.31%	2.44%
	$\nabla_{X_t} f_\phi$ Only	94.53%	0.83%	6.93%	1.65%	10.27%	0.19%	1.93%
ROPAX ferry	Full Model	58.98%	-16.73%	7.57%	-4.74%	6.78%	-1.02%	1.86%
	$\nabla_{X_t} f_\phi$ Only	88.48%	-2.80%	5.52%	0.38%	7.37%	-0.34%	2.15%

**Table 5:** This table provides the design feasibility rate and principal dimension errors relative to each test case for diffusion-generated samples using the full model and with feasibility guidance only.

The general trend among these test cases is that designs sampled with feasibility guidance only have higher feasibility rates and have tighter adherence to the test case's principal dimensions compared to hulls generated with the full model. This trend is seen in all five test cases. Generated hull designs within a 5% error tolerance will be selected for further design analysis. This tolerance is a reasonable margin for large ship hull designs. A ship's displacement can easily vary by this much through changes in cargo, fuel, water, etc. Sampling with only feasibility guidance yields, on average, 58.3% of hulls

generated within a 5% volume error across the five test cases. Sampling with the full model gives 37.0% of total samples within a 5% volume error tolerance. This measure was calculated with Equation 11 for each design test case.

$$\eta_{E_{V_{t*}}} = \eta_{feasible} \Phi \left( \frac{+5\% - \mu_{E_{V_{t*}}}}{\sigma_{E_{V_{t*}}}} \right) - \Phi \left( \frac{-5\% - \mu_{E_{V_{t*}}}}{\sigma_{E_{V_{t*}}}} \right) \quad (11)$$

In the equation,  $\eta_{E_{V_{t*}}}$  is the percentage of samples within a 5% volume error tolerance. This metric relies on the feasibility rate,  $\eta_{feasible}$ , and the Gaussian cumulative distribution between +5% and -5% error given the mean ( $\mu_{E_{V_{t*}}}$ ) and standard deviation ( $\sigma_{E_{V_{t*}}}$ ) of volume error.

## Drag Reduction with Guidance During Sampling

For each design test case, hull designs were optimized using *NSGA-II* to minimize the total resistance while satisfying the principal dimensions of the test case. After optimization, the total resistance of the 100 optimized hulls was calculated with the Michell Integral. The minimum total resistance calculated with the Michell Integral is listed in Table 6 for each test case. Similarly, the total resistance was calculated for the feasible hull designs among the 512 designs generated for each test case. The feasible hull designs were sorted into groups with volume errors less than 1%, 5%, and 10% relative to the target volume for each design test case. Then, the number of hulls with a total resistance less than the optimized minimum total resistance was collected. The number of these low resistance samples within each volume error tolerance is listed in Table 6. The final column in Table 6 lists the minimum total resistance among the diffusion-generated designs within a 5% volume error tolerance for each design test case. These results will be further analyzed in the Discussion Section.

Test Case	<i>NSGA-II</i> Min. $R_T$ [N]	Model	Number of Low $R_T$ Hulls with $E_{V_{t*}}$			Sample Min. $R_T$ [N]	$\Delta R_T$
			$\leq 1\%$	$\leq 5\%$	$\leq 10\%$		
Supercarrier	7,332,137.7	Full Model	0	5	11	4,883,089.3	-33.4%
		$\nabla_{X_t} f_\phi$ Only	0	1	1		
Kayak	11.18	Full Model	8	50	56	6.98	-37.6%
		$\nabla_{X_t} f_\phi$ Only	1	2	2		
NeoPanamax	3,931,834.1	Full Model	37	157	239	1,220,057.3	-69.0%
		$\nabla_{X_t} f_\phi$ Only	5	23	28		
Frigate	1,177,601.3	Full Model	30	130	178	874,617.0	-25.7%
		$\nabla_{X_t} f_\phi$ Only	26	87	114		
ROPAX ferry	2,512,677.3	Full Model	1	9	41	206,537.0	-91.8%
		$\nabla_{X_t} f_\phi$ Only	42	208	307		

**Table 6:** This table lists the number of feasible, diffusion generated hull designs having a total resistance less than the minimum total resistance found through optimization. The number of hulls with low resistance increases as the volume error tolerance is increased. The final column lists the reduction in total resistance seen by a hull within a 5% volume error generated by C-ShipGen.

In general, as the volume error tolerance is loosened, more diffusion-sampled hull designs will have lower total resistance than the optimized hull design. This trend is seen in samples generated using the full model and among samples generated using only classifier guidance. Additionally, for four test cases, the full diffusion model produces low resistance designs within a 5% volume error tolerance at a rate of 1.5x to 25x more frequently than without using performance guidance. In addition, the full diffusion model generated hulls with at least 25% less total resistance than the *NSGA-II* generated hulls while still aligning to the principal dimensions of each design test case. For the *ROPAX* test case, the diffusion model with only classifier guidance created low-resistance designs with much higher success than the full diffusion model. Further analysis of the test cases can be found in the Discussion Section.

To illustrate the diversity of designs generated by the diffusion model, a two-dimensional principal component analysis

(PCA) was performed with the design parameters from the training dataset, the diffusion-generated designs, and the *NSGA-II* sampled designs. The PCA was fitted with the training dataset. Figure 5 shows this PCA. The diffusion-generated samples maintain a high degree of diversity. This is expected as the diffusion model is trained to randomly generate designs that match the statistics of the training data. The optimized designs, however, are clustered around a single location on the PCA plot, suggesting these samples have low diversity.

After sampling, all feasible diffusion-generated designs and *NSGA-II* generated designs were simulated with the total resistance simulation. This was done to compare the regression model accuracy to the simulation data. Figure 6 shows the total resistance of each hull using both regression and simulation plotted against each other for the supercarrier design test case. The red dashed line shows perfect regression, meaning that the regression predicts the exact simulation. The generated samples show high accuracy with the regression, except for a few outliers. This is expected as the diffusion-generated samples statistically resemble the training dataset. This dataset was used to train both the regression model and the diffusion model. Because diffusion-generated designs will statistically resemble the training data, they should have higher accuracy with the regression model. The hull designs created through optimization are significantly under-predicted compared to the total resistance calculated with the simulation. As mentioned in the methods section, this result was expected as the optimization algorithm exploited the regression model to find a minimum in the model that does exist in the simulation. This trend is seen across optimized hulls from the other four test cases, shown in Figure 8.

To further visualize the resistance across the diffusion-generated samples, a kernel density estimate (KDE) of the distribution of the simulated total resistance is shown in Figure 7. Also included in the plot is the minimum simulated total resistance among hulls sampled with *NSGA-II*. The KDE shows that approximately fifteen percent of diffusion-generated samples for this design test case will have lower total resistance than samples generated with *NSGA-II* using the same surrogate model for drag prediction. This relative trend also appears with the other four test cases shown in Figure 9.

The optimized designs from the ROPAX ferry design test case exhibit the worst regression-simulation similarity among the test cases. The regression prediction for the optimized ROPAX ferry was off by nearly a factor of 10 compared to its simulation-calculated resistance. Further analysis of the error in simulation prediction is in the Results Section.

To exhibit some of the diffusion-generated hull designs, Figure 10 showcases the station lines of hulls from each test case. The Figure showcases the hull design sampled among the 512 with the minimum resistance within the 5% volume error tolerance for each design test case. The total resistance of these hulls is listed in Table 6.

## DISCUSSION

This section provides a discussion of the results of the study. The first subsection analyzes the diffusion model's ability to satisfy the principal characteristics from the design test cases. The second subsection discusses the study on generating low-resistance designs. A third subsection discusses the ROPAX design case study compared to the other design test cases. The final subsection discusses the limitations of the C-ShipGen model in designing real-world hulls.

### Targeted Sample Generation

The study's findings underscore the effectiveness of the conditional diffusion model in generating feasible designs that closely adhere to design requirements. The tolerance to the user-defined principal characteristics decreases when performance guidance is implemented with the model during sampling. Performance guidance reduces the diffusion model's ability to generate hulls within a 5% volume error tolerance by 36%. The next subsection will discuss how performance guidance produces low-resistance hull designs more frequently while maintaining the 5% volume error tolerance.

While not every individual design meets the entirety of the specifications provided by a user during sampling, the diffusion model proves to be a computationally inexpensive tool for producing samples closely aligned with intended principal di-

**Figure 5:** Two-dimensional principal component analysis of the hull parameterization shows the relative distribution between dataset hull designs, diffusion-generated hull designs, and optimized hull designs for the supercarrier test case. The optimized hulls have much less design diversity than the diffusion-generated designs.

**Figure 6:** Comparison of total resistance between simulation and regression for hull designs produced for the supercarrier design test case. The optimized designs have lower regression accuracy than the diffusion-generated designs.

mensions. This characteristic makes it particularly advantageous for early-stage design processes, where loosely following requirements allows for design exploration. The diffusion model produces many diverse designs for further in-depth design analysis. With an efficient down-selection process, many useful hull designs are quickly identified within a user-desired tolerance with C-ShipGen.

## Optimization versus Diffusion Models for Design Generation

Optimization represents a powerful approach to design exploration but has strong advantages and disadvantages. One key strength is the optimization's ability to generate samples within tighter tolerances to user-defined targets. Additionally, the optimization process excels at producing feasible designs with low resistance. On the other hand, design optimization for each test case can be slow and computationally expensive. For *NSGA-II*, increasing the population size increases the time complexity of the algorithm by  $O(N^2)$ . Increasing the number of objectives increases its time complexity by  $O(N)$  Deb et al. (2002). Optimization is limited by the diversity of samples and the computational complexity arising from increasing the number of samples. This inhibits design space exploration in early-stage design. Finally, as seen in the results, optimization exploits regression models, which leads to a loss in accuracy of the optimized design's prediction versus ground truth performance calculated with simulation. In this instance, the loss in accuracy of the total resistance regression surrogate model compared to the simulation leads to sub-optimal hull designs compared to those generated with the C-ShipGen model.

The diffusion model presents a contrasting set of advantages and challenges. The computation to generate designs is signif-

**Figure 7:** Kernel Density Estimate (KDE) of the distribution of the simulated total resistance across the diffusion-generated samples for the supercarrier test case. The distribution shows that some of the generated samples have a total resistance less than the minimum total resistance found using the total resistance prediction as a surrogate model with *NSGA-II*.

icantly faster, allowing more design space exploration and discovery over-optimization methods. Increasing the number of generated samples increases the time complexity of C-ShipGen by  $O(N)$ . Increasing the number of objectives increases the time complexity of C-ShipGen by  $O(N)$ . Secondly, this diffusion model produces new designs without model retraining, which allows significant flexibility in its use. This flexibility permits hull design across all scales of real-world displacement hulls within a large range of typical operating speeds. This flexibility is thanks to the diversity of the samples in the training data. Thirdly, leveraging the total resistance regression model during the diffusion sampling process is particularly advantageous. The regression model and the diffusion model were trained with the same dataset. Since the diffusion model is trained to generate designs with statistical similarity to the training dataset, the regression model has high prediction accuracy for diffusion-generated designs. This similarity between the training data and sampled designs is why C-ShipGen saw a significant improvement in total resistance among generated samples compared to *NSGA-II* using the same total resistance regression model. This trend was seen across the five design test cases in Figure 6 and Figure 8. This accuracy did not hold in optimization-generated designs. In addition, the diffusion model better leveraged the regression model in sampling. This is shown through the proportion of designs in each test case with lower total resistance than the samples generated with *NSGA-II* using the same regression model. Figure 7 and Figure 9 show that depending on the test case, roughly fifteen percent or more of the diffusion-generated samples will have a lower total resistance than samples generated using *NSGA-II*. However, the diffusion model has its own set of limitations. One major flaw is that the generated design needs to be sorted and filtered to identify low-resistance hull forms that meet the input conditioning within a desired tolerance. Additionally, while the diffusion model facilitates rapid design exploration, it does not provide a guarantee of finding an optimal solution, introducing an element of uncertainty into the design process.

Additionally, the diffusion model with performance guidance produces designs within a specified tolerance less frequently than the diffusion model without performance guidance, and even less frequently than optimization. Despite this compromise in tolerable design generation, these designs demonstrate a notable reduction in drag compared to their counterparts without performance guidance. Implementing performance guidance produces low resistance designs at a rate of 1.5x to 25x than the model without the implementation. The simultaneous benefits of lower drag and decreased feasibility highlight the nuanced impact of performance guidance on design outcomes.

## Total Resistance Comparison Between Simulation and Regression

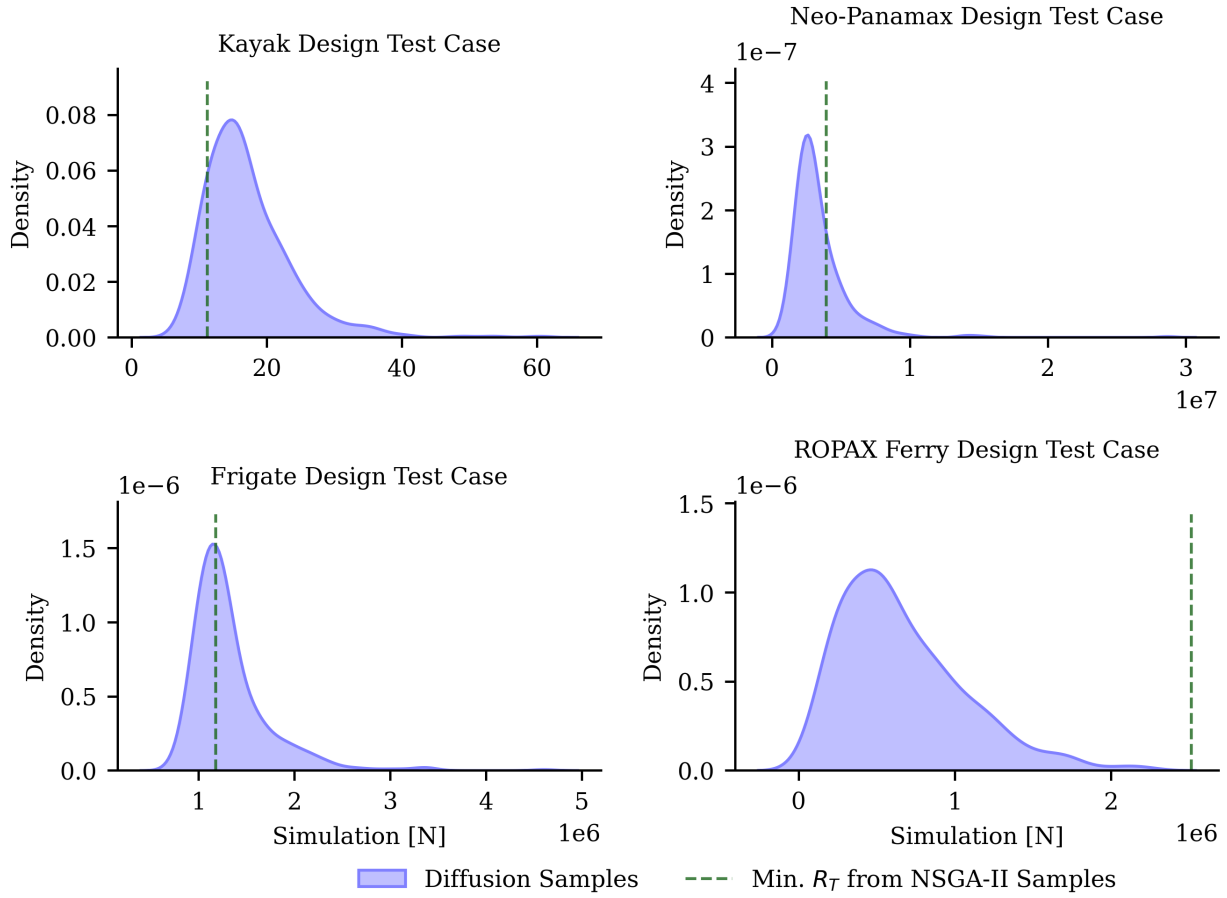

**Figure 8:** Comparison of total resistance between simulation and regression for hull designs produced for the other design test cases. The total resistance of optimized designs is less accurately predicted by the regression model than the diffusion-generated designs.

## Analysis on ROPAX Ferry Design

Despite the general success of the other design test cases, the ROPAX ferry design proved difficult for the diffusion model, the regression model, and the optimization algorithm. This design test case was inspired by a real-world ferry operating in the State of Massachusetts in the United States. This particular hull has a significantly higher length-to-draft ratio, beam-to-draft ratio, and block coefficient compared to other design test cases. These comparisons are also true compared to hulls in the training data. As this design is different than most of the training data, the outcomes of the test case were expected to be poorer. This is particularly true with the total resistance prediction model. The regression model had completely inaccurate predictions of total resistance for the *NSGA-II* generated samples. The diffusion-generated designs also had poor regression accuracy as well. A third consideration with this particular design that is outside the project's scope is that the resistance simulation itself is also highly inaccurate for this design. Michell's integral relies on the assumption that the hull is a slender body (Michell, 1898). The ROPAX design is not necessarily slender compared to the other hulls. A new simulation method is needed to reasonably calculate the drag on a hull design like this one.

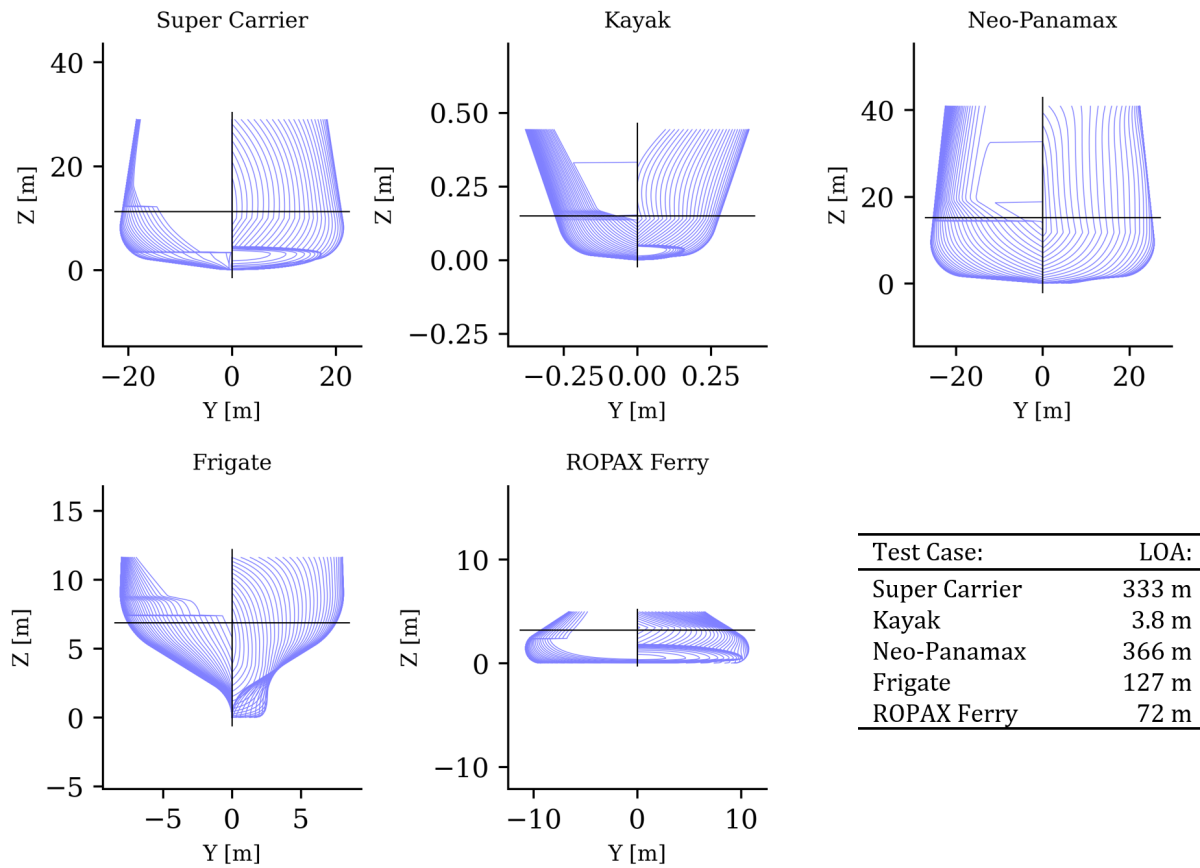

## Distribution of Simulated Total Resistance of Diffusion Samples

**Figure 9:** KDE plots of the remaining four design test cases. The plots showcase the statistical distribution of total resistance among the diffusion-generated samples compared to the *NSGA-II* generated samples. Depending on the test case, 15% or more of the generated samples will have less total resistance than samples produced using *NSGA-II* with the same surrogate model for total resistance prediction.

## Limitations of Hull Design with C-ShipGen

When designing any product with generative artificial intelligence, understanding the model's limitations will avoid negative consequences on real products designed with the model. C-ShipGen has several limitations. The first limitation of this model is the training data. C-ShipGen and other diffusion models generate designs statistically similar to the training data. Since C-ShipGen was trained on hulls that are not necessarily representative of real-world hull designs, C-ShipGen generates hulls that are not necessarily representative of real-world designs. The second limitation of C-ShipGen is the simulation used to generate the total resistance training data. While the Michell integral is not the most accurate simulation for real-world hull design, it was chosen to balance accuracy and computational cost. Creating training data with higher fidelity and more accurate simulations will give these models data with a better representation of real-world hull designs in water. In addition, leveraging more accurate simulations for creating training data will enhance claims of increased performance with generative design. The third limitation of C-ShipGen in its current implementation is that it only considers total resistance and volume displacement for design generation. Real ship hulls are designed considering other performance metrics such as seakeeping, stability, general arrangements, draft limitations, and countless other considerations for hull design.

**Figure 10:** The five hulls depicted are diffusion-generated hulls with the minimum total resistance within the 5% volume error tolerance for each design test case. The cross-section drawings showcase station lines for the bow on the right side and the stern on the left side. Also included is the LOA for each design.

Therefore, hulls designed with C-ShipGen are not necessarily capable of performing safely in the real world without further analysis. These are some of the limitations of the current implementation of C-ShipGen to create hull designs with low total resistance.

## CONCLUSION

This work generated ship hulls with low resistance using a conditional diffusion model that considers the desired principal dimensions of the hull during design generation. This diffusion model is trained on a large set of nearly 83,000 diverse hull designs that allow for a comprehensive design space exploration with the model. In addition, a regression model was trained to predict the total resistance of a hull with variable speed and draft. The gradients of this regression model allowed the diffusion model to generate designs with low resistance. This regression model was also used as a surrogate model to optimize hulls while constraining the designs to user-defined principal dimensions and design speeds. The optimization study was performed using *NSGA-II*. Five design test cases demonstrated the ability of C-ShipGen to generate hull designs across all scales of displacement hulls and many different dimensional properties found in different ship classes. Additionally, C-ShipGen was able to generate designs with greater diversity than *NSGA-II*, while creating designs with better predictive alignment between the regression model and the simulation used in the training data. A proportion of the diffusion-generated designs in each test also had a total resistance less than the samples generated with *NSGA-II*. In all five test cases,

C-ShipGen produced hull designs with at least 25% less total resistance than *NSGA-II* generated samples. An additional advantage of the diffusion model is that the diversity of these designs allows for efficient design space exploration in early-stage design.

Creating hull designs with reduced resistance will reduce the need to fuel ships, reducing the cost to operate the ship and reducing its emissions. Future work with generative artificial intelligence for ship design will continue to explore the systems-level design of ships. Training models to explore the nuanced complexity of designing a ship system can yield better efficiencies and reduce costs for the marine industry. Through this work, the economic prospect of leveraging generative artificial intelligence to design ship hulls is demonstrated by C-ShipGen.

## ACKNOWLEDGEMENTS

This research is funded by the United States Department of Defense, Office of Naval Research, via the National Defense Science and Engineering Graduate (NDSEG) Fellowship program. The authors thank MIT Supercloud for providing some of the computational resources needed to perform this work (Reuther et al., 2018).

## DATA ACCESS STATEMENT

Data, Code, and Trained models for C-ShipGen will be available upon publication at [https://decode.mit.edu/projects/C\\_ShipGen/](https://decode.mit.edu/projects/C_ShipGen/).

## DECLARATION OF GENERATIVE AI AND AI-ASSISTED TECHNOLOGIES IN WRITING

*Statement:* During the preparation of this work the author(s) used OpenAI's *ChatGPT* (version 3.5) and *Grammarly* to reduce word count. After using this tool/service, the author(s) reviewed and edited the content as needed and take(s) full responsibility for the content of the publication.

# Digital Twin-Enabled Response Function Analysis: A Synthetic Approach to Ship's Propulsion System Assessment

Oleksiy Bondarenko<sup>1,\*</sup> and Yasushi Kitagawa<sup>2</sup>

## ABSTRACT

*Analyzing the behavior of vessels in actual sea conditions is crucial for conceptual system design, safety and energy efficiency considerations. However, the essential seakeeping problem is reduced to the analysis of wave-hull interactions often neglecting consideration of the propulsion. But in the meantime, the synthetic consideration of wave-propulsion interactions is a key for safety and energy efficiency. Furthermore, safety evaluation of a ship's design with reduced propulsion power in adverse seas is vital for risk management. Response functions are commonly used to estimate propulsion system responses in incoming seaways. This paper proposes a synthetic approach using digital twin technology for rapid response function estimation. It introduces a companion linearized state-space model linked with the digital twin, enabling immediate retrieval of coefficients for response function analysis at the desired operating point. This integrated methodology provides a comprehensive representation of ship propulsion behavior in wave environments, offering a comprehensive framework for system performance assessment.*

## KEY WORDS

Propulsion system; state-space model; propulsion system dynamics; describing function analysis.

## INTRODUCTION

Over the last decade, concerns about environmental issues have spurred the maritime industry to undergo a major shift towards zero-emission shipping. Digital transformation is considered one of the drivers in transforming the maritime industry into a more sustainable and efficient transportation sector. With the advent of the Internet of Things (IoT) and the development of sensors and monitoring systems, a wide variety of data has become available for processing onboard or at on-shore data centres, delivering a number of new possibilities. However, raw data is of little value until it is turned into information to enable knowledge. In this context, the advancement in the digitalization of ship operations and the imperative to turn the raw data into knowledge for informed decision-making, have given rise to the development of another emerging technology – a digital twin. The digital-twin is an accurate virtual replica of its physical counterpart, that delivers valuable information by mapping the dynamic behavior in real time. For example, simulation-based analysis of operational data, where the error between predicted and actual responses may uncover system abnormalities. However, the utilization of such a complex tool cannot be justified as a universal tool for all kinds of applications. In particular, when it comes to predicting the expected significant value of a response ahead of time for a known spectrum of input disturbance, the response functions (derived from linear models) are preferable. Furthermore, the ship's hull seakeeping performance is commonly evaluated by using the response functions which translate waves into hull motion responses for a given wave frequency. In turn, wave and hull motions are the main cause of propeller torque fluctuation that disturbs the operation of the propulsion engine. Thus, the synthetic representation of the hull-propeller-engine mutual responses is highly relevant for the safety assessment of the ship propulsion system operation, especially in operation under extreme propeller load torque fluctuations (Sui 2022).

An early attempt at a synthetic consideration of ship propulsive performance in waves dates back to the late 70s (Naito 1979), where the linearized representation of the mutual relations among the functions of a ship propulsion system was derived and used for the prediction of speed loss of the ship in waves. Later Kim (1985) expanded the consideration of the ship propulsion system for the evaluation of propulsive dynamics in rough sea conditions. Recently, a notable effort on propulsion system dynamics and behavior in the time and frequency domains was made by Xiros (2002), where a linearized model is used for engine speed control synthesis, also taking into account turbocharger-engine interaction. An analysis of complex and extreme propeller-engine interaction in the case of ventilation and racing is reported by Bondarenko (2011, 2012). A more recent development of a linear representation of the core propulsion system is reported by Stapersma (2017) and in a companion paper by Vrijdag (2017). In that research, the linearized model of both uncontrolled and controlled systems was derived and used for time and frequency domain analysis of propulsion plant behavior in waves. It was concluded that the linearized model is a suitable tool for system analysis and controller development as long as the limitations of linearization are kept in mind.

Although a variety of linearization procedures and response function models can be found in the literature, an accurate estimation of the propulsion system response function requires detailed information about characteristics intrinsic to propulsion components such as hull, propeller, and engine; in the early stages of ship design, might not be available. Furthermore, ship in-service is characterized by a significant degree of uncertainty, and for this reason, the response function estimated from the “ideal” theoretical characteristics may not fit the actual system. At the same time, the digital twin binds information/data sources of the physical space, a set of dynamic models describing the physical counterpart, and a set of parametrized characteristics, parameters of which are instantiated explicitly for the specific ship in service. Thus, owing to the explicit functional relationships and parametrized characteristics at the core of the digital twin, the linearized representation of the propulsion system can be derived analytically.

This paper intends to provide a synthetic approach binding the identified parametrized models of the digital twin and the companion linearized state-space model, where the data feedback from the ship in service can be used to assess the propulsive performance in waves and review future ship designs. Moreover, to account for the engine torque limit function, the linearized model of the propulsion system was extended with a describing function - a quasi-linear representation of the hard nonlinearity.

## THE BASE SHIP PROPULSION SYSTEM

In the context of the defined objective, which is the assessment of the propulsive performance of a ship in waves, a generic ship propulsion system may be considered to be made of three main components: an engine producing the torque, a shaft transmitting the torque from the engine to the propeller, and a propeller delivering thrust to a hull. Additionally, the engine speed governor, which is a part of the engine, forms the shaft speed control loop. Figure 1 details the composition and mutual relations among the functions of the components.

The ship’s hull translation (surge) motion is based on a force balance between propeller thrust and hull resistance:

$$(m + m_x) \frac{dV_s}{dt} = T_p - R_t, \quad R_t = R_c + X_w \quad [1]$$

where  $m$  and  $m_x$  are the constant hull mass and added mass, correspondingly;  $T_p$  is the effective propeller thrust,  $R_t$  is the total water resistance composed of calm water component,  $R_c$ , and the added resistance due to waves,  $X_w$ . Here, it is worth noting that only time-averaged steady waves-induced forces acting on the ship hull are considered. In contrast, the time-varying oscillatory forces are neglected since the time scale is much shorter than that of the hull longitudinal velocity,  $V_s$ . Thus, equation [1] determines the steady-state position of the engine operating point.

The propulsion engine is directly interfaced with the propeller by means of shaft rotational dynamics, expressed as:

$$2\pi I_{sh} \frac{dn_{sh}}{dt} = Q_e - Q_p \quad [2]$$

where  $Q_e$ ,  $Q_p$  are the engine and propeller torques, respectively,  $I_{sh}$  is the moment of inertia of the rotating shaft system, including the engine, propeller and added mass of water,  $n_{sh}$  is the propeller shaft rotational speed which is also equivalent to the engine rotational speed, in case of direct coupling of propeller and engine. Note that the shaft speed control loop is also a part of the propulsion system, and the details will be covered later.

**Figure 1: The base ship propulsion system**

The static models of the effective propeller thrust and torque are based on the propeller open-water characteristics obtained in calm water conditions. These are given as follows:

$$\begin{aligned}
 T_p &= (1-t_p) \rho n_{sh}^2 D_p^4 K_t(J) \\
 Q_p &= \rho n_{sh}^2 D_p^5 K_q(J) \frac{1}{\eta_r} \\
 J &= \frac{U_p}{n_{sh} D_p}, \quad \because U_p = U_0 + u_p(t), \quad U_0 = V_s (1-w_p)
 \end{aligned}
 \tag{3}$$

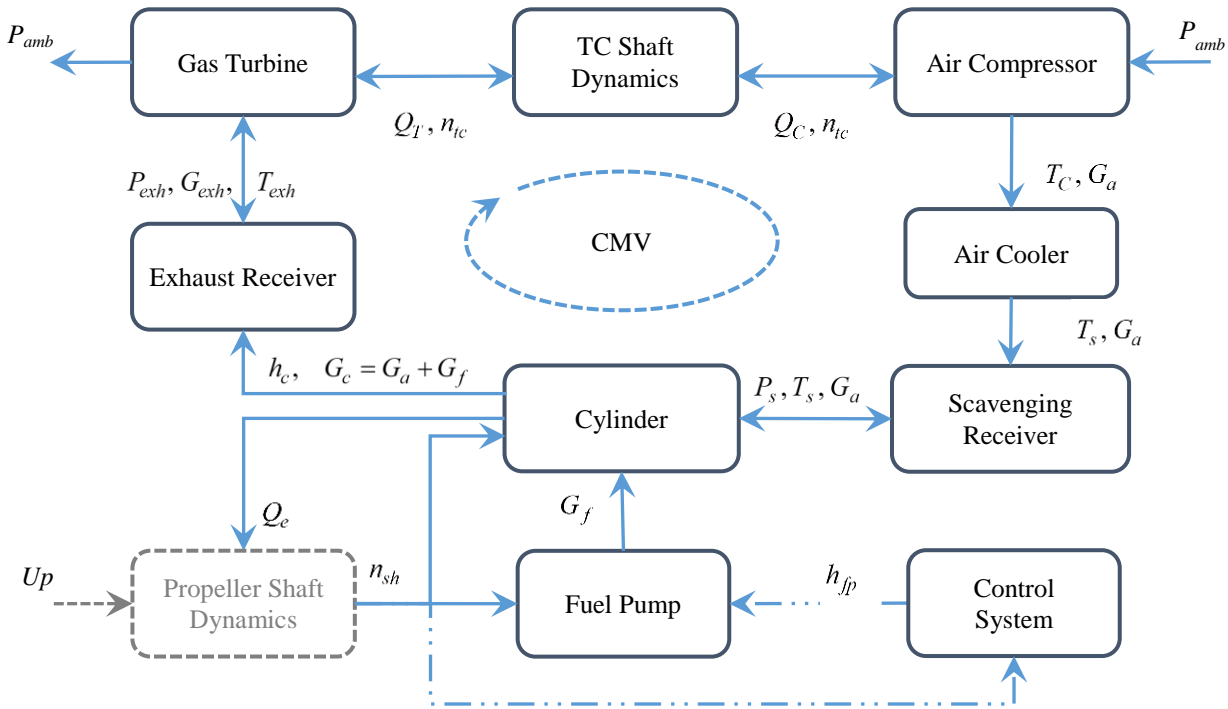

where  $t_p$  is the thrust deduction ratio,  $w_p$  is the wake fraction,  $\rho$  is the water density,  $D_p$  is the propeller diameter,  $J$  is the propeller advance ratio,  $K_q, K_t$  are the torque and thrust coefficients expressed as polynomial functions of the  $J$ , defined by an open propeller characteristic,  $\eta_r$  is the propeller relative rotation efficiency, and  $U_p$  is the effective inflow velocity composed of the steady-part,  $U_0$ , and fluctuating part,  $u_p(t)$ . The time-varying forces induced by waves on the ship's hull excite oscillatory hull motions, which, in turn, along with the wave orbital motion, induce a time-varying velocity field around the propeller. The in-line or axial component,  $u_p(t)$ , of the velocity field, gives rise to a change in the advance velocity  $U_p$  and consequently the advance ratio  $J$ . With time-varying  $J$ , the propeller operating point is moving on the  $K_q$  curve, inducing fluctuation in the propeller torque and, consequently, engine torque and revolution. Thus, effective inflow velocity acts as a link between wave-hull interaction and propeller-engine response, provided that the base ship propulsion system can be split into separate parts, and each can be investigated independently. Figure 2 illustrates the boundaries of each part.

**Figure 2: Decomposition of base ship propulsion system**

## Engine Model

Internal combustion engines remain an unavoidable part of the ship propulsion system, owing to the efficient conversion of fuel chemical energy into mechanical energy. The vast majority of merchant ships use low-speed, two-stroke marine Diesel engines as a prime mover. The objective of the engine model is to represent an external characteristic of the engine concerning the developed torque, which in the general case is a function of engine states such as rotational speed and air and fuel mass flows (Xiros 2002). In the field of propulsion system simulation, a cycle-mean value (CMV) engine modelling approach is commonly used for steady-state and transient performance evaluation (Hendrics 1989, Theotokatos 2010). The central assumption in the CMV modeling approach is that air and exhaust gases flow continuously irrespective of the intermittent nature of a cylinder scavenging process. Thus, the engine is considered a series of control volumes connected through flow restrictions, ensuring continuity of air and exhaust gas flows. The engine is decomposed into a finite number of elements, including the cylinder, air and exhaust gas receivers, turbocharger (TC) with a compressor and turbine, and an air cooler, as shown in figure 3 below.

**Figure 3: Composition of the propulsion engine**

The compressor and turbine are mechanically linked via the TC shaft. An air cooler is connected between the compressor and the air receiver. The fuel pump, i.e. fuel injector, is directly connected to the cylinder. The engine's cylinders are linked with the propeller through shaft rotational dynamics, expressed by the equation [2]. In turn, the engine torque is the result of an indicated mean effective pressure (IMEP),  $P_i$ , developed in the cylinder volume  $V_s$  during one cycle, minus a friction mean effective pressure (FMEP),  $P_f$ :

$$Q_e = \frac{(P_i - P_f)V_s}{2\pi} \quad [4]$$

The developed IMEP is a function of the engine states such as pressures,  $p$ , temperatures,  $T$ , and mass flows,  $G$ . The fundamental equations necessary to describe the temporal evolution of the engine state variables can be obtained from the following mass and energy conservation laws along with the ideal gas equation:

$$\frac{dm}{dt} = \sum_i G_i, \quad i \in \{a, exh, f\} \quad [5]$$

$$p = \frac{m}{V} \tilde{R}T \Rightarrow \frac{dp}{dt} = \frac{dm}{dt} \frac{\tilde{R}T}{V} = \frac{\tilde{R}T}{V} \left( \sum_i G_i \right), \quad \because T = \text{const} \quad [6]$$

$$c_v m \frac{dT}{dt} + u \frac{dm}{dt} = \sum_i h_i G_i \quad [7]$$

here  $u$  is the internal energy,  $\tilde{R}$ ,  $c_v$  are the thermodynamic constants, and  $m$  is the mass of the gas.

The air and exhaust gas mass flow rates, through the engine and turbine, respectively, are calculated under the assumption that an orifice with the equivalent mean effective flow area  $\mu\tilde{A}$  can characterize the engine cylinder as well as turbine. Thus, the flow of compressible gas is evaluated according to:

$$G_{(a,exh)} = \mu\tilde{A} \frac{P_{in}}{\sqrt{RT_{in}}} \Psi(p_{in}, p_{out}) \quad [8]$$

here, the subscripts, in/out, represent the inlet and outlet parameters of the considered element, correspondingly.  $\Psi = f(p_{in}, p_{out})$  is the throttling characteristic of the orifice.

The turbocharger, which is an integral part of the engine, contributes to the assurance of sustainable airflow necessary for optimal and efficient fuel combustion. The dynamic of the turbocharger, in terms of the rotational speed, is derived by applying the angular momentum conservation in the following form:

$$2\pi I_{tc} \frac{dn_{tc}}{dt} = Q_T - Q_C \quad [9]$$

$$Q_T = \frac{\eta_{iT}}{2\pi n_{tc}} G_{exh} C_{p,e} T_{exh} \left[ 1 - \left( \frac{P_{amb}}{P_{exh}} \right)^{\frac{k_e-1}{k_e}} \right] \quad [10]$$

$$Q_C = \frac{G_a C_{p,a} T_{amb}}{2\pi n_{tc} \eta_{iC}} \left[ \left( \frac{P_s}{P_{amb}} \right)^{\frac{k_a-1}{k_a}} - 1 \right] \quad [11]$$

where  $Q_T$  is the torque developed by the turbine due to the expansion of exhaust gas from pressure  $P_{exh}$ ,  $Q_C$  is the torque required by the compressor to compress the air to pressure  $P_s$  in the scavenging receiver,  $n_{tc}$  is the turbocharger rotational speed,  $I_{tc}$  is the inertia of the turbocharger shaft,  $\eta_{iC}$ ,  $\eta_{iT}$  are the isentropic efficiencies of the compressor and turbine, correspondingly.

The energy flow rate,  $h_c G_c$ , exiting the engine cylinder and taking part in the energy balance of the exhaust gas receiver in equation [7], is calculated by taking into consideration the energy conservation in the cylinder, averaged over one engine cycle, thus:

$$h_c G_c = G_a C_{p,a} T_s + G_f H_U - W_i, \quad \because W_i = \oint p_c dV \quad [12]$$

where  $W_i$  is the engine cylinder indicated work, which is the result of one complete engine cycle calculation. In the CMV approach, however, the complete combustion cycle simulation, as commonly accepted (Xiros 2002, Theotokatos 2010), has been seamlessly embedded by the coefficient  $\zeta_a$ , which denotes the proportion of the fuel chemical energy retained in the exhaust gas:

$$\zeta_a = 1 - \frac{W_i}{G_f H_U} \quad [13]$$

Thus, the energy rate of exhaust gas is considered an increase in the energy rate of scavenging air due to combustion in the following form:

$$h_c G_c = G_a C_{p,a} T_s + \zeta_a G_f H_U \quad [14]$$

This, admittedly, fosters the successful transition to the transfer function representation.

The engine fuel mass flow rate,  $G_f$ , is calculated as a linear function of the fuel pump index,  $F_p$ , as follows:

$$G_f = Z_c m_{fc_{mcr}} h_{fp} n_{sh} \quad [15]$$

where  $m_{fc_{mcr}}$  is the mass of fuel injected per cycle at MCR,  $Z_c$  is the number of engine cylinders, and  $h_{fp}$  is the fuel pump index determined by the engine control system. The subscript 'mcr' denotes values at the MCR point of the engine.

Finally, in the quasi-steady context of CMV, the IMEP is considered proportional to the fuel pump index, as follows:

$$P_i = \eta_{C_{eff}} P_{i_{mcr}} h_{fp} \quad [16]$$

Indeed, increasing the fuel index leads to an increase in the fuel amount per cycle per cylinder and thus a higher IMEP, provided that a perfect combustion regime is maintained. The latter holds true for the most practical operating points along propeller lines. However, in actual sea conditions, when the engine operating point most likely shifts towards a region of low speed and high torque the ability of the compressor to supply air for combustion tends to decrease. Consequently, the combustion process becomes more susceptible to variations in air-to-fuel ratio (AFR). Moreover, in transient conditions, the fuel amount, determined by the fuel index,  $h_{fp}$ , adjusts sufficiently fast following the demand in engine torque to keep the engine speed constant, as shown by equation [2]. At the same time, the air mass flow may be delayed compared to that of fuel due to the large inertia of the TC and the lack of a mechanical connection between the TC and the engine shaft. Indeed, the energy of the exhaust gas delivered to the turbine must first accelerate the TC shaft for the compressor to develop air pressure before the cylinder, imposing additional delay due to the presence of the exhaust gas and air receivers in between. Thus, in transient conditions, due to the engine response to propeller load fluctuation, the optimal AFR ceases to hold due to the delay in air supply, leading to engine performance degradation. Such a phenomenon clearly must be accounted for in the dynamic engine model. Therefore, the IMEP in equation [16] is modified with the coefficient  $\eta_{C_{eff}}$ , introduced (Medica 1988, Xiros 2002) to take into account the losses due to incomplete fuel combustion. Furthermore, a series of theoretical and experimental studies (Bondarenko, 2018; Bondarenko, 2023) have revealed the characteristics of combustion process degradation due to the depletion of air charge in the cylinder. Thus, the following combustion efficiency coefficient is introduced into the model:

$$\eta_{C_{eff}} = f(AFR) = C_0 AFR^{\frac{b_0}{AFR}}, \quad \therefore AFR = \frac{G_a}{G_f} \quad [17]$$

where  $C_0$  and  $b_0$  are the coefficients that represent the sensitivity of combustion efficiency to the AFR. Figure 4 illustrates a family of characteristics for different coefficient selections. As can be observed, the adopted model demonstrates a consistent decline in combustion efficiency when AFR falls below the nominal value ( $AFR < 1.0$ ), grounded on the experimental results.

**Figure 4: Combustion efficiency characteristics**

Apart from the presented fundamental algebraic and differential equations describing the engine components' behavior, there are certain empirical characteristics required to complete the model. These include effective turbine area,  $\mu \tilde{A}$ , compressor isentropic efficiency,  $\eta_{iT}$ , remained fuel energy proportion in exhaust gas,  $\zeta_a$ , FMEP,  $P_f$ , defined as follows:

$$\mu \tilde{A} = c_{\mu_0} + c_{\mu_1} \left( \frac{P_{amb}}{P_{exh}} \right) + c_{\mu_2} \left( \frac{P_{amb}}{P_{exh}} \right)^2 \quad [18]$$

$$\eta_{iT} = \eta_{iT_0} \left[ \frac{n_{tc}}{C_s} \left( c_{T_0} - \frac{n_{tc}}{C_s} \right) + c_{T_1} \right] \quad [19]$$

$$\zeta_a = c_{\zeta_0} + c_{\zeta_1} \frac{Q_e}{Q_{emcr}} \quad [20]$$

$$P_f = P_{i_{mcr}} \left( c_{f_0} + c_{\zeta_1} \frac{n_{sh}}{n_{sh_{mcr}}} + c_{\zeta_2} h_{fp} \right) \quad [21]$$

The outlined CMV modelling approach results in continuous, nonlinear, and fully parameterized first-order ordinary differential equations, describing the time evolution of the key engine states, as shown below. Such model formulation allows for the analytical transition to the linear state-space model, ensuring the effective binding of the linear counterpart to the original nonlinear model.

$$\frac{d}{dt} \mathbf{Y}(t) = \mathbf{F}(\mathbf{Y}, \boldsymbol{\theta}, h_{fp}, u_p), \quad \mathbf{Y} = [n_{sh}, n_{tc}, P_s, M_{exh}, T_{exh}]^T \quad [22]$$

here  $\mathbf{Y}$  is the vector of state variables,  $\boldsymbol{\theta}$  is a set of constants that parametrize the static characteristics of the engine components,  $h_{fp}$  is the input from a control system, and  $u_p$  is the disturbance resulting from the wave-hull interaction.

In past research (Bondarenko 2020, Bondarenko 2023) the adaptive parameters identification framework was developed. The framework integrates the core of the digital twin - a set of parametrized dynamic models - with information/data sources of the physical space. It is possible to identify the constants that parametrize the static characteristics of the engine components, tailored to the specific ship in service, in this way.

## Engine Control System

The control system of marine diesel engines aims at controlling their speed and load operating regimes. Inadequate control system dynamics may lead to incomplete fuel combustion, thermal and mechanical overload of the engine components, and excessive oscillation of the shaft rotational speed. As a rule, the control system of propulsion engines consists of a speed governor and several functional modules for protection against torque and thermal overloading. For the purpose of the present study, a Proportional-Integral (PI) + Proportional (P) governor structure is used as shown in figure 5 in the form of the Laplace domain block diagram (Gorb 1989). The PI+P structure mimics a popular and classic hydro-mechanical governor of Woodward. The linear part of the governor's dynamic can be represented in state-space form, as demonstrated below:

$$\begin{aligned} \frac{d}{dt} \mathbf{x} &= \mathbf{A} \mathbf{x} + \mathbf{B} u, \quad \mathbf{x} = [\bar{X}_{efb}, \bar{X}_{pp}]^T, \quad u = [n_{sp} - n_{sh}] \\ y &= \mathbf{C} \mathbf{x}, \quad y = h_{fp} \end{aligned} \quad [23]$$

$$\mathbf{A} = \begin{bmatrix} -\left( \frac{K_i K_m K_{su}}{T_{ss}} + \frac{1}{T_i} \right) & -\frac{K_i K_m K_{fb} K_{su}^2}{T_{ss}} \\ -\frac{K_m}{T_{ss}} & -\frac{K_{fb} K_m K_{su}}{T_{ss}} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} -\frac{K_i K_m K_{su}}{T_{ss}} \\ -\frac{K_m}{T_{ss}} \end{bmatrix}, \quad \mathbf{C} = [0 \quad 1]$$

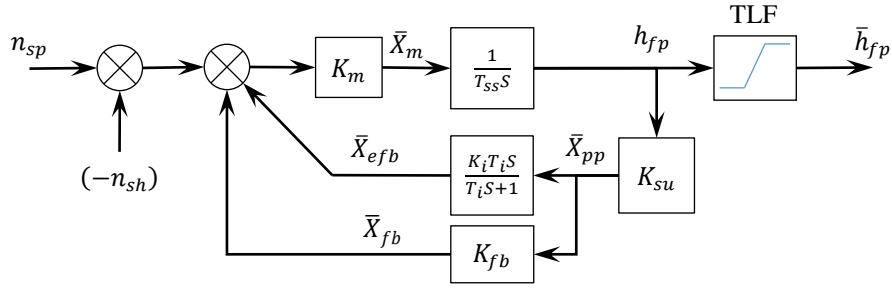

Figure 5: Governor functional block diagram

In order to prevent the engine from thermal and mechanical overloads, the engine control system includes a torque limiter function (TLF). The TLF provides saturation of the governor output at the upper boundary, limiting the fuel injection amount, and thus engine torque. Figure 6 illustrates characteristics of TLF implemented in the governor.

Figure 6: The TLF characteristic

$$h_{fp} = \begin{cases} h_{fp}, & \text{if } h_{fp} \leq +h_{fp} \\ +h_{fp}, & \text{if } h_{fp} > +h_{fp} \end{cases}$$

$$+h_{fp} = \begin{cases} 0.55, & \text{if } n_e \leq 0.5 \\ \frac{n_e}{0.95}, & \text{if } 0.5 < n_e \leq 0.95 \\ 1.0, & \text{if } n_e > 0.95 \end{cases} \quad [24]$$

## THE STATE-SPACE MODEL OF THE PROPELLER-ENGINE SYSTEM

As noted earlier, wave and hull motions are the main causes of propeller torque fluctuation, disturbing the operation of the propulsion engine. The response functions conveniently relate the system's response to a forcing function with the aid of appropriate Laplace transforms. Thus, the response functions, which translate waves into hull motions and, in turn, into propeller torque fluctuation, characterize the wave-hull-propeller interaction in the frequency domain (Bondarenko 2011). It is desirable to interface these characteristics into the analysis of propeller-engine interaction, resulting in a comprehensive assessment of hull-propeller-engine interaction. Since the equations representing propeller-engine interaction are non-linear differential equations, the linearization about an operating point is required. The response functions are obtained from the linear state-space representation for input disturbance.

Different types of nonlinearities intrinsic to the system require different linearization techniques. Thus, for weak types, such as nonlinearity due to the product of variables or nonlinearity due to polynomial characteristics, the standard approach, often called small signal increments, is the most suited. Whereas hard nonlinearity, such as saturation, requires a special technique often called harmonic linearization. At first, the linearization of the base propulsion system without TLF will be presented, followed by the introduction of describing function for a (quasi) linear description of the TLF.

### Linearization

The basic method of small increments is commonly used for the linearization of propulsion engine models (Mezherickiy 1971, Naito 1979, Stapersma 2017). The method allows for interpreting a nonlinear function as an explicit linear combination of the small increments of the constituent variables, simultaneously getting rid of constant parameters. For the sake of simplicity and illustration of the application of the method, the nonlinear equation of propeller shaft dynamics, equation [2],

will be processed from now on. Let's rewrite the equation [2] in the form of finite increments of the constituent variables about a steady-state operating point, simultaneously introducing normalization at that point:

$$\begin{aligned} \frac{2\pi I_{sh}}{Q_{p_0}} \frac{d\Delta n_{sh}}{dt} \frac{n_{sh_0}}{n_{sh_0}} &= \frac{\Delta Q_e}{Q_{p_0}} - \frac{\Delta Q_p}{Q_{p_0}}, \quad Q_{e_0} \equiv Q_{p_0}, \quad \frac{\Delta n_{sh}}{n_{sh_0}} \equiv \delta n_{sh}, \quad \frac{\Delta Q_e}{Q_{p_0}} \equiv \delta Q_e, \quad \frac{\Delta Q_p}{Q_{p_0}} \equiv \delta Q_p \\ \Downarrow \\ \frac{d}{dt} \delta n_{sh} &= \frac{1}{\tau} [\delta Q_e - \delta Q_p], \quad \tau = \frac{2\pi I_{sh}}{Q_{p_0}} n_{sh_0} \end{aligned} \quad [25]$$

Equation [25] requires further detailing of the torque functions, and following the method of small increments, the composite functions are decomposed by applying a logarithm, and then the partial differentiation is performed. Finally, by introducing coefficients of influence and substituting finite increments for differentials, the composite function is replaced by a linear combination of constituent variables. Thus, the transformation of the propeller torque function defined in equation [3] yields:

$$\begin{aligned} Q_p &= \rho n_{sh}^2 D_p^5 K_q(J) \frac{1}{\eta_r} \\ \Downarrow \\ \ln(Q_p) &= \ln(\rho) + 2\ln(n_{sh}) + 5\ln(D_p) + \ln(K_q) - \ln(\eta_r) \\ \Downarrow \\ \frac{dQ_p}{Q_{p_0}} &= 2 \frac{dn_{sh}}{n_{sh_0}} + \frac{dK_q}{K_{q_0}}, \quad \frac{dQ_p}{Q_{p_0}} \approx \frac{\Delta Q_p}{Q_{p_0}} \equiv \delta Q_p, \dots \\ \Downarrow \\ \delta Q_p &= 2\delta n_{sh} + \delta K_q \end{aligned} \quad [26]$$

The torque coefficient,  $K_q$ , holds the nonlinear functional relation in the polynomial form with the engine speed and inflow velocity and thus requires further linearization. Applying the Taylor series expansion, neglecting higher order term, the transformation yields:

$$\begin{aligned} K_q(J) &= q_0 + q_1 J + q_2 J^2, \quad J = \frac{U_p}{n_{sh} D_p} \\ \Downarrow \\ \Delta K_q &= \frac{\partial K_q}{\partial n_{sh}} \Delta n_{sh} + \frac{\partial K_q}{\partial U_p} \Delta U_p \\ \Downarrow \\ \frac{\Delta K_q}{K_{q_0}} &= \underbrace{\frac{\partial K_q}{\partial n_{sh}} \frac{n_{sh_0}}{K_{q_0}}}_{k_{q_1}} \frac{\Delta n_{sh}}{n_{sh_0}} + \underbrace{\frac{\partial K_q}{\partial U_p} \frac{U_{p_0}}{K_{q_0}} \frac{\Delta U_p}{U_{p_0}}}_{k_{q_2}}, \quad \frac{\Delta K_q}{K_{q_0}} \equiv \delta K_q, \dots \\ \Downarrow \\ \delta K_q &= k_{q_1} \delta n_{sh} + k_{q_2} \delta u_p \end{aligned} \quad [27]$$

Substituting the result of equation [27] into the result of equation [26] and collecting coefficients for the same variables, the transformation yields the following result:

$$\delta Q_p = (2 + k_{q_1}) \delta n_{sh} + k_{q_2} \delta u_p \quad [28]$$

Under similar considerations, the finite increment of engine torque,  $\delta Q_e$ , can be derived in the following form:

$$\begin{aligned}
\delta Q_e &= k_{imep} k_{C_{eff}} (\delta G_a - \delta G_f) + k_{imep} \delta h_{fp} - k_{fimep} \delta n_{sh} \\
\delta G_a &= (1 - k_{\Psi_a}) \delta P_s + k_{\Psi_a} (\delta M_{exh} + \delta T_{exh}) \\
\delta G_f &= \delta h_{fp} + \delta n_{sh}
\end{aligned} \tag{29}$$

The unwieldy expression for the engine torque results from the presence of the combustion efficiency coefficient in equation [16]. At the same time, it shows the interrelation of the engine torque increment with the increments of other engine state variables. Finally, by substituting equations [28] and [29] into equation [25], collecting and grouping coefficients for the same variables, the linearized and normalized equation of the engine shaft speed dynamics gains the following form:

$$\frac{d}{dt} \delta n_{sh} = a_{11} \delta n_{sh} + a_{13} \delta P_s + a_{14} \delta M_{exh} + a_{15} \delta T_{exh} + b_{11} \delta h_{fp} + k_{q_2} \delta u_p \tag{30}$$

Likewise, the linearized and normalized version of the rest of the state variables in equation [22] can be obtained, resulting in the linearized state-space description of the engine propulsion system (uncontrolled part) in terms of variables finite increments in the following form:

$$\begin{aligned}
\frac{d}{dt} \delta \mathbf{x} &= \mathbf{A} \delta \mathbf{x} + \mathbf{B} \delta \mathbf{u}, \quad \delta \mathbf{x} = [\delta n_e, \delta n_{ic}, \delta P_s, \delta M_{exh}, \delta T_{exh}]^T, \quad \delta \mathbf{u} = [\delta h_{fp}, \delta u_p]^T \\
\delta \mathbf{y} &= \mathbf{C} \delta \mathbf{x}
\end{aligned}$$

$$\mathbf{A} = \begin{bmatrix} a_{11} & 0 & a_{13} & a_{14} & a_{15} \\ 0 & a_{22} & a_{23} & a_{24} & a_{25} \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} \\ a_{41} & 0 & a_{43} & a_{44} & a_{45} \\ a_{51} & 0 & a_{53} & a_{54} & a_{55} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} b_{11} & k_{q_2} \\ 0 & 0 \\ 0 & 0 \\ b_{41} & 0 \\ b_{51} & 0 \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{bmatrix} \tag{31}$$

The coefficients of the system matrix  $\mathbf{A}$  and input matrix  $\mathbf{B}$  are analytically bound up with the original nonlinear equation [22], and thus can easily be evaluated at arbitrary operating points of the propulsion system. Furthermore, the uncontrolled state-space representation of the propulsion system can be turned into a controlled version simply by expanding and combining the state matrix  $\mathbf{A}$  and input matrix  $\mathbf{B}$  with the linear part of the governor's state-space description [23]. The transformation results in the updated matrices and vectors:

$$\begin{aligned}
\delta \mathbf{x} &= [\delta n_e, \delta n_{ic}, \delta P_s, \delta M_{exh}, \delta T_{exh}, \delta X_{efb}, \delta X_p]^T, \quad \delta \mathbf{u} = [\delta u_p]^T
\end{aligned}$$

$$\begin{aligned}
&\text{Engine} \\
&\mathbf{A} = \begin{bmatrix} a_{11} & 0 & a_{13} & a_{14} & a_{15} & 0 & \frac{b_{11}}{K_{su}} \\ 0 & a_{22} & a_{23} & a_{24} & a_{25} & 0 & 0 \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} & 0 & 0 \\ a_{41} & 0 & a_{43} & a_{44} & a_{45} & 0 & \frac{b_{41}}{K_{su}} \\ a_{51} & 0 & a_{53} & a_{54} & a_{55} & 0 & \frac{b_{51}}{K_{su}} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} k_{q_2} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \frac{1}{K_{su}} \end{bmatrix} \\
&\text{Governor} \\
&\mathbf{A} = \begin{bmatrix} b_{61} & 0 & 0 & 0 & 0 & a_{66} & a_{67} \\ b_{71} & 0 & 0 & 0 & 0 & a_{76} & a_{77} \end{bmatrix}
\end{aligned} \tag{32}$$

The obtained state-space description, either uncontrolled or controlled, defines the system's dynamic behavior in the time domain. However, in the context of propeller-engine interaction, the frequency domain behavior is of primary interest. Thus, the transition from the time domain to the frequency domain representation, in the form of the transfer function of the linear system from input,  $\delta u$ , to output,  $\delta y$ , can be easily obtained by applying the Laplace transformation to the state-space system in the following form:

$$W(s) = \frac{\delta y}{\delta u} = C(sI - A)^{-1}B, \quad s \equiv \frac{d}{dt} - \text{the Laplace operator} \quad [33]$$

$$H(\omega) = 20 \log_{10} |W(i\omega)|, [dB]$$

Equation [33] provides the plotting of Bode charts, which quantify the ratio of the system response magnitudes to the magnitude of the input disturbance in the range of frequencies. There are seven responses to the input disturbance of the inflow velocity in the context of the presented propulsion system.

## Time and Frequency Domain Validation

The linearization comes with a cost: the model is only valid for small variations around the steady-state point. So, the important question is how the state-space linearized model compares to the numerical non-linear model in both the time and frequency domains. To get insights into how both models behave, a numerical simulation was implemented in MATLAB/Simulink. The Panamax-size bulk carrier is used as a prototype ship for the numerical model. The hull form was designed at the National Maritime Research Institute (NMRI) with a target speed of 14.5 kt at 90% MCR. The principal dimensions of the hull and propeller are listed in Table 1. The required engine power was assessed as a result of propeller-hull matching for the desired target speed. The engine particulars are listed in Table 2. It is assumed that a ship advances with a constant speed,  $U_0$ , in head waves and experiences longitudinal (surge) motion. As mentioned before, the axial component of the velocity field around the propeller influences the behavior of the propulsion engine directly, thus is the most important for the investigation of wave-propeller-engine interaction (Bondarenko 2012, Taskar 2016).

The model of inflow velocity is composed of two terms (Nakamura 1975): due to the hull surge motion,  $u_{pm}$ , and due to the wave orbital motion,  $u_{pw}$ , as follows:

$$\begin{cases} u_p = u_{pm} + u_{pw} \\ u_{pm} = (1 - w_p) \{ U_0 - \omega_e \xi_a \sin(\omega_e t - \varepsilon_\xi) \} \\ u_{pw} = \alpha_w \omega \zeta_w e^{-k z_p} \cos \chi \cos(\omega_e t - k x_p \cos \chi) \end{cases} \quad [34]$$

where  $\omega_e$  is the encounter wave frequency,  $\xi_a$  and  $\varepsilon_\xi$  are the surge motion amplitude and phase, correspondingly;  $\omega$  is the incident wave frequency,  $\chi$  is the heading angle to waves,  $\zeta_w$  is the wave amplitude,  $k$  is the wavenumber ( $=2\pi/\lambda$ ) and  $\lambda$  is the wavelength,  $x_p$  and  $z_p$  are the coordinates of propeller position with respect to the hull centre of gravity,  $G$ . The dynamics of the subject hull dynamics as well as an effective wave amplitude coefficient  $\alpha_w$  are discussed in details by Kitagawa (2019). The time histories of inflow velocity fluctuation in irregular waves are generated based on linear wave theory and detailed discussion is not in the scope of this paper.

**Table 1: Principal particulars of a ship and propeller**

Item	Design Value
$L_{pp}$ (m)	217.0
$B$ (m)	32.3
$D$ (m)	12.2
Displacement (ton)	7.17e4
Service Speed $U_0$ (kt)	14.5
$C_B$	0.84
Propeller Series	Wageningen B
$D_p$ (m)	6.6
Blades	4
Pitch Ratio	0.65

**Table 2: Propulsion engine specification @ MCR**

Engine Type	Mitsui-MAN S50ME-T9
No of Cylinders	6
Bore/Stroke, [mm/mm]	500/2214
Power, [kW]	9640
Speed, [rpm]	119
IMEP, [bar]	22
Scav. Air Pressure, [barA]	4.4

Figure 7, the engine envelope, visualizes the combined engine speed and power responses to the generated inflow velocity fluctuation in irregular waves, followed by figure 8, where the time histories of the corresponding engine state variables'

responses, relative to the MCR point, are shown. These graphs clearly show that the behavior of the state-space linear and non-linear models is indistinguishable, except for a slight difference in the exhaust gas temperature responses. This variation can be attributed to the nonlinearity of the characteristic. The presented results do not directly include the effect of resistance increase in waves, as mentioned from the beginning; equation [1] is neglected due to the negligible effect of varying added resistance in waves on the propulsion engine. Instead, the focus is put on understanding the responses in waves due to fluctuating inflow velocity, which indirectly includes the effect of the resistance fluctuation. Finally, figure 9 shows the responses in the frequency domain. A general observation is that both systems show similar response magnitudes for the range of frequencies typical for ocean waves. Additionally, as expected from the time-domain results, the magnitude of the exhaust temperature response is lower in the linear case.

Figure 7: Engine operating point response on the engine envelope

Figure 8: Propulsion engine responses in time domain

**Figure 9: Propulsion engine responses in frequency domain**

Although the behavior of the linearized model compares fairly well with the full non-linear model, it has a major limitation: the non-linearity of the TLF that cannot be captured by a linear model in a straightforward manner. However, there is an approximate method of analysis in the frequency domain, also known as harmonic analysis, providing the replacement of each nonlinear element with a quasi-linear describing function. A brief description is provided in the subsequent subchapter.

### Describing Function Representation of the TLF Function

One way to deal with a nonlinear system is to linearize it with the help of a finite increment method. Linearization in the time domain requires the system under consideration to be composed of continuous and differentiable characteristics. However, this approach is ill-suited for studying the limiting or detrimental effects of nonlinearity. On the other hand, harmonic linearization is a way of describing hard nonlinear functions in the frequency domain (Csaki 1972).

Let's assume the nonlinear transformation function  $f(x,t)$  of the harmonic signal of the form  $x(t) = a \sin(\omega t)$ . The transformation results in the output  $y(t) = f(a \sin(\omega t), t)$ . The describing function gain,  $N(a, \omega)$  is the fundamental harmonic of the Fourier series representation of this periodic output  $y(t)$ , divided by the input amplitude  $a$ , as follows:

$$y(t) \cong A_0(a, \omega) + N(a, \omega) \cdot a e^{j\omega t},$$

$$N(a, \omega) = q(a, \omega) + jq'(a, \omega)$$
[35]

The coefficients  $A_0$ ,  $q$ ,  $q'$  can be found through the Fourier series expansion of the non-linear transformation function  $f(\bullet)$  as follows:

$$\begin{aligned}
A_0 &= \frac{1}{2\pi} \int_0^{2\pi} f(a \sin(\Psi)) d\Psi, \quad \because \Psi \equiv \omega t \\
q &= \frac{1}{a\pi} \int_0^{2\pi} f(a \sin(\Psi)) \sin(\Psi) d\Psi \\
q' &= \frac{1}{a\pi} \int_0^{2\pi} f(a \sin(\Psi)) \cos(\Psi) d\Psi
\end{aligned} \tag{36}$$

In the context of the nonlinear characteristic of TLF described by equation [24], and schematically shown in figure 10, the describing function gain can be derived as follows:

$$\begin{aligned}
A_0(a) &= \frac{1}{2\pi} \left[ \int_0^\beta a \sin(\Psi) d\Psi + \int_\beta^{\pi-\beta} {}^+h_{fp} d\Psi + \int_{\pi-\beta}^{2\pi} a \sin(\Psi) d\Psi \right] \\
&= \frac{{}^+h_{fp}}{2} - \frac{{}^+h_{fp}}{\pi} \sin^{-1} \left( \frac{{}^+h_{fp}}{a} \right) - \frac{a}{\pi} \sqrt{1 - \left( \frac{{}^+h_{fp}}{a} \right)^2} \\
q &= \frac{1}{a\pi} \left[ \int_0^\beta a \sin^2(\Psi) d\Psi + \int_\beta^{\pi-\beta} {}^+h_{fp} \sin(\Psi) d\Psi + \int_{\pi-\beta}^{2\pi} a \sin^2(\Psi) d\Psi \right] \\
&= \frac{1}{2} + \frac{1}{\pi} \sin^{-1} \left( \frac{{}^+h_{fp}}{a} \right) + \frac{1}{\pi} \frac{{}^+h_{fp}}{a} \sqrt{1 - \left( \frac{{}^+h_{fp}}{a} \right)^2} \\
q' &= \frac{1}{a\pi} \left[ \int_0^\beta a \sin(\Psi) \cos(\Psi) d\Psi + \int_\beta^{\pi-\beta} {}^+h_{fp} \cos(\Psi) d\Psi + \int_{\pi-\beta}^{2\pi} a \sin(\Psi) \cos(\Psi) d\Psi \right] \\
&= 0
\end{aligned} \tag{37}$$

**Figure 10: Schematic of nonlinear transformation of TLF**

The components obtained in equation [37] define the describing function as frequency-invariant and input amplitude-dependent, though. In order to confirm the obtained characteristics, a simple numerical experiment was set up: a harmonic signal of varying amplitude at a single frequency passes through the saturation non-linearity, and the estimated amplitudes ratio is plotted in figure 11 along with the corresponding describing function. The presented results of the numerical simulation suggest the non-linearity analysis capability by the describing function method.

Finally, it should be observed that the saturation type non-linearity, such as TLF, also introduces the DC component ( $A_0$ ), and to some extent, the AC component ( $N(a)$ ) is dominant; however, the larger the amplitude, the larger the bias. Definitely, in

harsh sea conditions when the engine operation in close vicinity of the limit is inevitable, the effect of the DC component becomes prominent, exacerbating the safety concerns of propulsion system operation. For the purpose of this research, investigating the wave-propeller-engine interaction, only the AC component is considered at the moment, while the simultaneous consideration of both components will be left for future analysis.

Figure 11: Describing function for saturation non-linearity

### State-Space Model of the Propulsion System with TLF in Frequency Domain

The describing function method has traditionally been used for two primary purposes: limit-cycle stability analysis and characterizing the input-output behavior of a non-linear system in the frequency domain. In this paper, the focus is put on the latter purpose, particularly to determine the amplitude-dependent frequency response of a nonlinear system.

The TLF is placed between the governor and the engine to saturate the fuel pump index input to the engine and prevent thermal overload. Thus, the describing function coefficient,  $N(a)$ , is introduced to the system matrix  $A$ , to the part related to the governor-engine interface, as shown by equation [38], and delivers the quasi-linear response function as in equation [39]

$$\delta \mathbf{x} = [\delta n_e, \delta n_{tc}, \delta P_s, \delta M_{exh}, \delta T_{exh}, \delta X_{efb}, \delta X_p]^T, \quad \delta \mathbf{u} = [\delta u_p]^T$$

$$\mathbf{A} = \begin{bmatrix} \text{Engine} \\ a_{11} & 0 & a_{13} & a_{14} & a_{15} & 0 & \frac{b_{11}}{K_{su}} N(a) \\ 0 & a_{22} & a_{23} & a_{24} & a_{25} & 0 & 0 \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} & 0 & 0 \\ a_{41} & 0 & a_{43} & a_{44} & a_{45} & 0 & \frac{b_{41}}{K_{su}} N(a) \\ a_{51} & 0 & a_{53} & a_{54} & a_{55} & 0 & \frac{b_{51}}{K_{su}} N(a) \\ \text{Governor} \\ b_{61} & 0 & 0 & 0 & 0 & a_{66} & a_{67} \\ b_{71} & 0 & 0 & 0 & 0 & a_{76} & a_{77} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} k_{q2} \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} 1 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & \frac{1}{K_{su}} \end{bmatrix} \quad [38]$$

$$\mathbf{W}(i\omega, a) = \frac{\delta \mathbf{y}}{\delta \mathbf{u}} = \mathbf{C} [\mathbf{A}(a) - i\omega \mathbf{I}]^{-1} \mathbf{B} \quad [39]$$

Here,  $a$  stands for the amplitude of the governor's response before the TLF, that is:

$$a \equiv \delta h_{fp} = |\mathbf{W}(i\omega, a)| \delta u_p, \quad \mathbf{C} = \begin{bmatrix} 0 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & \frac{1}{K_{su}} \end{bmatrix} \quad [40]$$

Thus, to produce the frequency response of such a quasi-linear amplitude-dependent response function, an iterative solution is required until the convergence of the describing function value. The elaborated procedure is as follows: set a specific value for  $\delta u_p$  from a range of input amplitudes covering the expected operating range of the system and set a range of frequencies  $[\omega_{min}, \omega_{max}]$  to span a frequency range of interest. Then, set  $N(a) = 1$  and evaluate the amplitude of response,  $a$ , for every frequency in the range, update  $N(a)$  and repeat the calculation until the convergence. It was found that a converged solution appears within a few iteration steps.

To illustrate the frequency response of the state-space system given the TLF activation, the simulation condition is set similar to that of figure 7, where the operating point is close enough to the limit line. To generate the amplitude-dependent DF, the six inflow velocity amplitudes in the range  $[0.08 \dots 0.20]$  were selected, and a set of frequencies covering the typical range of the ocean waves. Figure 12 illustrates the evolution of the describing function magnitude in the frequency domain. It is evident that the larger the input disturbance, the larger the response of the governor and, thus, the activation of the TLF function. Furthermore, figure 13 shows the frequency response of the propeller-engine system, and, as evident, the engine speed response increases as the input disturbance increases. This is because the increasing response,  $X_{pp}$ , of the governor linear part, also shown in figure 13, cannot reach the engine because of the TLF, whereas the response of the fuel pump index,  $h_{fp}$ , is suppressed. As for the air supply subsystem, including the compressor, receivers, and turbine, whose response is indicated by the TC rotating speed,  $n_{tc}$ , the effect of TLF is negligible owing to the large inertia.

Although the demonstrated effect of TLF is relatively small, it can be prominent for other operating points and dynamic properties of the speed control system, and the developed approach allows for the evaluation of various conditions in a straightforward and integrated manner.

## CONCLUSIONS

Frequency-response techniques and the use of response functions are valuable tools in the analysis of the ship propulsion system behavior in waves. However, accurate calculation of the propulsion system response function requires detailed information about characteristics intrinsic to constituent components. This paper proposes the digital-twin-enabled response function analysis technique for the problem of wave-propeller-engine interaction assessment. The core part of the digital twin is the nonlinear, fully parametrized model of propeller-engine dynamics. The parameters identification framework from past research ensures that models are tailored to the specific ship in-service. The companion linearized state-space model was derived analytically based on the structure of the digital twin. A remarkable aspect of the developed linearized state-space model is the introduction of the air supply subsystem (compressor, receivers, and turbine), which has a notable effect on engine performance. The coefficients of the derived state-space system are bound up with the nonlinear models underlying the digital twin. Thus, at any point in the ship operation, reflected by the digital twin, the state-space system matrices can be readily obtained, and then a variety of analyses can be performed. This is valid only under moderate sea conditions, though. On the other hand, in adverse sea conditions, the increased propeller load forces the engine operating point to move closer to the upper bound of the engine operation limit. At the same time, significant propeller torque fluctuations occur. As a rule, the governors of modern engines are equipped with torque-limiting functions, preventing the engine from overloading, and simultaneously restricting the maneuverability of the ship. The latter circumstance has raised serious safety concern about ships with reduced propulsion power, used for better energy efficiency (Shigunov 2018). The presence and activation of torque saturation make the problem of propeller-engine interaction highly nonlinear. Therefore, it is desirable to extend the analysis of linearized state-space systems to the consideration of systems with nonlinear components such as TLF. In this work, the effect of the nonlinear function was approximated by using the theory of harmonic linearization. Specifically, the output of the nonlinear function is represented by its Fourier series by assuming a pure sinusoidal signal of constant amplitude with no bias at the input and no subharmonics at the output. Thus, the describing function is then defined as the complex ratio of the fundamental term of the output to the input sinusoid. A simple example considered in the paper showed that the system responses to a variety of disturbance amplitudes can be studied in the frequency domain utilizing the linear system theory.

To wrap up, this paper proposes a synthetic approach to evaluating and assessing a ship's propulsion system. A digital twin precisely reflects the characteristics intrinsic to the ship in-service, and the companion state-space system, bound up with the digital twin, provides a foundation for wave-propeller-engine interaction analysis in the frequency domain. The harmonic linearization extends the technique to consider the nonlinearity of TLF. All components are mutually supportive, ensuring that the data feedback from the ship in service can be used to assess propulsive performance in waves and review future ship designs.

Besides all the aforementioned aspects, there is also a desire to extend the technique by combining the wave-hull interaction problem, providing a holistic assessment of ship operation in actual sea conditions, as shown by Bondarenko (2012). The required component is the response function of hull motions in waves, and Nielsen (2021, 2022) proposed a simple and practical method that can be used to tune the transfer function from in-service data of hull response measurement. This is the subject of ongoing research.

# Leveraging the concept of information-theoretic entropy to improve a multi-fidelity design framework for early-stage design exploration of complex vessels

Nikoleta Dimitra Charisi<sup>1,\*</sup>, Hans Hopman<sup>1</sup> and Austin Kana<sup>1</sup>

## ABSTRACT

*Early-stage design exploration is crucial since most of the major design decisions are locked-in and only small design modifications are possible at later stages. To assess the performance of the various design candidates while performing design exploration, there are available methods and tools of various fidelities. These methods can be combined to form a multi-fidelity (MF) framework that guarantees accuracy through the high-fidelity model and achieves faster computational speeds through low-fidelity models. The present study proposes the adoption of information-theoretic entropy to improve a MF design framework based on Gaussian Processes (GPs). Entropy quantifies the uncertainty associated with the prediction of the design space. We propose using this uncertainty metric both as a criterion to determine whether further designs should be sampled to construct a reliable approximation of the design space and as a criterion to establish in which optimization step the optimization of the covariance matrix for the MF-GPs should be performed. The approach was tested to benchmark analytical functions and to a ship design problem of an AXEfrigate. The approach holds potential in practical applications, as it aids in the determination of whether additional resources should be allocated for high-fidelity analysis to support early-stage exploration.*

## INTRODUCTION

Early-stage design of complex engineering systems is critical since it involves making the majority of key design decisions Mavris et al. (1998); Andrews (2018). These design decisions determine the overall configuration of the vessel, including main dimension selection, hull shape, and propulsion plant, among others. Committing to these decisions early in the design process results in a swift reduction of design freedom and entails a substantial overall cost allocation Mavris et al. (1998). Hence, it is crucial to perform a thorough exploration of the design space to identify trends and trade-offs, ultimately guiding well-informed design decisions.

In the initial stages of design, the primary focus is on recognizing design trends and crucial trade-offs within the broad design space Duchateau (2016). Typically, during this design stage, low-fidelity (LF) methods are employed. LF methods are

<sup>1</sup> Maritime and Transport Technology Department, Technical University of Delft, Delft, the Netherlands

\* Corresponding Author: N.D.Charisi-1@tudelft.nl

computationally cheap but fall short in terms of accuracy. Thus, with such tools, it becomes feasible to evaluate a vast number of designs. For instance, when assessing motions and loads, linear methods like potential flow can be employed as LF models. Yet, in certain scenarios, LF methods prove inadequate for the following reasons: (1) LF models may fail to capture the complex physical behavior of complex engineering systems, and (2) LF methods, by their very nature, are simplifications derived from more advanced methods, simplified based on assumptions that may not apply to novel designs. When LF models fail to accurately capture the physical behavior of the system, it becomes necessary to incorporate HF analysis earlier in the design process. For example, Sapsis (2021) demonstrated the influence of nonlinearities on the seakeeping and vertical bending moment of the tumblehome hull.

A promising approach to integrating HF analysis earlier into the design process involves the creation of multi-fidelity (MF) models. In essence, MF models combine LF models with a HF model, aiming to harness the accuracy offered by the HF model while benefiting from the computational efficiency provided by the LF models. Beran et al. (2020) assert that ‘analysis or design of a system is considered MF when there is synergistic use of different mathematical descriptions ... in the analysis or design procedure’. MF models have shown promise in diverse engineering fields, particularly in applications demanding computationally expensive iterations, such as design applications (e.g., Ng and Willcox (2015)), prediction of extreme loads (e.g., Drummen et al. (2022)), and solving partial differential equations (e.g., Perdikaris et al. (2017)).

In the context of information theory, entropy serves as a metric for quantifying the amount of information inherent in a message Shannon (1948). This concept can be extended to compute the information associated with an event, random variable, or probability distributions Murphy (2012). In the context of design applications, entropy can function as a metric for assessing the uncertainty associated with predicting the design space. Consequently, entropy can be utilized to enhance design exploration by quantifying such uncertainty.

Different entropy metrics have been employed to support engineering applications. Nevertheless, to the authors’ best knowledge, a research gap exists in utilizing entropy to enhance a MF design framework for the early-stage design of complex vessels. Therefore, this research establishes a MF design framework and explores the role of entropy in facilitating the design exploration of complex vessels. More specifically, the utilization of entropy is proposed to determine the necessary number of HF simulations for MF design optimization. As noted by Mainini et al. (2022), a mathematical formulation to determine the required number of HF simulations for MF analysis is currently lacking. The authors suggest that entropy can be considered as a suitable mathematical formulation for this purpose. Furthermore, as an expansion of Charisi et al. (2022b), we suggest that entropy can act as an indicator to perform kernel optimization throughout the optimization process.

## **RELEVANT WORK**

### **Early-stage design exploration of novel vessels with multi-fidelity models**

As previously stated, the importance of early-stage design lies in the crucial decisions that shape a vessel’s performance. To achieve a good design, ship designers must make well-informed decisions. This involves conducting a broad exploration of the design space, considering various concepts Van Oers et al. (2018). The goal of such exploration is to discern design trends and crucial trade-offs Andrews (2018), rather than offering highly precise values for specific key performance indicators (KPIs). The difficulty lies in striking a balance between attaining the necessary accuracy and managing computational costs, given our constraints in terms of both computation and time. When designing novel vessels, it becomes essential to incorporate HF analysis early in the process to effectively capture design trends Charisi et al. (2022a). However, achieving the required accuracy through HF tools results in escalated costs. These costs can be offset by integrating HF analysis via MF analysis.

State-of-the-art research incorporates MF analysis in ship design. In this section, characteristic examples of studies are presented, without aiming for an exhaustive literature review. The design optimization of SWATH hull forms was explored by Bonfiglio et al. (2018, 2020), who evaluated the vessel’s seakeeping using two methods: a strip theory and a boundary element method based on the potential flow assumption Bonfiglio et al. (2018). Additionally, the hull forms were assessed

**Figure 1:** Variability in uncertainty across the design process Mavris et al. (1998)

for calm water resistance using a Boundary Element Method (BEM) formulated approach, assuming a potential flow-like behavior as the LF model, and a solver based on the unsteady Reynolds-averaged Navier-Stokes (RANS) equation, serving as the HF model Bonfiglio et al. (2020). The MF model was built based on GPs. Serani et al. (2022) addressed the design problem of optimizing the DTMB 5415 hull form for seakeeping and resistance. The researchers employed various analysis models, ranging from potential flow to Reynolds-Averaged Navier-Stokes equations, to solve the physical problem. Different methods were employed to construct the MF surrogates, namely stochastic radial basis functions, Kriging partial least squares, augmented expected improvement-based Kriging, and mixed-fidelity neural networks. Gaggero et al. (2022) tackled the problem optimizing a marine propeller through two methods—utilizing an inviscid potential flow-based BEM approach as the LF method and employing an inviscid finite volume RANS solver as the HF method. All the studies report promising results.

As mentioned earlier, the primary objective in early-stage design is to identify the concept that best addresses the design problem through key decisions. However, a substantial portion of relevant research, including the research studies presented, has concentrated on hull optimization, primarily emphasizing quantities of interest like resistance or seakeeping. The authors have envisioned the possibility of advancing such frameworks to earlier stages in the design process to enhance decision-making effectiveness. The uncertainty of the design space prediction is a significant factor that can be utilized to facilitate the introduction of such methods earlier on in the design process.

Uncertainty is associated with the lack of knowledge North (2017). While uncertainty is closely connected to risk, the primary distinction lies in the ability to assign a quantifiable value to risk, a task that proves challenging in the realm of uncertainty Silver (2012). Mavris et al. (1998) highlighted that there is heightened uncertainty in the early phases of the design, as shown in Figure 1. This uncertainty is introduced by the assumptions, the analysis codes of various fidelities, economic uncertainty, or technological risks. Using information-theoretic entropy as a metric enables the quantification of uncertainty in predicting the design space. In this study, the objective is to leverage this uncertainty, measured through entropy, to facilitate the early-stage design of innovative vessels.

## Information theory: the entropy

According to Martignon (2001), information theory ‘is the mathematical treatment of the concepts, parameters and rules governing the transmission of messages through communication systems’. In 1948, Claude Shannon laid the foundation for information theory. The concepts and principles of information theory have expanded far beyond their original appli-

cation. Nowadays, they find application in various domains, including cryptography, machine learning, economics, and neuroscience. In the context of early-stage design, there is a direct link between design exploration and information theory via uncertainty. Krus (2013) states that ‘design theory should really be a theory of design information’.

Entropy, a foundational concept in information theory, can be understood as either the measure of information content or the degree of randomness associated with a discrete random variable Duplantier and Rivasseau (2018). Various mathematical formulations exist for entropy, with some of the most commonly used ones encompassing relative entropy, or commonly known as KL divergence, and mutual information. The relevant equations to be employed in this study are presented in a subsequent section.

Entropy has found application in research problems related to design optimization. Saad and Xue (2023) proposed using entropy as a means to identify design configurations with a high likelihood of attaining optimal solutions. In such content, entropy was applied to assess the partial configuration candidates represented as branches in the AND-OR tree, aiding in the elimination of improbable branches to lead to the optimal outcome. In addition, Krus (2013) suggested that the entropy rate, which is based on Shannon’s information entropy, can be a performance criterion to characterize the difficulty of different optimization problems. Farhang-Mehr and Azarm (2008) proposed an entropy-based metric to assess the quality of solution sets obtained during design optimization. The assessment is based on the distribution of the solution set over the pareto optimal frontier. Finally, Chaudhuri et al. (2020) proposed a MF design framework for risk-averse design optimization. The method is based on importance sampling and cross-entropy.

In this study, entropy serves as a metric to quantify the uncertainty within the early-stage design space. The proposal is to employ this metric as a termination criterion for concluding the design exploration process. The rationale behind this recommendation lies in the observation that, to the best of our knowledge, these problems typically operate under a predetermined budget. Thus, entropy can form a criterion to make an informed decision regarding the termination of the optimization process. Furthermore, the authors advocate for using entropy as an indicator for optimizing the covariance matrix via the optimization of the kernel function, as an extension of the method proposed in Charisi et al. (2022b). The technical details of the framework are elucidated in the following section.

## PROPOSED METHOD

This section outlines the technical aspects of the methods employed in constructing the proposed framework. Specifically, it offers a comprehensive overview of the framework itself and presents the mathematical formulation of MF-GPs, compositional kernels, Bayesian optimization, and information entropy.

### Proposed Framework

The flowchart illustrating the design architectural framework (DAF) is depicted in Figure 2. Organized around three primary blocks—generation, analysis, and optimization engines—the design framework shares commonalities with other design frameworks. However, the distinctive feature of this particular framework lies in the way the analysis and optimization engines are constructed to encompass the information entropy metrics. The analysis engine is dedicated to constructing the MF surrogate model for the design space. To enhance the precision of design space predictions, compositional kernels, as kernel functions, are employed to discern trends within the design space Charisi et al. (2022b). Entropy serves as a criterion for determining the optimization step where kernel optimization is most beneficial. Additionally, the optimization engine is designed to efficiently identify the optimal design point using Bayesian optimization. Entropy is incorporated into this phase of the framework as a criterion for terminating the optimization process.

**Figure 2: Flowchart of the design framework**

## Gaussian Processes, MF-Gaussian Processes and Compositional Kernels

### Gaussian Processes

GPs are used to build approximations of real-world processes  $f(x)$ . Mathematically, a GP is defined as “a collection of random variables, any finite number of which have a joint Gaussian distribution, and it is fully characterized by its mean and covariance function Rasmussen (2003)”. The mathematical formulation for the GPs is taken from Rasmussen (2003). The GP is fully defined by a mean  $\mu(x)$  and a covariance function  $k(x, x')$  according to Equations 1, 2, and 3. A common practice is to assign the prior a zero mean and a kernel function  $K_{ij} = k(x_i, x_j; \theta)$ .

$$f(x) \sim \mathcal{GP}(m(x), k(x, x')) \quad (1)$$

$$m(x) = \mathbb{E}[f(x)] \quad (2)$$

$$k(x, x') = \mathbb{E}[f(x) - m(x)][f(x') - m(x')] \quad (3)$$

The available analysis or experimental data can be described according to Equation ??:

$$y = f(x) + \epsilon, \epsilon \sim \mathcal{N}(0, \sigma_n^2 \mathcal{I}) \quad (4)$$

where  $f$  represents the function to be approximated and  $\epsilon$  represents the error term which is assumed to be normally distributed with variance  $\sigma_n^2$ .

GPs are part of the Bayesian methods, where a pivotal aspect of the analysis involves the prior distribution. The prior distribution encapsulates our pre-existing knowledge or assumptions about the unknown function  $f$ . The prior distribution of the observed data  $X$  and the test data  $X'$  is determined according to Equation 5.

$$\begin{bmatrix} y \\ f_* \end{bmatrix} \sim \mathcal{N} \left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} K(X, X) + \sigma_n^2 I & K(X, X_*) \\ K(X_*, X) & K(X_*, X_*) \end{bmatrix} \right) \quad (5)$$

where  $f_*$  are the function values evaluated at the test locations  $X_*$ . In Bayesian learning, the prior distribution is revised by incorporating the observed data, resulting in the formation of the predictive distribution. Mathematically, the prior distribution is conditioned on the observed data to form the predictive distribution according to Equations 6, 7, and 8:

$$f_* | X, X_*, y \sim \mathcal{N}(\mu_*, \sigma_*^2) \quad (6)$$

$$\mu_* = k_*^T (K + \sigma_n^2 I)^{-1} y \quad (7)$$

$$\sigma_*^2 = k_{**} - k_*^T (K + \sigma_n^2 I)^{-1} k_* \quad (8)$$

where  $K = K(X, X)$ ,  $k_{**} = k(x_*, x_*)$  and  $k_* = k(x_*)$ . In order to optimize the model's hyperparameters, the marginal log-likelihood was applied. The marginal log-likelihood is defined according to Equation 9.

$$\log p(y|x, \theta) = -\frac{1}{2} \log |K + \sigma_n^2 I| - \frac{1}{2} y^T [K + \sigma_n^2 I]^{-1} y - \frac{n}{2} \log 2\pi \quad (9)$$

### MF Gaussian Processes

The present study adopts the autoregressive scheme AR1 introduced by Kennedy and O'Hagan (2000). The scheme is based on the assumption that there is a linear dependency among different fidelity models. The mathematical formulation follows the description in Le Gratiet and Garnier (2014). The mathematical description of the bifidelity model is given since the case studies deal with bifidelity problems. The sub-models are linked according to Equation 10 and 11. The HF function connects to the LF function via a scaling function  $\rho$  and an additive function  $\delta$ . It is assumed that  $F_2$  refers to the HF function and  $F_1$  refers to the LF function. The function  $\delta$  is a GP which is independent of  $F_1$ .

$$F_2(x) = \rho(x)F_1(x) + \delta(x) \quad (10)$$

$$F_1(x) \perp \delta(x) \quad (11)$$

The predictive model is a multivariate normal distribution described by Equation 12, with a mean function according to Equation 13 and a variance according to Equation 14.

$$[F_2(x) | \mathbf{F} = \mathbf{f}, (\beta_1, \beta_2, \rho), (\sigma_1^2, \sigma_2^2), (\theta_1, \theta_2)] \sim \mathcal{N}(m_{F_2}(x), s_{F_2}^2(x)) \quad (12)$$

$$m_{F_2}(x) = \mathbf{h}(x)^T \beta + k(x)^T \mathbf{V}^{-1} (\mathbf{f} - \mathbf{H} \beta) \quad (13)$$

$$s_{F_2}(x) = \rho^2 \sigma_1^2 + \sigma_2^2 - \mathbf{k}^T \mathbf{V}^{-1} \mathbf{k}(x) \quad (14)$$

where the trend parameters  $\beta = \begin{pmatrix} \beta_1 \\ \beta_2 \end{pmatrix}$ , and  $\mathbf{f} = \begin{pmatrix} f_1 \\ f_2 \end{pmatrix}$ . The variance parameters  $\sigma_1^2, \sigma_2^2$  and the parameters  $\theta_1, \theta_2$  are the model's hyperparameters.

$$\mathbf{H} = \begin{pmatrix} \mathbf{f}'_1(x_1^{(1)}) & 0 \\ \vdots & \vdots \\ \mathbf{f}'_1(x_{n_1}^{(1)}) & 0 \\ \rho \mathbf{f}'_1(x_1^{(2)}) & \mathbf{f}'_2(x_1^{(2)}) \\ \vdots & \vdots \\ \rho \mathbf{f}'_1(x_{n_2}^{(2)}) & \mathbf{f}'_2(x_{n_2}^{(2)}) \end{pmatrix} \quad (15)$$

$$\mathbf{h}(x)^T = (\rho \mathbf{f}'_1(x), \mathbf{f}'_2(x)) \quad (16)$$

The covariance matrix is calculated as described in Equation 17.

$$\mathbf{V} = \begin{pmatrix} \sigma_1^2 R_1(\mathbf{D}_1) & \rho \sigma_1^2 R_1(\mathbf{D}_1, \mathbf{D}_2) \\ \rho \sigma_1^2 R_1(\mathbf{D}_2, \mathbf{D}_1) & \rho^2 \sigma_1^2 R_1(\mathbf{D}_2) + \sigma_2^2 R_2(\mathbf{D}_2) \end{pmatrix} \quad (17)$$

## Compositional Kernels

The covariance matrix conveys the degree of resemblance among data points Rasmussen (2003) and integrates prior beliefs and knowledge regarding the function  $f$ . The validity of the covariance matrix requires both symmetry and positive semi-definiteness. Prior research has examined basis functions used as kernel functions, which are defined as functions generating valid covariance matrices. For instance, the periodic kernel is employed for modeling repetitive functions. In this study, the framework introduced in Charisi et al. (2022b) was employed. The core idea was the development of compositional kernels, aiming to facilitate early-stage design analysis and optimization.

Compositional kernels, introduced by Duvenaud et al. (2013), are defined as a combination of a limited number of basis kernels through addition or multiplication. Choosing the basis kernels is intended to mathematically encapsulate the key features of the function  $f$  or, in the context of this specific research problem, the design space. The compositional kernels are built via discrete optimization. As the objective function, the Bayesian Information Criterion (BIC) was used as proposed in the original paper Duvenaud et al. (2013). BIC is defined according to Equation 18.

$$\mathcal{BIC} = k_{hyp} \ln n - 2 \ln L \quad (18)$$

where  $n$  is the number of training data,  $k_{hyp}$  is the number of hyperparameters, and  $L$  is the maximized likelihood value. BIC comprises two elements: a penalty term determined by the count of model parameters and a term derived from the likelihood function. The advantage of opting for BIC over maximizing the marginal log-likelihood is its attention to the complexity of the kernel function. By favoring functions with fewer hyperparameters, BIC aids in preventing overfitting.

## Bayesian Optimization

Bayesian optimization (BO) has found extensive application in addressing optimization problems characterized by objective functions that are costly to evaluate. It comprises three fundamental components: establishing the prior distribution, refining the prior distribution to derive the posterior distribution, and determining the subsequent sampling point Brochu et al. (2009). The initial two components are associated with shaping the surrogate model, while the last one is linked to the acquisition function. The MF surrogate model in the proposed framework was built via MF-GPs as described in the previous sections. The acquisition function establishes a strategy for assessing the utility of evaluating the objective function at specific points within the search space Di Fiore and Mainini (2024). The objective of the acquisition function is to strike a

balance between exploring new areas and exploiting known areas within the search space. For this research, Expected Improvement (EI) was employed as the acquisition function, as described in Equation 19.

$$\alpha_{EI}(y_{\text{best}}, \mu, \sigma) = - \left( \phi \left( \frac{y_{\text{best}} - \mu}{\sigma} \right) + \frac{y_{\text{best}} - \mu}{\sigma} \cdot \Phi \left( \frac{y_{\text{best}} - \mu}{\sigma} \right) \right) \cdot \sigma \quad (19)$$

$y_{\text{best}}$  represents the current optimum,  $\mu$  and  $\sigma$  denote the mean and covariance matrix, respectively, while  $\phi$  and  $\Phi$  refer to the probability density function and the cumulative distribution function, respectively.

## Information Entropy

Entropy measures the uncertainty that observers have about the state of a random variable  $X$  Varley et al. (2023). The entropy  $H[p(x)]$  of a distribution  $p(x)$  is a measure measuring the uncertainty in the distribution Rasmussen (2003). The integral can be replaced by a sum of discrete variables. The differential entropy for continuous variables is calculated according to Equation

$$H(X) = - \int_S f(x) \log f(x) dx \quad (20)$$

where  $S$  is the support of the probability density function. Regarding the multivariate Gaussian distribution, the entropy is defined according to Equation 21.

$$H[\mathcal{N}(\mu, \Sigma)] = \frac{1}{2} \log |\Sigma| + \frac{D}{2} \log 2\pi e \quad (21)$$

where  $D$  is the number of dimensions. Unlike entropy for discrete random variables, differential entropy can take negative values. The covariance matrix is guaranteed to be symmetric positive semi-definite. However, in instances where the covariance matrix becomes singular, the entropy value tends toward negative infinity. To mitigate this issue for singular matrices, the eigenvalues are computed. Any zero eigenvalues are replaced with a value of  $10^{-6}$ , and the covariance matrix is then reconstructed based on the adjusted eigenvalues using Equation 22.

$$A = U \Lambda U^{-1} \quad (22)$$

where  $A$  represents an  $n \times n$  matrix,  $U$  is an  $n \times n$  matrix containing the eigenvectors of  $A$ , with each column of  $U$  representing an eigenvector of  $A$ , and  $\Lambda$  is an  $n \times n$  diagonal matrix containing the eigenvalues of  $A$  along its diagonal elements.

The termination of the optimization loop occurs when the quantified uncertainty of the design space prediction, assessed through entropy, reaches a predetermined threshold. To ensure robustness, the criterion includes the condition that the value of entropy should not increase by more than a predetermined margin for  $n$  iterations. In summary, the formulation of the termination criterion can be found in Algorithm 1. A comparable concept was applied to the optimization criterion for compositional kernels. Entropy serves as an indicator to decide whether compositional kernel optimization should be conducted. The rationale behind this approach is that a notable decrease in entropy signifies a significant change in the predictive distribution. The formulation of the kernel optimization criterion is detailed in Algorithm 2.

```

**Algorithm 2:** Kernel optimization criterion

## Error metrics

Various error metrics were employed to evaluate the accuracy of the proposed framework. The Root Mean Squared Error (RMSE), as defined in Equation 23, was used to quantify the accuracy of the models in predicting the design space. Furthermore, the error metrics  $\epsilon_x$ ,  $\epsilon_f$ ,  $\epsilon_t$  characterize the normalized error in the design space, the objective function, and the Euclidean distance in the normalized  $x$ - $f$  hyperspace. Detailed descriptions of these metrics are provided in Equations 24, 25, and 26.

$$\epsilon_{RMSE} = \frac{1}{y_{max} - y_{min}} \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2} \quad (23)$$

$$\epsilon_x = \frac{\|\hat{x}^* - x^*\|}{\sqrt{N}} \quad (24)$$

$$\epsilon_f = \frac{f(\hat{x}^*) - f_{min}}{f_{max} - f_{min}} \quad (25)$$

$$\epsilon_t = \sqrt{\frac{\epsilon_x^2 + \epsilon_f^2}{2}} \quad (26)$$

## CASE STUDIES

The case studies encompass a simplified example, using the Jump Forrester function, to illustrate the rationale behind integrating information entropy into an early-stage design framework. Subsequently, two analytical problems will be addressed: the 1D Heterogeneous function and the 2D shifted rotated Rastrigin function. Finally, a realistic ship design is showcased, addressing the 2D design of the AXE frigates focused on optimizing the wave-induced vertical bending moment (VBM).

### A toy example: the Jump Forrester function

This simplified design problem aims to give a better understanding on how and why entropy is integrated in the design framework. The toy case study assumes a one-dimensional design space characterized by the Jump Forrester function as described in Equations 27 and 28. The initial dataset comprises 5 HF and 35 LF observations.

$$f_1(x) = \begin{cases} (6x - 2)^2 \sin(12x - 4), & 0 \leq x < 0.5 \\ (6x - 2)^2 \sin(12x - 4) + 10, & 0.5 \leq x \leq 1 \end{cases} \quad (27)$$

$$f_2(x) = \begin{cases} 0.5f_1(x) + 10(x - 0.5) - 5, & 0 \leq x < 0.5 \\ 0.5f_1(x) + 10(x - 0.5) - 2, & 0.5 \leq x \leq 1 \end{cases} \quad (28)$$

Figure 3 illustrates the evolution of error metrics and entropy throughout the optimization process. Evidently, an augmented

dataset correlates with heightened accuracy in the obtained results. This is a general trend which can be observed in both the evolution of  $H$  and  $\epsilon$  throughout the optimization. Figure 3a illustrates a notable decrease in entropy between iteration 10 and 11. The decrease in entropy is correlated with a reduction in the error metrics, as depicted in Figure 3b. It is evident that the variations in entropy do not perfectly align with changes in the error metrics. This underscores the importance of treating entropy as an indicator rather than an absolute measure.

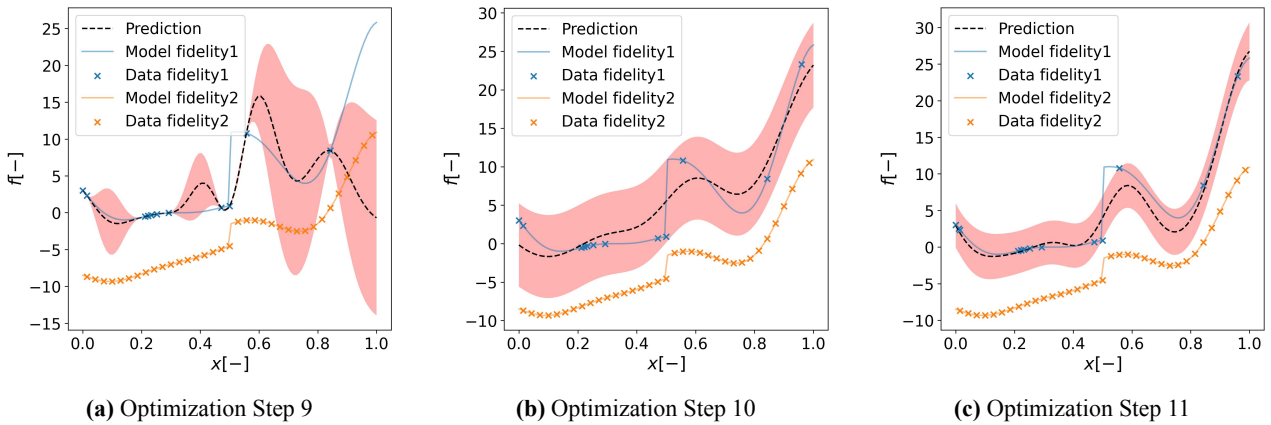

(a) Tracking  $H$  throughout the optimization iterations

(b) Tracking  $\epsilon$  throughout the optimization iterations

**Figure 3:** Comparing  $H$  with  $\epsilon$  error metrics

To further analyze the results, the design spaces for iterations 9, 10, and 11 are plotted in Figure 4. Specifically, Figure 4a displaying the prediction of the design space at step 9, reveals that the prediction is inaccurate across the domain and the variance is high. However, the area where the optimum lies is further explored, resulting in a lower calculated error. This localized behavior cannot be captured via entropy which is calculated over the entire design domain. Similarly, the design space in iteration 10, depicted in Figure 4b, is characterized by an inaccurate prediction of the design space and high uncertainty bounds. Entropy is slightly increased between iteration 9 and 10. In addition, the measured error is higher since the prediction fails to capture the area containing the optimum. Moving on to iteration 11, illustrated in Figure 4c, the prediction aligns more closely with the true design space, resulting in a significant reduction in both calculated error and entropy.

(a) Optimization Step 9

(b) Optimization Step 10

(c) Optimization Step 11

**Figure 4:** Design space for various optimization steps

## Analytical function 1D: the Heterogeneous function

A commonly employed analytical function is the Heterogeneous function, known for its localized and multi-modal behavior Mainini et al. (2022). The 1D Heterogeneous function is described by the Equations 29 and 30. The Heterogeneous function can be visualized in Figure 5.

$$f_1(x) = \sin 30(x - 0.9)^4 \cos 2(x - 0.9) + (x - 0.9)/2 \quad (29)$$

$$f_2(x) = (f_1(x) - 1.0 + x)/(1.0 + 0.25x) \quad (30)$$

**Figure 5:** Heterogeneous function

where  $0 \leq x \leq 1$ . In this case study, the initial training set comprised included 10 HF data fused with 35 LF data. The base case underwent 15 optimization steps. The parameters of this case study remained consistent when evaluating both the entropy-driven termination criterion and entropy-driven kernel optimization. Furthermore, recognizing the substantial impact of the training set on model performance, statistical insights were derived by employing 20 distinct training sets in both scenarios.

Regarding the entropy-driven optimization criterion, relevant statistics can be found in Tables 1 and 2 for the proposed and the base model, respectively. Six scenarios were examined, involving the increase of noise in the training data from 0.00 to 0.05. The comparison of mean error metric values is presented and visualized in Figure 6. The main observation is that, as anticipated, the error generally rises with an increase in noise level. In most instances, the proposed model demonstrates comparable or slightly elevated errors compared to the base model, while concurrently achieving significant computational savings. For instance, when  $\sigma_n = 0.04$ , the average number of iterations is 10.5, resulting in a 30% improvement compared to the 15 iterations in the base scenario.

Regarding the entropy-driven kernel optimization, the results can be found in Tables Tables 3 and 4 for the proposed and base models, respectively. The visualization of mean error metrics is presented in Figure 7. As illustrated in Figure 7, the proposed model demonstrates a comparable performance to the base model, and their results are closely aligned, thus the performance of the two models is similar.

## Analytical function 2D: the Shifted Rotated Rastrigin function

In this case study, the 2D shifted-rotated Rastrigin function was employed. This function is characterized by multi-modal behavior. To investigate this, a noise term  $e_{data}$  was added to the 2D shifted-rotated Rastrigin function, taken from Mainini et al. (2022). Thus, for this analysis, Equations 31 and 34 were used. The function can be visualized in Figure 8.

with  $\alpha(\phi) = \Theta(\phi)$ ,  $w(\phi) = 10\pi\Theta$ ,  $\beta(\phi) = 0.5\pi\Theta(\phi)$ ,  $\Theta(\phi) = 1 - 0.0001\phi$ . For the present case study, we chose  $\phi = 2500$ .

In this case study, the initial training set consisted of 10 HF data combined with 50 LF data. The base case underwent 15 optimization steps. Consistent with other studies, parameters were maintained constant during the assessment of both the entropy-driven termination criterion and entropy-driven kernel optimization. Statistical insights were obtained by using 20 different training sets in both scenarios.

Regarding the entropy-driven optimization criterion, relevant statistics can be found in Tables 5 and 6. The visualization of mean error metrics is presented in Figure 9. A notable observation is that, similar trends to the previous case study are observed, where the suggested model displays errors that are comparable or slightly higher than those of the base model, yet it concurrently realizes computational savings. The discrepancy between the models is more apparent, possibly due to the increased complexity of this problem. Notably, in this instance, the error does not escalate with the noise level.

Regarding the entropy-driven kernel optimization, the results can be found in Tables 7 and 8 for the proposed and base models, respectively. The visualization of mean error metrics is presented in Figure 10. The findings indicate a substantial enhancement in error metrics of the proposed model compared to the base case across various scenarios. These results are noteworthy, with a more pronounced improvement compared to the previous case study. This heightened improvement could be attributed to the increased complexity of the problem or the ability of compositional kernels to better capture the structure of the function.

## Ship design problem 2D: the AXE frigates

The AXE frigates are characterized by the inclusion of an AXE bow, a design initially conceived by Keuning et al. (2015). The AXE bow offers the potential to enhance a vessel's seakeeping capabilities, making it a compelling choice for frigates that must effectively carry out missions even in challenging weather conditions. The key performance indicator (KPI) for this design problem focuses on predicting the wave-induced VBM.

The VBM emerges as a significant load with substantial implications for ship structural design. It results from the uneven distribution of water pressure and gravity, resulting in the bending of the elastic hull structure Molland (2008). Wave loading conditions are assessed independently for each design variation. More specifically, we have chosen to examine the vessel in a sea state that maximizes wave-induced VBM, specifically when the wavelength equals the ship's length. Consequently, a regular sea state is selected and characterized by Equations 36 and 37 Tupper (2004). The vessel's speed was set to 0 knots. The problem is simplified into a 2D case, where only the vessel's length ( $L_{pp}$ ) and breadth ( $B$ ) are varied.

(d) Graph depicting the relationship between  $RMSE$  and  $\sigma_n$

**Figure 9:** Rastrigin function: Entropy-driven termination criterion, while varying the noise  $\sigma_n$

$$\lambda = L_{pp} \quad (36)$$

$$H = 0.607 \cdot \sqrt{L_{pp}} \quad (37)$$

In the frequency domain (FD) calculation of the wave-induced VBM, PRECAL software, developed by Marin, was employed. PRECAL is a dedicated tool designed to predict linear responses through potential flow calculations. The tool operates by: (1) dividing the wetted hull into multiple quadrilateral panels and defining flexural modes, (2) calculating hydrodynamic coefficients through solving the linearized boundary value problem, and (3) determining ship motions and loads using linearized potential flow. Additionally, it incorporates adjustments for viscous damping based on empirical corrections.

Furthermore, the time domain (TD) results were obtained using PRETTI\_R, a 3D time-domain nonlinear seakeeping and hydroelasticity tool. In contrast to PRECAL, PRETTI\_R is specifically crafted for predicting motions in high sea states, en-

compassing rigid-body motion, elastic deformation, and hydrodynamic loads. It is also capable of considering slamming and whipping loads. Developed as part of the Cooperative Research Ships (CRS) initiative, this software calculates the Froude Krylov force by integrating incident wave hydrodynamics and hydrostatic pressure across the vessel's hull surface. The diffraction force is estimated by scaling the FD diffraction force Response Amplitude Operator (RAO) with the incident wave amplitude. The radiation force is computed through a convolution integral involving an impulse function, and slamming force can be assessed using either the Generalized Wagner Model or the Modified Logvinovich Model. PRETTI\_R utilizes FD results to derive the required impulse functions.

The initial training set consists of 2 HF PRETTI\_R simulations (TD data) and 20 PRECAL simulations (LF data). The LF and the HF design space can be visualized in Figure 11. The optimization steps were configured to be 10. The outcomes are presented in Tables 9 and 10 for the entropy-driven termination criterion and kernel optimization, respectively. The data was gathered through 20 simulations utilizing various initial Design of Experiments (DoEs). In general, the results exhibit similar trends to previous case studies. The performance metrics of the proposed model slightly surpass those of the base model, with an associated reduction in computational steps to an average of 8.55 from the set 10 steps. Concerning the kernel optimization scenario, the performance metrics of the proposed model are improved compared to the base model.

## CONCLUSIONS

In summary, the paper proposes the integration of entropy, a mathematical concept from information theory, to improve a MF design framework for early-stage design exploration. Two concepts, namely the entropy-driven termination criterion and entropy-driven kernel optimization, were formulated and illustrated. The case studies encompassed analytical benchmark problems, including the 1D Jump Forrester and the 2D Shifted Rotated Rastrigin function, along with a 2D physical problem involving AXE frigate design where variations in  $L$  and  $B$  were considered.

Similar patterns were observed across the different case studies. Concerning the termination criterion, the performance metrics slightly exceeded those of the base model while concurrently achieving computational savings. This suggests the potential for a potent tool in design exploration, particularly when the goal is to discern design trends. Furthermore, the outcomes related to kernel optimization exhibited enhancements in most cases and comparable results in others. This underscores the concept's potential in integrating compositional kernels within a design optimization loop.

The inclusion of entropy in design exploration is rooted in the concept that entropy can serve as an indicator of how comprehensively the design space has been investigated. It is crucial to emphasize that entropy is not presumed to be an absolute performance measure akin to error metrics. Instead, its significance lies in the fact that in practical design exploration problems, calculating error metrics is not feasible. To advance this concept, exploring its scalability to higher-dimensional problems is an area that needs further research. Additionally, determining the critical parameters for the method is a case-dependent and challenging aspect in real-world applications.

## ABSTRACT

*The current sea margin estimate applied in early ship design, commonly assumed 15-20% extra installed engine power, is not based on calculations, but has nonetheless become an industry standard. These sea margin estimations, applied in early ship design, are insufficiently accurate. This paper evaluates if a data driven approach is suitable to more accurately predict the sea margin in early ship design. Using operational data this method considers the whole operational profile of the vessel not limited to design or calm water conditions. A case study is performed where a data driven model is trained to make power predictions, subsequently this trained model is used to make calm water predictions. This proof of concept illustrates the potential of proposed method to be utilised for sea margin estimations in early ship design.*

## KEY WORDS

Sea Margin; Early Ship Design; Operational Data; Data Driven Model; Calm Water Predictions.

## INTRODUCTION

In the early design stage of a vessel, many characteristics of the vessel are determined and fixed. When considering the propulsion system and power train, these choices have a large impact on the future emissions of the vessel, and care is required so as not to install too much power. A key parameter in this estimation is the sea margin, an addition of 15-20% to compensate for any unknowns and issues related to sailing on the oceans instead of in calm water (Esmailian et al. (2022), Islam and Soares (2022)). To the best of the authors' knowledge, there is no clear explanation for this value, and it has been maintained at this value despite improvements in estimation techniques and other scientific advances. As this directly impacts the installed power, reconsidering this value is warranted.

As explained, the sea margin is additionally installed engine power to attain added resistance due to external conditions, such as resistance from wind, waves, and/or fouling. To more accurately estimate the sea margin, the required extra power is needed to accurately estimate the added resistance. Based on the added resistance, a more accurate assumption for the required sea margin can be made, or at least a start can be made with understanding how this sea margin ensures safety and comfort during operations. To enhance the accuracy of models that predict the sea margin, it is essential to first assess the existing methods used to calculate added resistance. The following paragraphs will detail this evaluation.

## Literature Review

This section evaluates the current methods for calculating the added resistance: traditional methods, towing tank testing, and computational fluid dynamics.

### *Traditional Methods*

A significant component of added resistance is wave resistance, which is defined as the resistance encountered by a ship as it moves through water. More precisely, "*the steady motion of a ship in initially smooth water assuming an ideal fluid*" (Bertram (2012)). Often considered to be the first breakthrough in wave resistance calculations is the 1898 paper of J.H. Michell, using a triple integral to calculate the wave resistance of a ship (Michell (1898)).

Another well-known method is Holtrop-Mennen, which can predict the resistance and propulsion data for different hull designs using regression analysis. First, in 1982, their method was used to develop a formula based on full-scale data and model experiments (Holtrop et al. (1982)). Subsequently, in 1984, the method was refined with more data and model tests to improve overall power predictions. The earlier method proved insufficient for more high-speed vessels at Froude numbers above 0.5 (Holtrop (1984)). In 1984, Holtrop and Mennen developed a formula to calculate the resistance, Equation 1, (Holtrop (1984)).

$$R_{Total} = R_F(1 + k) + R_{APP} + R_W + R_B + R_{TR} + R_A \quad (1)$$

In which  $R_F$  is the frictional resistance;  $(1 + K)$  is the form factor of hull;  $R_{APP}$  is the appendage resistance;  $R_W$  is the wave resistance;  $R_B$  is the additional pressure resistance of bulbous bow near the water pressure;  $R_{TR}$  is the additional pressure resistance due to transom immersion and  $R_A$  is the model ship correlation resistance. This is a parameter-set that describes the hull and is used to calculate the total resistance, the formula is made up out of the; frictional resistance, dependant on the form factor of the hull, the appendage resistance, wave resistance, bulbous bow pressure resistance, transom immersion pressure resistance and model-ship correlation resistance.

As this method relies on analysis of a finite combination of full-scale data and model tests, estimations and assumptions within the used parameters allow for less detail and robust results. When unorthodox combinations of parameters are used, it leads to inaccurate results (Holtrop et al. (1982)). This causes the regression method not to be the best fitting method analysing the vessel after construction (Petersen et al. (2012)).

As ship resistance calculations tend to focus on the resistance of ships through water, an under-exposed factor in overall resistance is wind loading. Not surprising as water is approximately 800 times more dense than air, however the surface area of ships above water can impact overall resistance (Blendermann (1994)). Particularly in the case of cargo ships, for instance, the surface area of the loaded vessel above water can be quite substantial. Blendermann (1994) identified parameters to calculate aerodynamic forces and moments to numerically simulate ship behaviour. This experiment was executed with different wind tunnel tests on scale models.

Resistance factors of hull coating are generally neglected, or general assumptions are made in traditional resistance calculations. Almost all ships have anti-fouling paint applied to their underwater hulls. The general state of this coating, combined with slime, shell, and weed growth, adds resistance as the ship moves through the water. Townsin (2003) describes a general roughness parameter to calculate the penalty of fouling, the ship's speed loss at constant power.

### ***Direct Model Testing in Towing Tanks***

Experimental Fluid Dynamics, based on scaled ship models tested in towing tanks, provide an alternative to the traditional methods. The first internationally recognised towing tank experiments, are the results of the experiments executed by David Watson Taylor, published in his 1910 book "The speed and power of ships". In his book, Taylor describes the estimation of the flow resistance of 80 vessels that were model-tested in a towing tank. The sequential testing of variations in design characteristics of the models led to estimations of ship resistance (Taylor (2013)). The experiments by Taylor attributed a great deal to the knowledge of the impact of certain design choices that can be made in ship design. As experimental research relies on the repeatability of experiments in a fixed set of conditions, the smallest variation in conditions will lead to different results. Neglecting to conduct the experiments in identical temperature conditions by Taylor led the US Navy to carry out a re-analysis of the Taylor Standard Series in 1954 to correct for this variation in experimental conditions (Gertler (1954)).

The downsides to model tests are accuracy due to scaling and the overall costs of the experiments. Furthermore, the accuracy of towing tank can fluctuate as scaling problems tend to lead to a difference in wave behaviour between scale models and full size ships (Bertram (2022)). Testing in a towing tank is an expensive and time-consuming experiment that can cost tens of thousands of euros per test (Barczak (2020)).

### ***Computational Fluid Dynamics***

Computational fluid dynamics (CFD) is a form of fluid mechanics that uses numerical analysis and data structures to analyse fluid flows, and it can be used to simulate and calculate the flow around and, therewith, the added resistance of a hull-form. CFD was first developed in the 1950s with the emergence of the computer, as this opened up an more efficient method of the computation of complex partial differential equations like finite element methods (FEM) and finite difference methods (FDM) (Chung (2002)). Dynamic flows over intricate shapes can be calculated and analysed for both aerodynamics and hydrodynamics (Anderson and Wendt (1995)). In the 1960s simplified boundary layer equations were solved for ship hulls, those more basic elementary flow models led to less accurate results (Bertram (2022)). A Reynolds Averaged Navier-Stokes Solver (RANS) method was developed in the 1980s and was improved greatly with stern flow prediction in the 1990s and a numerical method for three dimensional flows was described (Chen et al. (1990)). However, because of insufficient knowledge about modeling of turbulence, propeller simulations were largely inaccurate (Zhang et al. (2006)).

To verify CFD model calculations a ship model was made open source available. The KVLCC (KRISO Very Large Crude Carrier model) was designed, analysed in both towing tank and CFD (Van et al. (2000)). Later, in 2005, a second model with a slight difference in hull shape was developed (Hino et al. (2021)). The hull lines, rudder, and propeller data are open source and available for validation and verification (Kvale (2014)). This model is used on a large scale in academics to increase the accuracy of CFD calculations. Sadat-Hosseini et al. (2013) verified a technique to calculate the added resistance of short and long waves using the KVLCC2 vessel.

Using numerical models for predicting ship performance in the design phase is becoming more common since the computational power of computers is far greater than it used to be, and RANS equations can now be more easily solved using CFD. The KVLCC2 vessel was used to predict and verify added resistance at constant forward velocity (Ozdemir and Barlas (2017)). In recent years, an effort has been made to make CFD more efficient. The CFD modelling process, which can last several weeks to months, is aided by the experience of ship designers. Because of this experience, the engineer can set design parameters to control the overall design process. The effectiveness of this process relies on the engineer's skill.

Cui et al. (2012) adopted a machine learning approach to the early design phase in an effort to increase the robustness of the design. Weatheritt et al. (2017) used a machine learning approach on data in a CFD experiment to study linear and non-linear relationships using the least-squares regression technique. Zhao et al. (2020) build on this research using machine learning to develop a CFD training framework of RANS models.

CFD is often perceived to be time-consuming, complex, and expensive. With the computational power increase of computers and the user interface changes, this image problem might be fading, as the alternative, model testing in towing tanks, is time-consuming and expensive as well (Gatin (2019)).

## **Problem Definition**

From the literature, it can be concluded that currently used methods to estimate the added resistance have their upsides and downsides. The traditional methods are more than 80 years old, based on ships from then and on only a selection of hull forms, making them not widely applicable to currently designed vessels. Towing tank tests lack accuracy due to scaling, are time-consuming, and expensive. Finally, CFD simulations are also expensive and considered time-consuming and complex. This illustrates that the current methods to calculate added resistance are not the most suitable to incorporate in a model to predict the sea margin in early ship design. Therefore, this research investigates whether we can utilise operational data to estimate the added resistance more accurately.

## **METHOD**

A novel model has been developed and proposed to explore the possibility of using operational data to estimate added resistance. This model, which is currently based on operational data from a single cargo vessel, serves as a proof of concept. Successful validation of this model would allow for its expansion to include data from additional vessels, thereby enhancing its applicability and robustness. In this section, the method is presented. First, the scope of the research is described. Then, in the second section, a description of the data is given. Finally, in the third section, the model description is presented.

### **Scope**

This research covers the development of a model based on the data of one cargo vessel. The dataset consists of approximately 90,000 data points. The developed model is, in principle, suitable to make predictions based on data from this same vessel or sister vessels with similar dimensions. Nonetheless, when desired it is also possible to train the developed model with data from other vessels and therewith also make it able to make predictions about different vessels. However, this will not be investigated in this paper.

### **Data Description**

In this research, real-world operational data from a single cargo vessel over a time span of two years is used. This data is combined with meteorological data from the Copernicus C3S Knowledge Base (Hersbach et al. (2023)). The data can be grouped into two categories: i) endogenous data, which describe the behaviour of the vessel, such as consumption of the main engine, the speed over ground, and the course over ground, and ii) exogenous data, which describe the metocean conditions, such as wind speed and direction, and wave height and direction. A summary of the operational data categorised by source is presented in Table 1.

**Table 1:** Summary of the Selected Operational Data categorised by Source

Source	Feature	Unit
Royal Wagenborg	Fuel Oil Consumption of ME	[t/day]
	Speed over Ground	[knots]
	Speed through Water	[knots]
	Draft Forward	[m]
	Draft Aft	[m]
	Shaft Generator Power	[kW]
	Deadweight	[t]
	Mean Engine Fuel Type	[MGO/HFO]
Copernicus Knowledge Base	Wind speed at 10 m (north-south)	[m/s]
	Wind speed at 10 m (west-east)	[m/s]
	Temperature at 2m	[K]
	Pressure at Mean Sea Level	[Pa]
	Mean Wave Direction	[deg]
	Significant Wave Height	[m]
	Wave Peak Period	[s]

Royal Wagenborg has provided data logs from a single cargo vessel over the period between April 13th, 2020, and April 13th, 2022. With a sampling interval of 5 minutes, various measurements, control settings, and manually entered voyage parameters were logged. Based on the GPS position and time, this data has been combined with hindcast weather data from the ERA5 dataset (Hersbach et al. (2023)). This weather data is available at one-hour intervals and a spatial scale of 0.5 degrees latitude and longitude (about 55 km). Relevant variables were selected, for the selection see Table 1, and interpolated in space along the ships track.

## Model Description

In this paragraph, the setup and development of the model are explained. The explanation is divided into a few separate sections due to the nature of the work. First, the data preparation and combining of the two datasets is explained. Following, the model development and training are explained, and finally, the model implementation to predict the vessel's performance in calm water is elaborated upon.

### Data Preparation

The first step in preparing the data is combining the two datasets to determine the weather conditions the ship is encountering. This is done based on location and time. For nondimensionalisation and scaling of derived variables some fixed reference values are applied, these are presented in Table 2.

**Table 2:** Fixed Reference Values

Variable	Symbol	Value	Unit
Length between Perpendiculars	LPP	130	[m]
Beam	B	15	[m]
Lightship Weight	LSW	3300	[t]
Height to top of Wheelhouse	H	25	[m]
Water Density	$\rho_{water}$	1025	[kg/m <sup>3</sup> ]
Acceleration of gravity	$g$	9.81	[m/s <sup>2</sup> ]

Following this first step, to evaluate the performance of the vessel, all measured conditions are expressed relative to the vessel, this means for example an apparent wind angle and apparent wind speed (Figure 1). In addition, derived variables are calculated that aid in interpreting the data, such as the wave encounter angle (WEA)

and rate of turn (ROT). All the derived variables calculated based on the measured variables are presented in Table 3.

**Figure 1:** Graphical Representation of Relative Wind and Speed Calculation

Based on the length, the deadweight, the light ship weight, the forward and aft trim and textbook knowledge the *trim* (T), the *displacement* (D), and the *mean draft* (MD) are calculated. With the course over ground, ship speed, wind speed,  $\rho_{air}$ , and Equation 2 the *relative wind* ( $v$ ), the *apparent wind angle* (AWA), and the *dynamic wind pressure* ( $Q_{wind}$ ) are calculated, a graphical representation of this calculation is presented in Figure 1.

$$Q_{wind} = \frac{1}{2} \rho_{air} |v|^2 \quad (2)$$

With the course over ground, the mean wave direction, and Equation 3, the *WEA* is determined.

$$WEA = \text{mean wave direction} + 180 - \text{course over ground} \quad (3)$$

As a final step, also based on the graphical representation in Figure 1 and with the course over ground, the ships speed, and Equations 4 and 5, the *rate of turn* (ROT), *longitudinal acceleration* ( $A_x$ ), and the *transverse acceleration* ( $A_y$ ) are calculated. With that, all necessary derived parameters (Table 3) required as input for the model have been determined, and thus, the model can be developed.

$$ROT = \frac{dCOG}{dt} \quad (4)$$

$$A = \frac{dV}{dt} \quad (5)$$

**Table 3:** Derived Variables

Derived Variable	Symbol	Unit
Trim	T	[rad]
Displacement	D	[t]
Mean Draft	MD	[m]
Relative Wind Intensity	$v$	[m/s]
Apparent Wind Angle	AWA	[rad]
Dynamic Wind Pressure	$Q_{wind}$	[Pa]
Mean Wave Drift Force	MWDF	[N]
Wave Encounter Angle	WEA	[rad]
Rate of Turn	ROT	[deg/min]
Longitudinal Acceleration	$A_x$	[m/s <sup>2</sup> ]
Transverse Acceleration	$A_y$	[m/s <sup>2</sup> ]

### Model Development

For the power prediction model a two step approach is required. First, the model needs to be developed and trained based on the parameters mentioned above. In the second step, the developed model is used to predict the required power in calm water conditions. The goal is to develop a model that can predict the required power given (average) speed, loading, and environmental conditions. Subsequently, the model will be implemented to predict the corrected required power, given speed, the design draft, and calm environmental conditions. Before constructing the model, some dependencies between the input variables have to be established.

In ship design, the power at the propeller shaft is of interest because this is measured during sea trials and separates the hydrodynamic performance from mechanical and thermal efficiencies. However, from the operational data, only fuel consumption is usually available to measure propulsive power when the shaft power is not measured. Therefore the model will aim to predict fuel consumption in ton per day.

The resistance is split into individual contributions, which are modelled independently. Some modelling assumptions have already been made here to avoid infinite values in the model. Towing power is defined by speed through water, not speed over ground. The reason is that the towing speed-power curve (corrected to calm-water) is a property of the ship, while the speed-over-ground-power curve is a property of the ship and the local current. In other words, the corrected power data will not coincide with a single curve when plotted against speed-over-ground. The resistance contributions are modeled linearly using coefficients such as, calm water, wind, and wave influence.

$$P_{tow} = V_w(R_{calm} + R_{wind} + R_{wave} + R_{inertia}) \quad (6)$$

The friction, pressure, and wave-making resistances are all modeled to scale with the dynamic pressures.

$$Q_w = \frac{1}{2}\rho_w V_w^2, \quad Q_a = \frac{1}{2}\rho_a V_a^2 \quad (7)$$

No Froude-number effect is modelled, so the model should only be applied to displacement vessels well below the critical Froude number. The reference area for calm water resistance is an indication of the wetted area based on the main dimensions and the draft. The reference area for wind resistance is an approximate frontal area above the waterline, including the accommodation.

$$R_{calm} = LPP * (C_{calm}B + C_{draft}T) * Q_w \quad (8)$$

$$R_{wind} = C_{wind}(\alpha_{wind}) * (H - T)B * Q_a \quad (9)$$

The wave-induced resistance is based on the significant wave height  $H_s$ , the wave encounter angle  $\alpha$ , and the wave length  $\lambda_p$  at the peak period, resulting in Equation 10. This is, in essence, the mean wave drift force (Journ  e et al. (2015)) with a coefficient consisting of a spline (in the frequency/wavelength) (Press et al. (2011)) and a Fourier series (in the wave encounter angle).

$$R_{wave} = C_{wave} \left( \alpha, \frac{\lambda_p}{LPP} \right) \frac{1}{16} \rho_w g B H_s^2 \quad (10)$$

We aim to develop a model that defines the speed-power curve under specific conditions: calm water, no wind, and constant speed and direction. This model will consider a vessel at its design draft, maintaining an even keel and consistent power output. To extract this knowledge from the model, we first need to develop and train it. Earlier sections have already established the model's input parameters and their interdependencies. The model's input features and target feature are summarised in Table 4.

**Table 4:** Input Parameters of the Model

Input and Target Features	Symbol
LPP	$LPP$
Beam	$B$
Speed	$V$
Trim	$T$
Displacement	$D$
Relative Wind Intensity	$v$
Apparent Wind Angle	$AWA$
Dynamic Wind Pressure	$Q_w$
Wave Encounter Angle	$WEA$
Rate of Turn	$ROT$
Longitudinal Acceleration	$A_x$
Transverse Acceleration	$A_y$
Measured Fuel Consumption	$FOC$

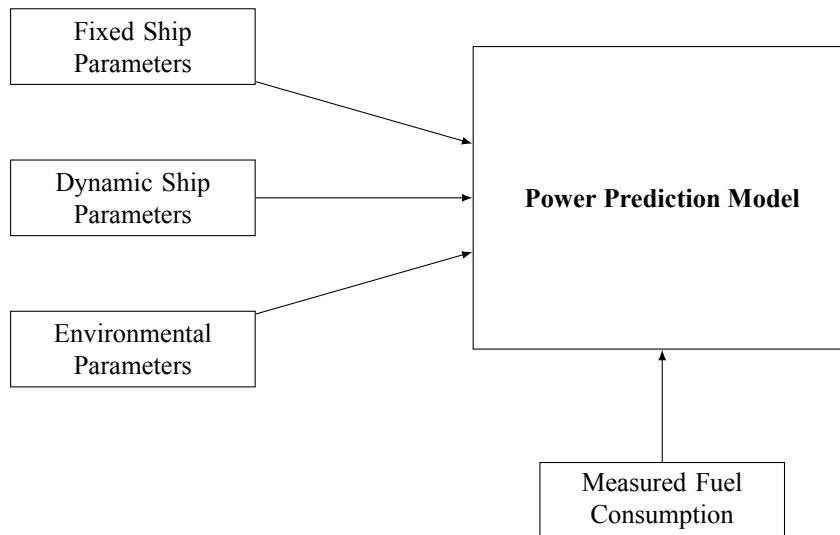

One of the objectives of this study is to develop a model for predicting the  $FOC$  based on the input parameters outlined in Table 4. This learning problem can be formulated as a supervised Machine Learning (ML) problem, specifically a regression problem (Shalev-Shwartz and Ben-David (2014)). In regression analysis, an input space  $\mathcal{X} \subseteq \mathbb{R}^d$  is comprised of  $d$  features (in this case, the parameters in Table 4) and the output space,  $\mathcal{Y} \subseteq \mathbb{R}$ , corresponds to  $FOC$ . A dataset of  $n$  examples, denoted as  $\mathcal{D}_n = (\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)$ , represents input/output relationships where  $\mathbf{x}_i \in \mathcal{X}$  and  $y_i \in \mathcal{Y} \forall i \in 1, \dots, n$ . The aim is to learn the unknown input/output function  $\mu : \mathcal{X} \rightarrow \mathcal{Y}$  based solely on  $\mathcal{D}_n$ . An ML regression algorithm  $A$ , characterized by its hyperparameters  $\mathcal{H}$ , selects a model  $f$  from a set of potential models  $\mathcal{F}$  based on available data  $A_{\mathcal{H}} : \mathcal{D}_n \times \mathcal{F} \rightarrow f$ . The set  $\mathcal{F}$  is typically unknown and depends on the choices of  $A$  and  $\mathcal{H}$ .

Many different ML algorithms exist in the literature (Shalev-Shwartz and Ben-David (2014); Chandrashekar and Sahin (2014)) but, as the no-free-lunch theorem states (Wolpert (2002)), there is no way to determine a-priori the best ML algorithms to use for a specific application. Since our goal is to establish a proof-of-concept, we have opted to use a Regularized Least Squares (RLS) model as our benchmark. This decision is supported by the fact that linear regression models are frequently employed in similar engineering contexts. Additionally, preliminary exploratory data analysis revealed a linear correlation between several input parameters and the target feature  $FOC$ . Thus, initiating our investigation with a linear model as a benchmark provides a logical and strategic starting point. RLS is a regression method that introduces a regularization term to the traditional least squares problem to control the complexity of the model and prevent overfitting. The objective of RLS is to minimize the sum of squared residuals, similar to ordinary least squares, but with an additional penalty term that discourages

large values of the model parameters. The regularization term is typically a function of the model parameters, such as the L2 norm (also known as Ridge regression) or the L1 norm (also known as Lasso regression). The L2 norm encourages small parameter values, leading to a more stable model with lower variance, while the L1 norm can lead to sparse solutions, where some parameters are exactly zero, effectively performing feature selection. The balance between the fit to the data and the regularization is controlled by the only hyperparameter of this algorithm  $\lambda$ . A larger  $\lambda$  increases the impact of the regularization term, leading to a simpler model, while a smaller  $\lambda$  allows the model to fit more closely to the data, potentially at the risk of overfitting. The accuracy of model  $f$  in approximating  $\mu$  is evaluated using a prescribed metric  $M : f \rightarrow \mathbb{R}$ . Multiple metrics are available for regression analysis in ML (Aggarwal (2015)). However, due to the physical significance of  $FOC$ , this study will focus on three primary metrics: Mean Absolute Error (MAE), Mean Absolute Percentage Error (MAPE), and the Coefficient of Determination ( $R^2$ ). A statistically consistent model selection and error estimation process was conducted to identify the optimal hyperparameters and evaluate the performance of the final model based on the desired metrics.

We divide all available data into two subsets: training and test sets. Specifically, 80% of the data is allocated for training the model, which uses measured power as its input (as shown in Model in Figure 2). Following the training phase, we utilize the remaining 20% of the data as a test set to validate the model's performance. This approach ensures that we can assess the model's accuracy and generalizability to unseen data.

The results from this validation of the model are described in the model implementation paragraph.

**Figure 2:** Training and Development of Power Prediction Model

### ***Model Implementation***

The first step is to employ the model developed in the previous section to predict the calm water speed-power curve, which assumes no wind, constant speed and direction, design draft with even keel, and constant power take-off. The performance of the model is assessed through error estimation and model validation, as depicted in Figure 3 and summarized in Table 5. These visual and tabular representations indicate that the model achieves a satisfactory level of accuracy. However, there remains potential for enhancement. Consequently, pursuing further research with alternative (non-linear) modeling approaches represents a viable direction for future studies.

**Figure 3:** Scatterplot Predicted versus Measured

**Table 5:** Error Estimates of the Model

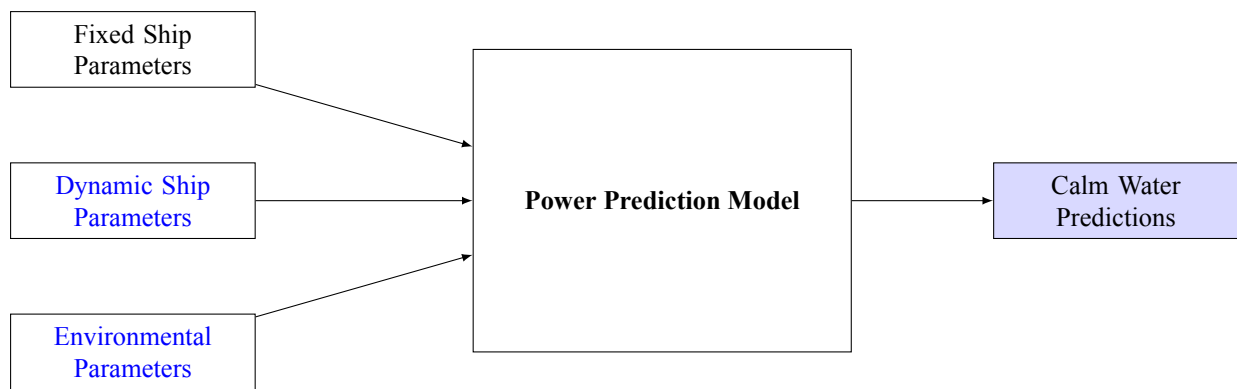

Metric	Accuracy
MAE	$0.64 \pm 0.0070$
MAPE	$17.79 \pm 0.1281$
$R^2$	$0.706 \pm 0.0163$

The second step involves using the model to generate power predictions under calm water conditions. This step requires modifications to some of the input parameters previously utilized for model development, as detailed in Table 4 and Figure 2. These parameters are adjusted to reflect calm water conditions and are displayed in blue in Table 6 and Figure 4. Additionally, it is important to note that the power measurements, which were initially used as inputs in the model, are no longer included.

**Table 6:** Input Features of the Model

Input Feature	Alteration
LPP	as before
Beam	as before
Speed	as before
Trim	Design Draft
Displacement	Design Draft
Relative Wind	No wind
Apparent Wind Angle	No wind
$Q_{wind}$	No wind
Wave Encounter Angle	No waves
Rate of Turn	No Rate of Turn
Longitudinal Acceleration	No Acceleration
Transverse Acceleration	No Acceleration
Measured Fuel Consumption	No input

With these altered input features we will test our hypothesis, *that it is possible to make calm water predictions based on real-world operational data*. In the next section, the results are presented and discussed.

**Figure 4:** Implementation Power Prediction Model

## RESULTS & DISCUSSION

In this section, the results of the calm water predictions are presented and discussed. In the scatter plots, the fuel consumption (t/day) is on the y-axis, and the speed over ground (knots) is on the x-axis. The original measured fuel consumption of the main engine, denoted by  $y$ , is depicted in blue, while the predictions of fuel consumption, corrected for factors such as draft, maneuvering, and weather conditions, are illustrated in orange.

Figure 5 shows a scatter of the measured fuel consumption, and in Figure 6, the measured and the corrected are reported.

**Figure 5:** Speed-Power Plot based on the Measured Operational Data

**Figure 6:** Speed-Power Plot with Measured and Corrected

In Figure 6, it is clear that the corrected data points (orange) are less scattered than the original measured operational data (blue). Furthermore, it is observed that the orange scatters approach the fitted red line. This fitted line is an ideal representation of the developed model, meaning the calm water situation. The orange scatters approaching the fitted line illustrate that the proposed methodology is capable of correcting for weather conditions, but also that there is still room for improvement. Moreover, it can be observed that the two cloudy protrusions in the blue scatter (coming from the center of the plot pointing towards the top left of the plot, between 4 and 8 knots, and 12.5 and 15 t/day) are no longer visible in the calm water predictions. This is a positive confirmation of correcting for weather conditions, as these two protrusions represent two storms (on 27 December 2020 and 11 March 2021). Also, these two protrusions make it clear that the weather conditions (in this case, the two storms) result in a significant involuntary speed reduction, leading to a speed between 4 and 8 knots with a fuel consumption between 12.5 and 15 t/day.

**Figure 7:** Speed-Power Plot with Corrections for All Parameters Except Wind

**Figure 8:** Speed-Power Plot with Corrections for All Parameters Except Waves

When making the calm water predictions, several intermediate steps are taken between Figure 5 and Figure 6. The intermediate steps most interesting to discuss are the situations without the correction for wind (Figure 7) and without the correction for waves (Figure 8). When making the corrections for all parameters except for wind, we get the results plotted in Figure 7. Alternatively, when making the corrections for all parameters except for waves we get the results plotted in Figure 8. When evaluating the difference between the two situations, Figure 7 and Figure 8, it can be seen that for the conditions the vessel encountered between April 2020 and April 2022, the waves appear to have a larger impact on the fuel consumption. This can be best seen when looking at the orange scatter clouds between 4 and 8 knots and comparing the change in these clouds between the measured data (Figure 5), the corrections except wind (Figure 7), and the corrections except waves (Figure 8). When comparing these two predictions with the measured data and each other, it is evident that the effect of the waves is larger than the effect of the wind. Furthermore, when looking at Figure 6, it can be observed that the model still has some difficulty completely filtering out the effect of these two storms, as the orange cloud between 4 and 8 knots remains more scattered than at higher speeds.

**Figure 9:** Histogram of the Distribution of the Fuel Consumption at 7 knots

To properly evaluate and compare the distribution, three histograms are plotted in Figures 9, 10, and 11. These histograms are cross-sections of the distribution of the fuel consumption at low, design, and high speed. Furthermore, a summative table presenting the mean and variance at all speeds between 7 and 14 knots is given in Table 7. When evaluating the distribution of the fuel consumption at low speed, 7 knots (Figure 9) it is clear that the spread has decreased between the measured (blue) and the predicted calm water (orange) fuel consumption. The measured fuel consumption is spread between 6.5 and 14.5 tonne per day, and the calm water predictions are spread between 6.75 and 12. This reduced the range from 8 for the measured data to 5.25 for the predicted

calm water. Also, when comparing the distribution of the measured and predicted, it can be observed that the orange graph is far more like a bell curve than the blue distribution.

**Figure 10:** Histogram of the Distribution of the Fuel Consumption at 9 knots

When evaluating the distribution of the fuel consumption at the design speed, 9 knots (Figure 10), it is clear that also at this speed, the spread has decreased between the measured (blue) and the calm water (orange) fuel consumption. The measured fuel consumption is spread between 7 and 14 tonne per day, and the calm water predictions are spread between 8 and 12. This results in a reduction from 7 for the measured data to 4 for the predicted calm water. Furthermore, when comparing the distributions, it can be observed that, in this case, the orange distribution is more in the shape of a bell curve than the original blue distribution.

**Figure 11:** Histogram of the Distribution of the Fuel Consumption at 14 knots

When finally also evaluating the distribution of the fuel consumption at high speed, in this case, 14 knots (Figure 11), it is clear that also at this speed, the spread has decreased between the measured (blue) and the calm water (orange) fuel consumption. The measured fuel consumption is spread between 8 and 18 tonne per day, and the calm water predictions are spread between 14 and 20. Meaning that also, for this situation, there is a significant decrease in the range, from 10 for the measured to 6 for the calm water predictions. Furthermore, when comparing the distributions in Figure 11, it can be observed that the orange graph is more in the shape of a bell curve than the blue distribution. However, for this speed it is also noted that the bell curve has shifted from the original center around 12 tonne per day to a new center around 17.

**Table 7:** FOC Mean and Variance at Different Speeds

Speed [knots]	FOC Mean [t/day]		FOC Variance [t/day]	
	Measured	Calm Water	Measured	Calm Water
7	11.41	8.48	5.62	0.65
8	9.96	9.29	4.86	0.99
9	9.37	9.29	3.90	1.08
10	8.89	10.19	2.05	0.92
11	9.38	11.42	2.03	0.99
12	9.85	12.51	1.77	1.19
13	10.73	14.80	2.64	2.16
14	12.54	17.65	5.32	4.10

When comparing the mean and variance of the measured and the calm water prediction in Table 7, it can be seen that the variance has decreased at all speeds. Furthermore, it becomes clear that at the lower speeds, the mean in the calm water predictions is lower than the corresponding mean of the measured data, while at the higher speeds, the calm water mean is higher than the corresponding mean of the measured data. These reductions in range and shifts of the mean to lower fuel consumption at reduced speeds not only validate the concept of the proposed method but are also highly explicable. In Figure 9, it can be seen that the corrected predicted fuel consumption (orange) has shifted to the left, a lower fuel consumption. When evaluating Figure 10, it can be seen that for this speed, the predicted fuel consumption is more centered compared to the measured fuel consumption. Finally, when looking at Figure 11, the fuel consumption at 14 knots, it can be seen that the predictions have moved more to the right. This seems very logical because the lower and higher speeds are outside the normal operating envelope of the vessel. The lower speeds with high fuel consumption are involuntary, in this case mostly due to storms. The higher speeds with low fuel consumption are only possible with positive help from a tailwind and/or current. This means that when we remove the meteorological effects, low speeds with high fuel consumption and high speeds with low fuel consumption no longer occur.

Overall, it is observed that the predicted calm water fuel consumption has a decreased variance relative to the variance of the original measured fuel consumption. Furthermore, the histograms in Figures 9, 10, and 11 confirm what is also observed in Figure 6 that the developed method for making calm water predictions works as it results in less scattered data points, all more centered around the fitted line. Implying the developed method works.

## CONCLUSIONS

This paper presents a method to make calm water power predictions. This is achieved through a data driven model based on operational data. A case study proved the concept and showed the potential of this method. It illustrated that operational data can be used to make calm water predictions, correcting for meteorological effects. When comparing the calm water power predictions with the actual delivered power the sea margin can be calculated. The proposed methodology will enable a more accurate sea margin calculation in early ship design and will thus allow for a better understanding of the required power. This will lead to a better-informed decision-making process regarding the propulsion system and/or the possibilities of alternative fuels, thus having a positive effect on the footprint of a vessel.

This novel approach for sea margin estimation offers a quick and substantiated estimation in the early-design stage of a ship, making it a promising starting point for further research. Recommendations for further research comprise further developing the model by testing different algorithms, including more data from different vessels to train and test the model, and finally evaluating whether a pattern in sea margin for certain passages can be recognised.

# Knowledge Graphs underpinning ship digital twins for decarbonisation options assessment

Bill Karakostas<sup>1,\*</sup> and Antonis Antonopoulos<sup>2</sup>

## ABSTRACT

*We propose the concept of a Knowledge Graph as a data management and inference machinery that underpins digital twins of ships. The Knowledge Graph is a directed graph connecting dependent and independent model variables of interest in the digital twin, where the correlations between variables are continuously updated based on data received from the physical ship. The paper outlines a methodology for constructing the Knowledge Graph and proposes metrics that help to calculate the effectiveness of decarbonization solutions based on changes to the strength of data correlations. The proposed methodology allows for the extrapolation of decarbonization technology potential across specific vessels, fleets, operational patterns, and lifecycle phases.*

## KEY WORDS

Digital Twin, Knowledge Graph, Correlation Graph, Ship Decarbonisation, Wind Assisted Propulsion

## INTRODUCTION

The digitalisation of shipping to accelerate decarbonisation, supported by data gathered from sensors and ship systems (Agarwala et al, 2022), is a promising approach (Ksetri, 2021). Particularly relevant is *Digital Twin* (DT) technology, initially used by NASA, but applied in recent years to smart manufacturing, transport, smart cities and other areas. DTs enable the creation of a digital representation of a ship, which is fed with data acquired by the physical ship via sensors. These digital representations can then be used to analyse ship-related functions and processes, and actuate systems on the physical ship responsible for engine management, navigation and others.

A ship digital twin therefore, can be viewed as a virtual replica of its physical counterpart that is not static but dynamic, with a bidirectional relationship to the physical system. Use of DT in shipping can result in reducing costs and improving time effectiveness and quality.

A broad definition of a knowledge Graph is as a graph of data intended to accumulate and convey knowledge of the real world, whose nodes represent entities of interest and whose edges represent relations between these entities (Hogan et al, 2022). Knowledge graphs are knowledge-based models that utilize graph links to connect entities in a particular domain and to augment the existing knowledge by using queries and other types of inferences. A knowledge graph therefore is ideally suited for modelling knowledge in the domain represented by the physical counterpart of the DT. Moreover, the knowledge graph links data about the physical system as these are collected by the digital twin. Such data types may include:

- geometrical data, e.g. CAD models of the ship
- event based data for events generated by the physical ship throughout its operation, and
- time series data such as speed, fuel consumption, etc, collected from the ship, as well as data such as sea state, direction, collected from the ship's environment.

A knowledge graph can be used as the data engine management, and also as the inference engine of the DT, that acts on the datasets received from the physical ship to make inferences such as predictions of future states of the ship, and also to evaluate

the actual current state of the ship and compare with the expected one, thus supporting anomaly detection (the existence of an abnormal state), and error and fault diagnosis.

This paper builds upon foundational work on digital twin technology and knowledge graphs as tools for supporting the decarbonization of the shipping industry (Antonopoulos et al, 2023). In the research presented in (Antonopoulos et al, 2023), a digital twin of maritime vessels was developed to provide a platform for simulating and evaluating the impacts of various decarbonization technologies. Key to that approach is the use of knowledge graphs for maintaining ontologies, storing simulation models, and correlating these models with a combination of measured and estimated variables.

The novel contribution of this paper is on enriching knowledge graphs with dynamic features by introducing a computational framework that establishes quantifiable links between system parameters. By utilizing measures such as correlation, we enable precise comparisons between data-driven ship models and their theoretical counterparts.

The paper is structured as follows: Initially, the paper outlines the methodological framework within which the proposed technique is applied. The next section provides a formal definition of the Knowledge Graph and illustrates it with an example. Then, a procedure for constructing a Knowledge Graph is proposed. Next, we introduce metrics that are based on statistical analyses of the datasets collected by the digital twin. Again, an example is used to illustrate the various proposed metrics. Following that, a case study is shown where a sample data set and Knowledge Graph is used to analyse and quantify the effectiveness of a hypothetical wind-based decarbonisation technology introduced on a ship. We conclude the paper with an overview and critique of the proposed approach and with suggestions for further research.

## **ENCODING DOMAIN-SPECIFIC KNOWLEDGE OF DIGITAL TWINS USING KNOWLEDGE GRAPHS**

Within the maritime sector, a DT is conceptualized as a real-time digital counterpart of a physical entity, such as a ship, port, or maritime operation [Madusanka et al, 2023]. Specifically, a ship's DT represents an exact digital reflection of the physical vessel, encapsulating its structural design (like hull type and layout, hull parameters), onboard equipment (engines, propellers, rudders), and operational functionalities (propulsion, navigation, cargo handling). This comprehensive digital model integrates technical specifications, component designs, and operational data within a fleet management framework, facilitating the computerized simulation and optimization of ship operations across various performance metrics with a focus on environmental sustainability.

Digital Twins engage in a two-way communication with the ship's Information and Communication Technology (ICT) infrastructure [Tao et al, 2018], utilizing data collection techniques and devices to continuously update the digital model with real-time information from the physical vessel. This dynamic learning process allows the DT to accurately reflect the physical ship's lifecycle, offering insights into its present condition and forecasting future states through simulations and predictive analytics.

A ship DT is built around measurable parameters and can be structured into a network of interconnected modules, such as propulsion systems, voyage and fleet management systems. These modules may also be integrated with broader digital twins that encompass ship operations management or the entire spectrum of ship design, construction, and lifecycle management. The primary goal of employing a ship DT is to facilitate both reactive and predictive decision-making processes, aiming to achieve objectives that include reducing environmental impact. The insights gained from one ship's DT can often be applied to others, enabling data and knowledge sharing in advancing green shipping practices. This prerequisite a degree of interoperability between digital twin instances, which can be achieved by using a common ontology, as suggested by (Hiekata et al, 2010).

Digital Twin technology has found application across various maritime domains, including shipbuilding, offshore oil and gas exploration, marine fisheries, and renewable marine energy production (Zhihan et al, 2023). For instance, (Coraddu et al, 2019), have developed a data-driven digital twin for ships, capitalizing on vast datasets from onboard sensors to estimate speed loss due to marine fouling, showcasing the practical utility of digital twins in enhancing maritime operations.

## **KNOWLEDGE GRAPH FORMAL DEFINITION**

### **Rationale**

Knowledge graphs are sophisticated semantic networks acting as knowledge bases, structured like directed graphs (Qiu et al, 2017). They function by organizing data into triples of (subject, predicate, object) from semi-structured or unstructured sources, thereby enabling advanced knowledge retrieval and reasoning capabilities (Wei et al, 2018). Knowledge graphs are adept at modelling complex relationships within domains, linking disparate pieces of information, and supporting a wide range of applications including knowledge retrieval, question and answer (Q&A) systems, recommendations, and visualization.

Initially developed for extracting knowledge from extensive datasets, knowledge graphs are now a cornerstone in the semantic web, setting a benchmark for efficient information retrieval and usage. Their utility spans various sectors, notably in industry

for tasks such as maintenance planning of sophisticated equipment (Xia et al, 2023), and predictive maintenance for hydraulic systems (Yan et al, 2023).

Within the maritime and shipping sector, knowledge graphs have found applications in analyzing ship collision accident reports to enhance maritime traffic safety. (Zhang et al., 2020), have developed a knowledge graph for maritime dangerous goods, streamlining the knowledge retrieval of hazardous materials, automating the assessment of cargo stowage and segregation, and advancing the intelligent transport of dangerous goods. Similarly, (Langxiong et al, 2023) crafted a Ship Collision Accident Knowledge Graph, aiding in uncovering accident correlations and streamlining the judicial and investigative processes for marine accidents.

Crucially, knowledge graphs have become integral to augmenting the functionality of Digital Twins. By mapping entities, their relationships, and attributes in an organized fashion, they offer a systematic approach to collating and interlinking data within the DT framework. In maritime contexts, they enable comprehensive representations of vessel ecosystems, covering equipment, maintenance histories, and compliance with regulations. These interconnected networks support predictive analytics, risk evaluations, and the simulation of various scenarios, enhancing operational decision-making. By bridging real-time and historical data, knowledge graphs also underpin predictive maintenance strategies, facilitating early detection of potential failures, thus ensuring operational reliability and safety.

A related modelling formalism, *dependency graphs*, have been studied as part of engineering design (Rötzer et al, 2022). There is a variety of such graphs based on their formal underpinning and role in the design/manufacturing cycle. Effect Graphs, for instance are qualitative models built to produce early qualitative statements about the system behaviour. Directed Acyclic Graphs (DAG) or causal diagrams as described by (Pearl, 1995).

The Knowledge Graph we propose is a dependency network of dependent and independent model variables of interest, where the links show the strength of correlation associations between the variables. The Knowledge Graph utilizes the ship data collected by the DT to learn the strength of the correlations between system variables and to represent them as rule nodes. Association rule learning is a rule-based machine learning method for discovering interesting relations between variables in large databases. (Agrawal et al, 1993). Association rule mining has been studied since the 1990s in domains such as supermarket transactions. However, in such domains there are not many theoretical models to cross validate against the empirically mined association rules. In contrast, the association rule we propose utilizes both theoretical and data driven ship models.

The Knowledge Graph can therefore, be considered as a qualitative statistical summarizer of the ship's models parameters of interest, reflected in the strength of associations between the key variables that represent the system and its environment.

As shown in Figure 1, the knowledge graph models dependency rules such as statistical correlations of the data collected from the physical ship and its environment. The rules describe statistical dependencies (correlations) between independent variables (factors) and dependent variables (factors) of interest. For instance, independent factors include ship speed and direction as well as environment factors such as ship state. Dependent factors include ship fuel consumption and emissions.

The exact relationships between independent and dependent variables are complex and mostly nonlinear. Complexity means that the independent variables may be correlated with each other as well as with the dependent variables

To calculate the strength of the influence of each independent variable on a dependent variable, standard correlation analysis techniques such as Pearson for linear, and Spearman, for nonlinear correlations, can be employed. For instance, although ship speed is positive related to fuel consumption for very low speeds the polarity of the relation is reversed as in such speed, the friction is increased and requires more power to overcome.

**Figure 1: Knowledge Graph in the context of the digital twin**

## Formal Definitions

Let  $X$  be a finite set of independent variables ('factors')  $x_1, \dots, x_n$ , and  $Y$  a finite set of dependent variables  $y_1, y_2, \dots$

Each factor  $x$  in  $X$  draws values from a finite countable set of ordered values called the domain of  $X$  and denoted as  $Dom(x)$ . We use  $val(x_i)$  to refer to a value drawn from  $Dom(x_i)$ .

Similarly, each dependent variable  $y$  in  $Y$  draws values from a finite countable set of ordered values denoted as  $Dom(y)$ .

We define a *record type*  $r$  of variables  $x_1, \dots, x_k$ ,  $k \geq 1$ , as a tuple  $(val(x_1), \dots, val(x_k))$  with  $k \geq 1$  where  $x_i \neq x_j$  for all  $i, j$ .

We define a set of correlation rules  $C$  where  $c \in C$  is a tuple  $(x_1, \dots, x_n, y)$ , and the strength of the rule  $c$   $corr(c)$  as a function  $corr$  returning a value between 0 and 1.

We define a Knowledge Graph as a directed graph  $\langle V, E \rangle$  where  $v \in V$  is a variable from  $X \cup C \cup Y$  and  $e \in E$  is a tuple  $(x, c)$  where  $x \in X$  and  $c \in C$  or  $\{c, Y\}$  where  $c \in C$  and  $y \in Y$ .

Informally, factors are connected to rules and rules are connected to dependent variables. A rule  $(x_1, \dots, x_n, y)$ , shows the correlation of factors  $x_1, \dots, x_n$  with the dependent variable  $y$ , while the weight on the edge between rule and dependent variable corresponds to the strength of the correlation. The correlation strength can be the result of a theoretical formula or an empirical (e.g. regression) formula.

## Example

Figure 2: Knowledge Graph for Fuel Consumption

Figure 2 shows a small sample Knowledge Graph. The modelled factors are *Speed*, *Wind Strength* and *Wind Direction*. All these factors are quantized as discussed in the next section, and draw values from their respective domains. For instance, *Wind Strength* draws values from the domain of integers between 0 and 9 following the Douglas Sea Scale units of measurement. The three factors are connected to rule nodes. Consequently, the rule nodes connect to dependent variables of interest, in this case to *Fuel Consumption*. The labels on edges between rules and dependent variables show the strength of the correlation.

## PROCEDURE FOR CONSTRUCTING KNOWLEDGE GRAPH

The main steps in constructing a Knowledge Graph are as follows

1. Identify subsystems and components of the ship system.
2. Identify additional systems that the current system interacts with/is part of.
3. Identify model variables (endogenous as well as exogenous) that describe the behaviour/performance of the system/subsystem/component.
4. Define the Knowledge Graph vertices (nodes) in terms of the variables in Step 3.
5. Discretise continuous or numerical variables into categorical variables.
6. Determine dependencies between independent variables and dependent ones using theoretical models, experimental data and expert knowledge/Create one rule vertex per rule in the Knowledge Graph.

## Discussion on the proposed Knowledge Graph construction procedure.

In general, quantizing/binning of continuous variable introduces non-linearity and tends to improve the performance of the model. It can be also used to identify missing values or outliers. We quantise the values of the independent factors using natural (e.g. physics dictated, as well as business related criteria, using ordered categorical variables).

### Example

Although vessel speed can be modelled as a continuous variable, we discretise it according to speed categorisation that is dictated by physics/ operational and legislation constraints. So, speed is discretised according to the categories of normal, slow steaming and extra slow steaming. Table 1 shows examples of quantizing ship and environment variables.

**Table 1: quantizing variables**

Record id	Avg. Speed (knots)	Speed quantized	Avg wave height (m)	Waves in Douglas Sea Scale	Fuel consumption rate (lt/min)	Fuel consumption rate quantized
T1	22	<i>n</i> (normal)	6.5	7	14	<i>h</i> (high)
T2	19	<i>ss</i> (slow steaming)	3	5	10	<i>m</i> (medium)
T3	21	<i>n</i> (normal)	2	4	8	<i>l</i> (low)
T4	15	<i>ess</i> (extra slow steaming)	1	3	6	<i>vl</i> (very low)

### Metrics

In this section we define metrics related to the numbers, frequency of occurrence and correlations in the dataset available to the DT and consisting of measurements taken from the physical ship, discretised and grouped into records. We define a record instance of a record  $r$  an appearance of a record of type  $r$  in the dataset.

### Expected Frequency

Expected frequency  $E_f(r)$  is a measure of how frequently instances of record of type  $r$  are expected to appear in the dataset. It is based on the strength of correlation between variables appearing in the record according to the existing knowledge (theoretical and/or empirical) of the domain.

### Example

Assuming high (0.9) correlation between ship speed and fuel consumption and the following quantization of speed and fuel consumption:

$Dom(Speed): \{ ss, n \}$  with  $ss < n$

$Dom(FuelConsumption) : \{ l, h \}$  with  $l < h$ .

If speed and fuel consumption were totally uncorrelated we would expect to find all combinations  $(ss, l), (ss, h), (n, l), (n, h)$  with equal probability of 0.25.

However because of the assumed correlation we expect to find record types  $(ss, l), (n, h)$  with probability 0.9 and record types  $(n, l), (ss, h)$  with probability 0.1

However, not all combinations are equally represented in the dataset due to measurement limitations. For instance, it may be possible to measure some particular combinations of factors due to technical and physical limitations such as very strong winds co-occurring with high vessel speeds. Therefore, we introduce the concept of *support* below.

## Coverage

Coverage for a record of type  $r$  is the number of record instances in the dataset divided by the number we could theoretically find in a dataset of that size. For example, because of the strength of the correlation between speed and fuel, we could expect on average 10 instances of record (*low speed, high fuel*) in a sample of 100 instances, If we find instead 5 instances of the record the coverage is 5/10 or 0.5

When *coverage* < 1 for a record type it means that the record type is *underrepresented* in the dataset while > 1 means the record type is *overrepresented*

## Counterrecord

A counterrecord of record type  $r:(x_1, x_2, \dots, x_k, y)$  with respect to some correlation rule  $c$  is a record type  $\check{r}:(x_1, x_2, \dots, x_k, y')$  where  $y \neq y'$  has expected frequency  $Ef(\check{r}) < Ef(r)$

For instance, if the association between speed:( $l, h$ ) and fuel consumption:( $l, h$ ) is strong positive (with for example, 0.9 strength) we expect to find record instances of type ( $l, l$ ) and speed: ( $h, h$ ) with high frequency and records of type ( $l, h$ ) and ( $h, l$ ) with lower frequency in the dataset. Thus record types ( $l, h$ ) and ( $h, l$ ) are counterrecords of ( $h, h$ ).

We use  $\hat{R}_c$  for the set of all counterrecord types of  $r$  under correlation rule  $c$ .

## Association rule strength

The strength of an association rule  $c$  for a record of type  $r$  is defined as

$$\sum_{\check{r} \in \hat{R}_c} (Ef(\check{r})) * \frac{|r|}{|\check{r}| * Ef(r)} \quad [1]$$

Where  $|\check{r}|$  is the cardinality of the set of all counterexamples found in the data set.

The summation of expected frequencies of counterrecords in formula [1] can be explained with this example: If we have 3 types of counter records and we find one instance per counter record and the expected frequency of each counter record is 1/30 and 5 record instances with frequency 0.9, we obtain the association rule strength as  $3 \times 1/30 \times (5/3 * 0.8) = 0.13$

## CASE STUDY

### Background

We illustrate our approach with a hypothetical example about the introduction on a ship of a fuel consumption reduction technology that is based on wind assist propulsion (WASP). It is well known today that the use of wind is one of the solutions to substitute existing fossil-based propulsion technologies. The sizing of wind assists devices such as sails and kites needs to take into account the propulsion system. Therefore, vessels equipped with variable pitch provide a greater range of applicability. Moreover, analytical models for kite have been developed (Leloup et al, 2016). Models of the operation of wing sails have calculated the Energy Efficiency Design Index (EEDI) change for specific commercial routes, identifying a potential reduction of 18% (Yong et al, 2019).

### Estimating the correlation strengths

The correlation graph of Figure 3 is small as it is only used to illustrate the principles of our approach. A real life scale knowledge graph would also include variables such as fuel consumption/mile, wind direction, wind speed, vessel speed and propeller pitch. The new WASP technology is expected to negatively correlate fuel consumption with wind power, i.e. as the wind power increases, the new technology will utilize it to reduce required engine power, and hence, fuel consumption. The size of our synthetic data is small compared to a real life scenario where the data set could contain thousands or millions of records collected over large time periods, and is used to illustrate the proposed approach. It is envisaged that the Knowledge Graph would periodically carry out the calculations described below as the ship conditions change, on very large datasets that are updated over the ship's lifecycle. The impact of both speed and wind strength on fuel consumption has been investigated both empirically and theoretically. More specifically, the weather a ship encounters during voyage has significant influence on her fuel consumption, in particular relating to prevailing wind and waves (Bialystocki and Konovessis, 2016).

Accordingly, prior to introducing the new technology the correlation between wind strength, speed and fuel consumption rate for the particular vessel was calculated experimentally and theoretically as shown in the Knowledge Graph of Figure 3. As

per Figure 3, there is a very strong positive correlation between speed and fuel consumption rate (0.9) and a strong (0.7) positive correlation between wind strength and fuel rate consumption.

The factors' corresponding domains after discretization are:

Speed:  $\{(n)ormal, (s)low\}$  steaming.  $m(anouvring)\}$

Wind Strength:  $\{0..9\}$

Fuel Consumption Rate:  $\{n(ormal), l(ow), h(igh)\}$

The sample dataset received by the digital twin is shown in Table A1 in appendix A.

To assess the effectiveness of the decarbonisation technology based on the collected data we need to pose several questions and analyse the dataset using the metrics that we defined previously. The different analyses are further discussed below.

**Figure 3: Correlation graph for Speed, Wind Strength and Fuel Consumption**

*The coverage of the dataset for every speed-wind strength combination*

The total number of record types is  $\|Dom(Speed)\| \times \|Dom(WindStrength)\|$  i.e. 30. The coverage of the different record types  $Speed \times WindStrength$  is shown in Table 2.

**Table 2: Coverage of record types**

Record type	(n,0),(n,2),(n,3),(n,4),(n,5),(n,6),(n,7),(n,8),(n,9) (ss,0),(ss,1),(ss,2),(ss,5),(ss,6),(ss,7),(ss,8),(ss,9) (m,0),(m,1),(m,2),(m,3),(m,4),(m,5),(m,6),(m,7),(m,8),(m,9)	(n,1), (ss,3), (ss,4)
Expected Coverage	2/3	2/3
Actual Coverage	0	2

The reasons that most record types are underrepresented on this occasion is the small size of our dataset. In real life underrepresentation could be interpreted as caused by:

- Data corresponding to underrepresented record types were difficult to collect due to limitations of the measuring apparatus, Measuring or recording errors
- Due to the rarity of the physical events corresponding to the record type. For instance, sea scales of strength between 3-5 are more commonly experienced in open seas than those of strength 0, 1, 8, 9.

*Examine the sensitivity of the new technology to wind strength i.e. whether it works better with higher or lower wind strengths*

To analyse that, we compare the frequency of occurrence of record types (S:\*any\*, WindStrength:0-4, FuelConsumption:h), with those of record types (S:\*any\*, WindStrength:5-9, FuelConsumption:h)

According to the dataset of Table 1, the new technology tends to be more strongly associated with low fuel consumption at low wind strengths. Of course, that can be explained that other confounding factors such as ship wind resistance have a stronger effect on fuel consumption than the new technology at high wind speeds.

### *Identify potential situations where the technology causes increased fuel consumption results*

For this type of analysis we need to enumerate all counterrecord types of records where fuel consumption is medium or low and compare the frequency of the record with that of the counterrecords.

Counterrecord types of  $(m,l)$  are  $(m,m),(m,h)$ . From the association rule strength we expect to find 2 counterrecord instances, however 5 instances were found in the dataset. This means that the new technology can have unintended increase in fuel consumption at maneuvering speeds.

Counterrecord types of  $(s,m)$  are  $(s,h),(s,l)$ . From the association rule strength we expect to find 2 counterchord instances, however 4 instances were found in the dataset. This means that the new technology can have unintended increase in fuel consumption at slow steaming speeds.

However, all above analysis results should be interpreted in the context of the dataset size and coverage of each record type.

### *Calculate the overall fuel improvement potential of the new technology*

We need to test whether the new tech reduces the strength of the association between speed and fuel consumption and increases the strength of the association between wind strength and fuel consumption

By applying equation [1] to the dataset we obtain the revised correlation strengths as shown in Table 4.

**Table 3 revised correlation strengths after new decarbonization technology**

$ R_{\text{Speed}} $	$ \hat{R}_{\text{Speed}} $	$c(\text{Speed} \rightarrow \text{Fuel Consumption})$	$ R_{\text{Wind Strength}} $	$ \hat{R}_{\text{Wind Strength}} $	$c(\text{Wind} \rightarrow \text{Fuel Consumption})$
4	5	~0.11	4	11	~0.65

From the results shown in table 3 we observe that the strength of the correlation between speed and fuel consumption has been reduced from 0.9 to 0.11. This means that speed is no longer the main determinant of fuel consumption. Similarly, the strength of the wind and fuel consumption has increased from 0.1 to ~0.65, meaning that wind strength is now the significant determinant of fuel consumption. This of course assume that all other factors have remained unchanged after the introduction of the new technology.

## **CONCLUSIONS**

In this paper we presented the theoretical foundation of an approach to encode quantified domain-specific knowledge, followed by practical examples, and demonstrate its application in a use case focused on wind-assist technology. While this work primarily explores the methodology's principles and provides a preliminary report, it lays the groundwork for future development and implementation of a holistic decision-support framework aimed at decarbonizing the shipping industry with the use of DTs and knowledge graphs. The proposed Knowledge Graph correlates independent and dependent variables that model the physical system in a digital twin. Knowledge Graphs in general, are an important technology for data representation and knowledge inference in many industrial domains. (Abu-Salih, 2021). The Knowledge Graph connects theoretical and empirical ship knowledge with the data received from the ship throughout its operation.

The purpose of the proposed Knowledge Graph is to compare the theoretical with empirical model of the ship in order to identify discrepancies. Such discrepancies can then be interpreted as anomalies, or as changes to physical ship parameters, and used to compare 'before' and 'after' scenarios. This is also the approach employed in this paper where the Knowledge Graph is used to analyse the impact of decarbonization technologies on the ship's operational parameters. This dynamic characteristic of the knowledge graphs enables the optimization of predictive capabilities for computational efficiency, and facilitates the encoding of knowledge patterns that can be transferred across different instances of digital twins. By leveraging quantifiable associations, we can effectively analyze and quantify the effectiveness of newly introduced decarbonization technologies within an existing ship's system. Such analyses allow for the drawing of insightful conclusions regarding system changes brought about by the integration of new subsystems and their impact on system parameters. Through this novel integration of dynamic knowledge graphs and digital twin technology, our work lays a foundation for a more informed and

effective application of decarbonization technologies across the maritime industry, ensuring a strategic approach to mitigating environmental impact while maintaining operational efficiency.

The research presented in this paper aims to support the development of a knowledge graph for encoding domain-specific knowledge generated by the digital twin. The knowledge graph is not just a static repository of data but a dynamic system that integrates, processes, and standardizes knowledge for easy access and application. The proposed knowledge graphs catalogs simulation outcomes, operational insights, and environmental data, transforming raw data into actionable intelligence.

The encoding process involves several key steps: Firstly, simulation models within the digital twin generate data reflecting the performance and environmental impact of various decarbonization technologies under different operational scenarios. This data, along with measured data, is then contextualized within the knowledge graph, which correlates it with existing operational parameters, environmental conditions, and technology performance metrics. Through semantic tagging and linkage, the knowledge is not only stored but also interconnected in meaningful ways, facilitating complex queries and analysis (Fonseca et al, 2022).

Using ontologies to maintain a shared vocabulary and structure, allows for the consistent interpretation of data across different digital twin instances. This standardization is crucial for enabling the transfer of knowledge between instances, ensuring that insights gained from one vessel or fleet can inform decisions on others, even if they operate under differing conditions.

The ultimate goal of this methodology is to enable the extrapolation of decarbonization technology potential across various maritime contexts. By analyzing data from specific vessels or fleets, our approach can predict the effectiveness of decarbonization technologies in different operational patterns (e.g., speed, route, and cargo type) and throughout different phases of a vessel's lifecycle (e.g., design, mid-life retrofitting, and decommissioning). This predictive capability allows ship owners, operators, and industry stakeholders to make informed decisions on adopting decarbonization technologies, tailored to their specific needs and circumstances.

To conclude, our work seeks to bridge the gap between theoretical decarbonization potential and its practical application, offering a scalable and adaptable tool for accelerating the shipping industry's transition towards a more sustainable future.

It must be emphasized that a knowledge graph is never complete or entirely encompassing the modelling perspectives for a ship. It is instead modelled from the perspective of the stakeholders who use the Knowledge Graph/ digital twin in order to study and understand the physical ship. Also, some types of data that may be of interest may not be represented in the digital twin due to technology limitations or even due to non technical reasons (e.g. confidentiality issues).

Additionally, the increasing utilization of Knowledge Graphs as parts of digital twins raises questions about their quality and robustness. (Abu-Salib, 2021). Both model quality and the quality of the underlying data needs to be present for the inferences and predictions made with the use of the Knowledge Graph to be trustworthy. The size and dynamicity of the data sets handled by the DT requires data quality assurance techniques to be automated and integrated in the overall Knowledge Graph infrastructure. As part of future research, we propose techniques of self-reflection and self-correction to be utilized by the Knowledge Graph in order to always remain a reliable and up to date representation of the physical ship.

## DATA ACCESS STATEMENT

No research datasets or repositories were used in this paper.

## DECLARATION OF GENERATIVE AI AND AI-ASSISTED TECHNOLOGIES IN WRITING

*Statement:* During the preparation of this work the author(s) did not use any generative AI and AI-assisted technologies

## CONTRIBUTION STATEMENT

**Author 1:** Conceptualization; data curation,; writing – original draft. **Author 2:** methodology, review and editing.

## ACKNOWLEDGEMENTS

# Prediction of main engine power of oil tankers using artificial intelligence algorithms

Darin Majnarić<sup>1,\*</sup>, Nikola Anđelić<sup>2</sup>, Sandi Baressi Šegota<sup>2</sup>, and Jerolim Andrić<sup>1</sup>

## ABSTRACT

*In the preliminary ship design, the accurate determination of a vessel's main engine power is one of the most critical aspects next to service speed, main particulars, and cargo capacity. However, this task can be quite intricate due to its reliance on an extremely great number of influencing factors. In the research that is presented in this paper dataset of 357 oil tankers was gathered and developed to research the idea in which genetic programming is applied to the mentioned dataset to obtain mathematical equations (MEs) that can estimate the ship's main engine power with high accuracy. The highest estimation accuracy of MEs is achieved by tuning the GP hyperparameter values through the random hyperparameter search (RHS) method. The initial dataset was divided into train and test datasets in a 70:30 ratio. The train dataset was used to train GP in a 5-fold cross-validation process and after the process was done the obtained MEs were evaluated on the test dataset. To evaluate the GP training testing process several evaluation metrics were used i.e., coefficients of determination ( $R^2$ ), mean absolute error (MAE), root mean square error (RMSE), and length of obtained MEs. The conducted investigation showed that GP generated MEs that can estimate ship main engine power with high accuracy.*

Preliminary ship design; Genetic programming; Main engine power; Random hyperparameter search; 5-fold cross-validation

## INTRODUCTION

In the initial design phase of ship design, it is necessary to select key values that define the general characteristics of the ship. These initial values can be specified as requirements by the client or determined by the naval architect. Main particulars, cargo capacity, service speed, and main engine power are among the values that form the foundation of the ship design process.

Upon defining the primary project inputs, the naval architect can roughly estimate the main engine power required to propel the ship and consequently determine the type of main engine needed. When establishing these initial values, which serve as the starting point for the entire design process, the designer must consider limiting factors such as port and channel specifications. The sizes of channels significantly constrain ship dimensions, as evident from the names of standard oil tanker categories such as Panamax and Suezmax, which are designed to navigate through specific channels. Therefore, initial ship design phase takes into consideration the mentioned requirements but also the limits of the environment in which the ship will be operating. It's evident that the entire design process relies heavily on accurately establishing initial values. Improved estimation of these values will likely result in fewer iterations later in the process, thereby shortening the design time. This correlation is evident in the widely adopted ship design spiral, where naval architects encounter fewer cycles. Ship design spiral was introduced by Evans (7) and is set up in a way in which as mentioned designer starts with rough design values and is through iterations arriving at final ship values and final design. There were many modifications made to the entire process

with the goals of shortening it, reducing required effort, automating certain aspects, and enhancing the overall quality of the process. For example, the design spiral itself was modified by Andrews (1), later on, Watson developed two design spirals of which one was for warships and the other for merchant ships (18). Further Rawson and Tupper have introduced more steps in their design spiral with which main design parameters were separated into the components (15). To reduce the number of iterations in the design spiral and to "prepare" the process, so that it can accommodate different types of vessels Papanikolaou (12) has presented a ship design procedure in the form of a straightened spiral. As presented there was constant effort to improve the process itself and through time new methods are being developed and proposed. Besides improvements on the process itself as already mentioned it was recognized that initial values have a significant impact on the rest of the design process and also the final results. Therefore efforts were also placed into the improvement of the initial values with which the design process is starting. Multiple approaches were developed and utilized to predict initial values. Most efforts were directed toward predicting the main particulars. Among the first to develop and apply statistical regression equations was Piko who used the nonlinear approximation method (14). Later on, Papanikolaou used the power regression model for initial values prediction as deadweight as an input (13). Linear 2nd-degree polynomial together with a power regression model was used by Kristensen to predict initial values which were in his research focused on container ships (8).

In recent years, new approaches for predicting initial ship values have been developed and used. Among them most significant is the utilization of artificial intelligence algorithms. Specifically, a lot of research has been conducted on the possible usability of artificial neural networks (ANN). For example, in his research, Clausen has (4) used Bayesian network and regression analysis at the same time as ANN for the estimation of ship main particulars. Ekinci (6) was predicting the main parameters of oil tankers as well by using ANN and the method that has shown as most successful was the Model Trees (M5P) method. When considering ship types most of the research was been conducted on container ships, Majnarić et al. (10) developed a database of 250 container ships which was analyzed with ANN to get high accurate estimation of initial ship values. Additionally, research was also conducted on the utilization of synthetic data to get to the amount of data that can be usable for ANN (9). The research focused on the estimation of ship length between perpendiculars was conducted by Cepowski et al. (2) and by using ANN they have produced two equations for preliminary design purposes. Part of the overall research focused on the implementation of artificial intelligence algorithms was also focused on the prediction of main engine power. In the research (3) authors have used a set of ANNs to update the design equations for the estimation of main engine power and fuel consumption on top of which it was proposed how to estimate CO<sub>2</sub> emissions. Similar research was carried out by Ozsari (11) at which ANN was used to predict main engine power and pollutant emission. Develop model was presented and proposed for future studies on fuel consumption and energy efficiency.

From the previous literature overview, it can be noticed that the majority of used AI algorithms were ANNs. The main problem with ANNs is that they can't be easily transformed into simple mathematical equations due to a large number of interconnected neurons. The other problem is that they require considerable computational resources for storing trained models (memory) and for processing new data samples (CPU power). So, in this paper, the idea is to apply genetic programming symbolic regressor (GPSR) to obtain symbolic expressions (SEs) that could estimate the ship's main engine power with high estimation accuracy. The benefit of using GPSR is that the trained AI model does not require string after it was trained since it after each execution generates SEs i.e. mathematical equation that connects input variables with the target (output) variable). In order to determine the optimal combination of GPSR hyperparameter values for generating SE with high estimation accuracy, the random hyperparameter value search (RHVS) method was developed and applied. To create a robust system of SEs the GPSR will be trained using a 5-fold cross-validation method. A database of Oil tankers was developed so that genetic programming could be applied to obtain mathematical equations that can be used for accurate estimation of main engine power. However, the dataset created for this research had to be preprocessed (outliers removed, synthetically oversampled). Based on the detailed literature overview and the idea in this paper the following questions arise:

- Is it possible to obtain SEs using GPSR that could estimate main engine power with high estimation accuracy?
- Do data preprocessing techniques (outliers removal) and synthetic oversampling have any effect on the estimation accuracy of the trained GPSR model i.e. obtained SEs?
- Can the RHVS method be utilized to find the optimal combination of GPSR hyperparameters, leading to SEs with the highest estimation accuracy achieved by GPSR?
- Is it possible to obtain a robust system of SEs using a 5-fold Cross-Validation process for the estimation of electrical power output?

The outline of this paper consists of the following sections: materials and methods, results and discussion, and conclusion. In materials and methods, the dataset is described as well as the statistical analysis performed. Besides that, in the materials

and methods section, the GPSR is described as well as, the evaluation metrics used and the training-testing procedure. The results section contains the description of the best set of SEs obtained with the optimal combination of GPSR hyperparameter values, and evaluation metric values. The conclusion section contains the conclusions drawn from this research ed based on the results and discussion given in the previous section.

## MATERIALS AND METHODS

This section of the paper will begin by detailing the initial creation of the database, emphasizing its quality assurance measures. Subsequently, an analysis of the database will be presented. Finally, dataset statistics will be provided and analyzed at the conclusion of this section.

### Database

For this study, a dataset of 357 oil tankers was developed. Information for each ship was collected, including net tonnage (NT), service speed (v), and main engine power.

Additionally, to the mentioned data deadweight tonnage (DWT) and length overall (LOA) were collected as well but were not used in this study other than for the representation purposes of main data.

The decision was made to collect data directly from classification society databases, as the quality of results and analysis depends on the input data. Three maritime classification societies had open and maintained databases available to the public (Register; Veritas; DNV) and were used to collect the data. The databases of these classification societies exhibited some inconsistencies in data presentation, and at times, information was missing. Inconsistencies were observed in the form of misplaced commas in values, leading to physically impossible scenarios, as well as incorrect numbers resulting in significantly inflated or deflated values. For example, incorrect values, when located at the first digit of the ship's service speed, introduced significant oscillation from the usual speed expected for a ship of a certain length and main machine power. Therefore, all of these questionable values were identified, checked, and either corrected or obsoleted. For Genetic programming, it is preferable to have larger databases, so that training and validation sets can be of sufficient size, ensuring that the database size does not limit the analysis. Because of this, the intention was to gather as much data as possible. In cases where data was missing or incorrect, best efforts were made to fill in the gaps. Missing or incorrect values were addressed only if the information was available from shipowners' websites or by directly contacting shipping companies. The important quality check performed on the developed database aimed to identify sister ships and recurring vessels, which were subsequently removed to prevent any distortion of the final results. In order to keep the database relevant it was filled in only by the ships built from the year 2000 and onwards. Distribution of the ships through the years is visible at the figure 1.

**Figure 1.** Distribution of ships in the database through the built years

The mentioned deadweight tonnage that was as already specified collected additionally, was used in this research only to

present the ship categorization. In 1 ship categorization is presented based on typically used ship categorization in the industry.

As expected, most of the collected ships belong to the smallest Panamax category, while there are only two records of ultralarge crude carriers (ULCCs). Although more ULCC records were initially present in the database, some were obsoleted. For example, in one instance, there were four sister ships, but only one record was retained. Including records of sister ships in the database would introduce clusters that could distort the dataset and compromise the reliability and realism of the analysis.

**Table 1:** Distribution of ships through classes

Sub-types	DWT range		Number of ships
Panamax	-	79,999	197
Aframax	80,000	119,999	68
Suezmax	120,000	199,999	47
Very large crude carrier (VLCC)	200,000	319,999	43
Ultra large crude carrier (ULCC)	320,000	-	2

## Dataset statistics

The dataset consists of 357 samples and three variables i.e. net tonnage, service speed, and main engine power. The initial statistical analysis of the dataset i.e. the number of samples (count), mean, standard deviation (std), minimum (min), maximum (max), and GPSR variable representation is listed for each dataset variable in Table 2.

**Table 2:** Initial statistical analysis of the dataset

	Net Tonnage (NT)	Service	Engine Power (KW)
count	357		
mean	30213.52	14.03221	11890.5
std	32342.13	1.360539	8332.385
min	5.49	8	1118
max	112192	16.8	51913
GPSR Variable Representation	$X_0$	$X_1$	$y$

From Table 2 it can be seen that all three dataset variables have the same number of samples (357) which means that there are no missing values in the dataset. The mean, std, min, and max values show that net tonnage and engine power have a larger value range than the service variable. This variation in the value range of the dataset variable would indicate that the scaling/normalization technique is required. However, the idea in this paper was to perform the investigation with the original range of dataset variable values. The GPSR variable representation shows how the dataset variables will be represented in the symbolic expressions obtained with this method. The input variables Net Tonnage (NT) and Service (input variables) will be represented in symbolic expressions as  $X_0$  and  $X_1$ , respectively. The plots Engine Power versus Net Tonnage (NT) and Engine Power versus Service are shown in Figure 2.

(a) Engine versus Net Tonnage (NT) plot (The green lines represent the gaps)

(b) Engine versus Service plot

**Figure 2:** Initial plots of dataset input variables versus the Engine power

From Figure 2 it can be noticed that data is scattered. However, some general trends can be noticed for lower values of net tonnage (NT) (0-60000). There are also gaps where no samples consist for example net tonnage (NT) first gap (22700 - 28000), second gap (37000 - 43000), and third gap (55000 - 95600). Besides the gaps in the general data trend, there are also a number of outliers i.e. samples that greatly deviate from the general data trend and should be somehow handled. Regarding the Engine power versus service plot, the general trend could be noticed for lower values of the engine power however the majority of data is scattered in 12 to 16 range Service values. The next step in dataset analysis is to perform Pearson's correlation analysis to determine the correlation between input and output variables. Pearson's correlation between two variables can be in the -1 to 1 range. The -1 value indicates perfect negative correlation between two variables and indicates that if the value of one variable increases the value of the other variable will decrease and vice versa. The value of 1 indicates a perfect positive correlation where an increase of one variable will increase the value of the other variable and vice versa. The worst possible correlation value is 0 between two variables which indicates that the increase/decrease in one variable value will not affect the other variable. The results of the Pearson's correlation analysis in the form of the heatmap are shown in Figure 3.

**Figure 3:** Results of Pearson's correlation analysis in the form of the heatmap

From Figure 3 it can be noticed that the Net Tonnage (NT) has a high positive correlation value (0.86) with the main engine power while the Service has a low positive correlation (0.29) value with the main engine power. Regarding the correlation between the net tonnage (NT) and the service speed variable, the correlation value is 0.18 which is the lowest correlation between the two variables in this dataset. This value indicates that the change in Net Tonnage (NT) will have a very small

effect on the Service variable, and vice versa. The value of 1 on the diagonal line in the heatmap indicates that the variable is correlated with itself. Outliers and boxplots play crucial roles in data analysis. Outliers, which are data points significantly different from others, can distort interpretations and analyses, making their identification important. Boxplots offer a concise visual representation of data distribution, displaying key summary statistics such as median, quartiles, and outliers. They facilitate a quick understanding of data spread, central tendency, and variability, aiding in comparison across different groups or categories within a dataset. Moreover, boxplots are robust to skewness and outliers, providing reliable insights even with non-normally distributed data. Their effectiveness in communicating findings makes them valuable tools for analysts to convey insights to stakeholders succinctly. Overall, outliers and boxplots are essential in detecting anomalies, summarizing distributions, comparing groups, and communicating data characteristics effectively. The results of outlier detection are presented in the form of the boxplot and shown in Figure 4.

**Figure 4:** Distribution of dataset variables.

As observed in Figure 4, all dataset variables exhibit outliers to some extent. To enhance estimation accuracy with the GPSR, these outliers need to be addressed. The capping method known as median absolute deviation (MAD) was employed for outlier removal. MAD is a robust statistical measure of dispersion, offering reduced sensitivity to outliers compared to measures such as standard deviation. To apply the MAD method for capping outliers, the following steps were followed: Firstly, the median of the dataset was calculated to establish the central tendency. Next, the absolute deviations of each data point from the median were computed to capture the variability. Subsequently, the median of these absolute deviations (MAD) was determined. Finally, MAD was multiplied by a constant factor, typically 2 or 3 (in this case, 3), to establish the threshold for identifying outliers.

$$LT = \text{median} - (3 \cdot \text{MAD}), \quad (1)$$

$$UT = \text{median} + (3 \cdot \text{MAD}), \quad (2)$$

Here, LT and UT denote the lower and upper thresholds, respectively, beyond which any data points are regarded as outliers and may be either capped or removed. Any data points outside these thresholds can be considered outliers and in this paper, these outliers were removed. Generally, this is a very useful method when dealing with skewed or non-normally distributed data where traditional methods like standard deviation may not be appropriate due to sensitivity to outliers. With the application of this outlier removal method, the outliers were successfully removed from the dataset as seen from Figure 5.

**Figure 5:** The distribution of dataset variables after application of MAD outlier capping method.

When Figure 4 and 5 are compared it can be noticed that the outliers (black dots) were removed from dataset variables (Net Tonnage (NT) and Engine Power (KW)), however, some small number of outliers remains in the Service dataset variable. With the application of the MAD capping the majority of outliers were successfully removed however the number of dataset samples was reduced from the original 357 to 307 samples. After the outliers were removed from the dataset using the MAD method the plots Engine versus Net Tonnage (NT) and Engine versus Service are shown in Figure 6.

**(a)** Engine versus Net Tonnage (NT) plot after outliers were removed using MAD technique

**(b)** Engine versus Service plot after outliers were removed using MAD technique

**Figure 6:** The Engine power versus net tonnage and service after outliers were removed using MAD technique

As seen from Figure 6 it can be noticed that the MAD technique has removed outliers from the dataset. This is especially valid when Figure 6a is compared to Figure 2a. Besides outliers that greatly deviate from the general data trend a large number of samples were removed in which Net Tonnage (NT) exceeded 90,000. This is due to the large gap in data since the majority of samples in terms of Net Tonnage (NT) are concentrated in the 0 to 60,000 range.

The other problem with the obtained dataset is the small number of samples and the idea is to see if somehow the number

of samples could be synthetically generated. In this paper the averaging method is considered that consists of the following steps:

1. sort the dataset samples from minimum to maximum value of the target variable (main engine power),
2. for dataset samples in range from 1 to the maximum number of dataset samples:
  - create an average dataset sample between the current sample and the sample + 1, sample + 2, sample + 3, sample + 4, sample + 5, sample + 6, and sample + 7 for all dataset variables,

3. concatenate the original dataset with newly created samples,
4. repeated the process an arbitrary number of times.

In this paper, the process of creating the average values was repeated 3 times. By doing so the number of samples was enlarged from 307 up to 76460.

**Figure 7:** The Engine power versus net tonnage and service after average oversampling was performed

As seen from Figure 7 visually the number of samples was greatly increased. The advantage of the average oversampling is that the gaps (in the case of Net Tonnage) are filled but the problem is the small number of outliers generated (samples that deviate from the general data trend). The correlation plot of the final synthetically oversampled dataset is shown in Figure 8.

**Figure 8:** The correlation heatmap of the synthetically enlarged dataset.

When Figures 3 and 8 are compared it can be noticed that with the application of outlier removal and the synthetic oversampling, the correlation between Net Tonnage (NT) and the main engine Power was increased from 0.86 to 0.96, between Service and main engine power (KW) the correlation was increased from 0.29 to 0.77. It can be also noticed that the correlation between Net Tonnage and Service speed was increased from 0.18 to 0.67. This final version of the dataset obtained using outlier removal and synthetic oversampling will be used in genetic programming symbolic regressor to obtain symbolic expressions for estimation of main engine power.

## Genetic programming symbolic regressor

The genetic programming symbolic regressor begins its execution by randomly creating the population of naïve symbolic expression by random selection of input variables, constant values, and mathematical functions to estimate the target value. The estimation accuracy of the initial population is generally very low. However, with the application of genetic operations such as crossover and mutation through a consecutive number of generations in the end the symbolic expression is obtained that estimates the target variable with certain accuracy. Since the GPSR has a large number of hyperparameters the random hyperparameter values search method was developed and applied to find the optimal combination of hyperparameter values using GPSR will produce the SE with high estimation accuracy. The process of developing the RHVS includes the following steps:

1. Definition of the initial value range for each GPSR hyperparameter value,
2. Testing the lower and upper boundaries of each GPSR hyperparameter to see if the GPSR can successfully be executed i.e. produce the SE,
3. If the GPSR fails in its execution due to a specific hyperparameter boundary value adjust the hyperparameter value range.

In the RHVS method, the optimal values of the following hyperparameters were searched:

- Population size – the size of the population (SEs) that will be evolved during its execution
- Number of generations – The maximum number of generations for which GPSR will be executed. This is also one of the termination criteria which means that GPSR will terminate the execution after the predefined number of generations is reached.
- Tournament size – the tournament size is the size of a randomly selected population in each generation that will compete to become the parents of the next generation. In every tournament selection, there is only one winner and on this winner, genetic operations such as crossover or mutation are performed.
- Initial depth size – inside the GPSR the population members are represented as tree structures which means that the size of the population member is presented in terms of depth measured from the root node up to the deepest leaf in the tree structure. It should be noted that the initial depth size is defined as a value hyperparameter indicating the range of the population member's depth size. For example (3,12) indicates that the initially created population the depth of population members will be in 3 to 12 depth.
- Crossover probability value – probability value of crossover operation performed in each generation. The crossover is performed using two tournament selection winners. On both tournament selection winners, the random sub-tree is selected and the sub-tree from the second tournament winner replaces the sub-tree of the first winner to create offspring for the next generation.
- Subtree mutation probability value – the probability value of the subtree mutation. This operation and other mutations used in this research require only one tournament selection winner on which the random sub-tree is selected and replaced with a randomly created sub-tree by randomly picking constant values (from a predefined range), input variables, and mathematical functions.
- Point mutation probability value – is the probability value of the point mutation genetic operation. In point mutation, the nodes are randomly selected on the tournament winner and replaced. In other words, the randomly selected constant value node is replaced with a constant value, the input variable with other input variables, and mathematical functions with randomly picked mathematical functions. However, when mathematical functions are replaced with other randomly selected mathematical functions the number of arguments in the original mathematical function must be the same in the mathematical function that will replace the original one.
- Hoist mutation probability value – In hoist mutation, the random subtree is selected on the tournament winner, and on that tree a random node is selected. Then the randomly selected node is “hoisted” i.e. it replaces the entire randomly selected subtree.
- Range of constant values – the range of constant values that will be used in GPSR to develop the initial population, to perform the different mutation operations.
- Stopping criteria – is the predefined minimum value of the fitness function. In the case of GPSR, the fitness function is the Mean Absolute error defined with the equation:

$$MAE = \frac{\sum_i^n (y_{ti} - y_{pi})}{n}, \quad (3)$$

Where  $y_{ti}$ ,  $y_{pi}$ , and  $n$  are the true target value, predicted target value and the number of dataset samples. So, in the case of stopping criteria if the fitness function value of only one population member falls below the predefined stopping criteria value the GPSR execution will terminate and the GPSR will give as the output the best SE. In other words, the stopping criteria are the second GPSR termination criteria, alongside the number of generations.

- **Max Samples** – the fraction of the samples that will be drawn from the training dataset and used to evaluate each SE. The max samples are a useful tool to see how the SE performs on the unseen data during the execution. The output value in this case will be out of bag or raw fitness value. For example, if you use a training dataset you can specify a very small portion of that dataset that will not be used during training i.e. it will be unseen by SEs during training, and in each generation, the majority of the training dataset will be used to calculate the fitness value while this small portion will be used to calculate the raw fitness value. Generally, the raw fitness value should be close to the real fitness value in order to at the end obtain SE with high estimation accuracy.
- **Parsimony coefficient** – is the coefficient used in the parsimony pressure method to stop the bloat phenomenon. This phenomenon occurs when the size of the population members rapidly grows from generation to generation without any indication of lowering the fitness value. In extreme cases, this bloat phenomenon can cause the GPSR to quickly terminate due to memory overflow or it can execute after a long time with an extremely large size (1000 or more elements in SE). The coefficient is the most sensitive one which means that small values can lead to extremely large population members (SEs) while large values can lead to small SEs with low estimation performance.

It should be noted that the sum of all genetic operations (probabilities) must be equal to 1 or slightly lower than 1 for example 0.99. If the value is smaller than 1 then some tournament selection winners enter the next generation unchanged i.e. the genetic operations were not applied to some tournament selection winners. In all GPSR investigations, the following mathematical functions were used addition, subtraction, multiplication, division, square root, absolute value, sine, cosine, tangent, natural logarithm, and logarithm with bases 2 and 10. However, division, square root, natural logarithm, and logarithm with bases 2 and 10 had to be modified to avoid imaginary or not number values which could lead to failed GPSR executions.

The division function was modified in the following way:

$$y_{DIV}(x_1, x_2) = \begin{cases} \frac{x_1}{x_2} & \text{if } |x_2| > 0.001 \\ 1 & \text{if } |x_2| \leq 0.001 \end{cases} \quad (4)$$

The square root function was modified in the following way:

$$y_{SQRT} = \sqrt{|x|} \quad (5)$$

The natural logarithm and logarithm with bases 2 and 10 are modified in the following way:

$$y_{LOG}(x) = \begin{cases} \log_i(|x|) & |x| > 0.001 \\ 0 & |x| < 0.001 \end{cases} \quad (6)$$

Where  $i$  represents the base of the logarithm (e, 2, and 10). It should be noted that  $x_1$ ,  $x_2$ , and  $x$  in previous equations do not have any connection with the input variables used in this research. They are only used here to describe the modifications made to the aforementioned mathematical functions.

**Table 1:** The RHVS ranges for previously described hyperparameters are listed

Hyperparameter	Range
Population size	1000-2000
Number of generations	25 - 50
Tournament size	100-500
Initial depth size	3-18
Crossover	0.001-1
Subtree mutation	0.001-1
Point mutation	0.001-1
Hoist mutation	0.001-1
Range of constant values	-10000 - 10000
Stopping criteria	$1 \times 10^{-9} - 1 \times 10^{-3}$
Max samples	0.99-1
Parsimony coefficient	$1 \times 10^{-6} - 1 \times 10^{-1}$

### Evaluation metrics

The evaluation metrics used in this research were coefficient of determination ( $R^2$ ), mean absolute error (MAE), and Root mean square error (RMSE). The  $R^2$  can be defined as:

$$R^2 = 1 - \frac{\sum_i (y_i - f_i)^2}{\sum_i (y_i - \bar{y}_i)^2}, \quad (7)$$

Where  $y_i$  is the real value (target variable),  $f_i$  is the predicted value and the  $\bar{y}_i$  is the mean value of the real data. The MAE was previously defined in the description of GPSR as it was used as a fitness function for the evaluation of population members. RMSE stands for Root Mean Square Error. It is a commonly used metric to evaluate the performance of a regression model. RMSE measures the average magnitude of the errors between predicted values and actual values. Mathematically, RMSE is calculated as follows:

$$RMSE = \sqrt{\frac{1}{n} \sum_i^n (y_i - f_i)^2} \quad (8)$$

Where  $n$  is a total number of samples.

## Training-Testing Procedure

The training-testing procedure is graphically shown in Figure 9.

**Figure 9:** The scheme of training GPSR using the 5FCV process and RHVS method for GPSR random hyperparameter selection.

The training-testing procedure shown in Figure 9 consists of the following steps:

1. The dataset obtained after preprocessing (elimination of outliers and oversampling) is divided on training and testing datasets in 70:30 ratio. The training dataset will be used in GPSC and will be trained using 5FCV while the test dataset will be used from the evaluation of SEs obtained with GPSC.
2. The random selection of GPSC hyperparameter values using the RHVS method and training of GPSC using 5FCV. It should be noted that after each split in 5FCV (5 splits in total) the SE is obtained so this means that after 5FCV a total of 5 SEs will be obtained using GPSC.
3. After training was done evaluate the obtained SEs using R2, MAE, and RMSE evaluation metric methods. Since after 5FCV, the GPSC generated 5 SEs the evaluation metric values have to be obtained for each SEs on train and validation sets. The mean and std values of the aforementioned metric methods are obtained and if the mean value of R2 is higher than 0.85 the process continues to the testing phase. However, if the R2 is lower than 0.85 the process continues from the beginning i.e. by selecting the random GPSC hyperparameter values using the RHVS method.
4. In the testing phase the test dataset (30% of the initial) dataset is provided to the 5 SEs and the output is generated. This output is compared to the original output and the R2, MAE, and RMSE mean and std values are obtained. Finally, if the mean R2 value is higher than 0.85 the process is completed. Otherwise, the process starts from the beginning i.e. from the RHVS method.

## RESULTS AND DISCUSSION

The best set of SEs obtained in this research was achieved using the following combination of hyperparameters listed in Table 4.

**Table 4:** Optimal combination of GPSR hyperparameter values

	Population size	Number of generations	Tournament size,	Initial depth size	Crossover	Subtree mutation
Case 1	1126	25	350	(6, 11)	0.0035	0.9667
	Point mutation	Hoist mutation	Range of Constant Values	Stopping Criteria	Max Samples	Parsimony Coefficient
Case 1	0.019	0.0102	(-8861.28, 1162.32)	$6.91 \times 10^{-7}$	0.995	0.0098

As seen from Table 4 the best set of SEs was obtained with GPSR in which the population consisted of 1126 population members that were evolved for 25 generations. These two hyperparameters are near the lower boundary used in the RHVS method (Table 3). The dominating genetic operation was subtree mutation (0.9667) while other genetic operations had values in the 0.0035 to 0.019 range. The stopping criteria value was defined so low any population member never reached it during the execution of GPSR which means that the dominating termination criteria in all these investigations was the number of generations. The parsimony coefficient was near the upper boundary (Table 3) which prevented the occurrence of bloat phenomenon and generated smaller SEs. The example of SE is shown in Eq.(9).

$$y = 67.06\sqrt{|X_0|} \left( \tan(\log(\max(\min(-3953.5, 1.443 \log(0.43|\log(X_0)|))), \right. \\ \left. \min(0.93 \log(X_1), 1.2\sqrt{\log(\frac{X_0}{X_1}) + \sqrt{X_0}}) - \sin(\log(\min(|X_1|, \right. \\ \left. 1.4 \log(\min(-7556.63, X_0)))))) \right)^{\frac{1}{2}} - \sqrt{|\log(0.00031 \log(X_0))(X_0 + \sqrt[9]{X_0} - 7073.28)|} + 10.31 \quad (9)$$

As seen the Eq.(9) is not so large however it requires both input variables. It should be noted that using the 5FCV training process the GPSR generated five different SEs to estimate the target variable. The evaluation metric values (R2, MAE, and RMSE) were obtained on both training and testing datasets. The mean and standard deviation values are shown in Figure 10.

(a) Mean  $R^2$  value with standard deviation obtained with GPSR generated SEs on the synthetically oversampled dataset.

(b) Mean MAE and RMSE values with standard deviation obtained with GPSR generated SEs on the synthetically oversampled dataset.

**Figure 10:** Evaluation metric values of SEs obtained with GPSR trained on the synthetically oversampled dataset.

As seen from Figure 10 the mean value of  $R^2$  is pretty high with a small standard deviation value. The  $MAE$  and  $RMSE$  values are low when these values are compared with the range of the target variable (Table 5). After the 5 SEs obtained on the synthetically oversampled dataset are evaluated on the initial dataset (307 samples) i.e. the dataset obtained after outlier removal using MAD capping the following evaluation metric values are obtained and listed in Table 5.

**Table 5:** Summary of Data

Metric	Value
$R^2$ Mean	0.883
$R^2$ STD	0.0113
$MAE$	1205.92
$\sigma MAE$	105.094
$RMSE$	1736.75
$\sigma RMSE$	83.67

The results from Table 5 have shown that the obtained SEs using GPSR on the synthetically oversampled dataset have slightly lower estimation accuracy when applied on the initial dataset (outliers removed). This is because the obtained SEs follow the general trend of the data however there are some samples that deviate from the general trend. The graphical representation of the Engine versus Net Tonnage (NT) and Engine versus Service is shown in Figure 11.

**(a)** Engine versus Net Tonnage (NT) comparison of real data and estimation made by all five best equations obtained with GPSR.

**(b)** Engine versus Service comparison of real data and estimation made by all five best equations obtained with GPSR.

**Figure 11:** Comparison of estimation made by five best equations obtained with GPSR and the real data (dataset with removed outliers).

As seen from Figure 11 the best SEs captured the trend in the data. This can be seen from Figure 11a where Engine Power (KW) versus Net Tonnage (NT) is shown.

## CONCLUSIONS

As presented in this paper, a dataset was developed that consisted of 357 oil tankers for which data was collected as net tonnage (NT), service speed (v), and main engine power. The original dataset variables contained several outliers which had to be removed since they greatly influenced the estimation accuracy of the trained AI model. After the removal of the majority of outlier dataset samples the dataset was synthetically oversampled by the introduction of averaging samples. This modified dataset was used in GPSR with the RHVS method that was trained using 5FCV. After the application of this procedure, the 5SEs were obtained. The best set of SEs achieved great estimation accuracy of main engine power on synthetically oversampled datasets and the initial dataset without outliers. Based on the conducted investigation the following conclusions can be drawn:

- The SEs with high estimation accuracy of main engine power can be obtained using GPSR however the accuracy is dependent on two factors i.e. dataset quality, a combination of hyperparameters.
- Dataset preprocessing methods (outliers removal) and synthetic oversampling greatly contributed to the GPSR-generated SEs since the GPSR produced the SEs with high estimation performance.
- The RHVS method proved to be useful in finding the optimal combination of GPSR hyperparameters using which the SEs obtained with GPSR have achieved high estimation performance
- The 5FCV proved to be a useful method for training the GPSR since using this approach a robust set of 5 SEs was obtained.
- Approach can be used in the preliminary phase of ship design to generate a value of main engine power.
- Based on the results initial main engine power value will be an accurate estimation and therefore close to the value that will be reached at the end of the design. With that fewer iterations will be needed during the design development process.

The equations developed through this approach have the potential to be utilized during the initial design phase of ship development. The practicality of this approach lies in its speed and accuracy, making it a valuable complement to existing methods for estimating initial engine main power. Furthermore, based on this research equations produced by this method can eventually even be used as a sole source of initial values.

The proposed approach in this paper has its pros and cons. The pros are:

- The outlier removal and synthetic oversampling are great approaches in dataset preparation which will be used for train of AI algorithm,
- The GPSR in combination with RHVS and 5FCV is a great method to obtain a robust set of SEs with high classification Performance.

The cons of the proposed research are:

- Removing outliers removes the number of original dataset samples, and in general, the trained AI model on the dataset without outliers cannot predict the outliers. The other problem with outliers removal using this approach is that the majority of outliers i.e. values of Net Tonnage (NT) higher than 50000 were removed from the original dataset. So this approach could be used for Net Tonnage in the 0 to 55000 range.
- The GPSR with RHVS and 5FCV can take some time to obtain a robust set of 5SEs with high estimation performance because the optimal combination of GPSR hyperparameters cannot be found instantly and each combination of GPSR hyperparameter values had to be tested in GPSR which is trained using 5FCV. This means that GPSR will be trained 5 times on different splits of the training sets i.e. generating 5 SEs in the process.
- This approach may not be suitable for designing oil tankers that deviate from typical designs.

Based on the pros and cons of the proposed research methodology future work will be focused on exploring alternative artificial intelligence algorithms (Neural networks) to see if better estimation accuracy of engine power could be obtained.

Besides the alternative artificial intelligence algorithms in the future work different input variables will be considered since the correlation between Net Tonnage (NT) and the Service with the Engine Power (KW) is initially too low.

## DATA ACCESS STATEMENT

The dataset used in this study is available on request.

# MariData – Digital Twin for Optimal Vessel Operations Impacting Ship Design

Jochen Marzi<sup>1,\*</sup>, Stefan Harries<sup>2</sup>, Benjamin Schwarz<sup>3</sup>, Martin Scharf<sup>4</sup>, Katharina Demmich<sup>5</sup>, Martin Pontius<sup>5</sup>

## ABSTRACT

*Energy efficiency is a key element for reduced shipping emission to meet future environmental regulations. Both design and operation play an important role to meet this goal and the perfection of the interplay between these aspects promises quick improvements to meet the requirements of short term emission standards. The MariData project [<https://maridata.org>] developed a forward-looking energy management and decision support system (DSS) for ship operation based on rational methods and data created during ship design and sets out to bridge the gap between design and optimized operation. The “digital performance twin” of a vessel, which is based on design data, is enhanced with lifecycle data covering the entire operational envelope and provides valuable feedback into design processes.*

## KEY WORDS

Simulation; Operational profile; Digital twin; Weather routing; Navigational support; Design Feedback.

## INTRODUCTION

Shipping emissions are increasingly in the focus of public interest and political as well as regulatory attempts are being made to reduce such GHG emissions. While the majority of the maritime industry appears to concentrate on new generations of e-fuels to meet future emission standards, the question of sufficient availability and price is still uncertain. On the other hand, perfections of design and operational performance promise significant improvements of the energy efficiency of individual vessels and thus the whole of maritime operations, likely to meet emerging requirements for the 2030 emission goals. Departing from a vast experience of design improvements, the MariData project and its team members set out to develop a forward-looking energy management and decision support system (DSS) for ship operation based on rational methods and data created during ship design. In a first step, a digital twin of the vessel and its performance related properties is created, which can be derived from design data. Here, technologies from the EU HOLISHIP project (Papanikolaou, et al., 2022), (Papanikolaou, 2018) are applied to generate extensive surrogate models which cover the entire operational envelope including also degradation of the hull surface condition due to fouling which leads to increased resistance over time. This “digital design twin” is a fundamental prerequisite to determine optimal energy consumption during all phases of operation. In a second step a model of the engine / machinery system on board is created which provides another facet of the digital twin. In combination, these models allow to determine the total energy consumption on board for a large variety of operational conditions experienced during the lifetime of a vessel and form the basis for a continuous comparison of the target performance of the ship with actual data provided by comprehensive on-board data collection. Combining this energy model with advanced route planning is done on the basis

of a combination of different geographic information and satellite weather data as well as weather forecasts. While ship safety is a key prerequisite, the information how the vessel will behave under projected environmental forecast data allows optimizing voyage planning using a variety of different target functions including minimal voyage time and / or fuel consumption or emissions. On the operational end, MariData presents planning and actual information to the ship crew through a dedicated advanced user interface, which allows for a permanent target performance comparison and decision support for corrective measures. By using advanced design data, MariData bridges the gap between modern design systems and operation. In one direction, the wealth of information created during design will be applied for optimized operation whilst in the other direction, statistical information obtained during – practical – operation will influence future designs.

## **DIGITAL TWIN FOR OPTIMAL VESSEL OPERATIONS**

### **R&D Project MariData**

The German national R&D project MariData (Comprehensive technologies for ship energy management) started in 2019 to explore the efficient use of energy during shipping operations. Energy efficiency has always been a key concern for both, shipbuilding and shipping. Whereas in the past it was mainly economic reasons that motivated the search for a low power requirement for a ship, nowadays ecological reasons and compliance with statutory regulations to reduce emissions are coming strongly to the forefront with at least equal weight. These concerns call for a consistent strategy of energy efficiency as well as a significant reduction of exhaust emissions not only in the construction but also substantially in the operation of ships.

The energy consumption of merchant ships is largely determined by their hydrodynamic characteristics and the systems onboard. In some cases, up to 90% of primary energy consumption is used for propulsion and must, therefore, be optimally managed. MariData's goal is to develop, improve and classify simulation-based modules for ship energy management based on information created during the design phase of a vessel.

Together with geospatial information and a DSS that brings together technical, environmental and economic data, energy consumption information is integrated into a platform that can be used both onboard the ship and shore-based by a shipping company. The platform provides on-line simulations for decision support to the ship's management, as well as assistance with short-, medium- and long-term forecasts and decisions related to ship operations.

A key element of the project's development is the energy model in form of a Digital Twin. Today, Digital Twins play an increasingly important role in the maritime industry: during design, production and operation of ships and other assets, they offer a large potential to improve the "product" in terms of (i) better understand the performance of the asset, (ii) study possible ways of improving it and (iii) predict and optimize operational behavior (e.g. with regard to scheduling maintenance, avoiding failure and improving energy efficiency). The concept applied in MariData is founded on a sophisticated and accurate simulation based energy which is in turn largely based on design data. This is accomplished with on-board measurements and allows to provide instant feed back for the operational optimisation. Although we consider the crew as part of the system, i.e. there will be no automatic manipulation of operational parameters, this concept can be regarded as a Digital Twin, though possibly not in the strict definition of the term. Rather than acquiring only measured operational data, often affected by sensor errors, the model is made up from large sets of simulations, e.g. for the energy requirements due to resistance and propulsion under various conditions of operation. This allows, together with reliable forecasts of environmental conditions, to plan and optimize voyages with increased reliability. The knowledge of all relevant parameters, wind, waves, currents etc. and the respective behavior of the vessel increases the accuracy of predictions and forecasts for the energy consumption during passages which in turn will yield a much higher accuracy in predicted and achieved fuel consumption for a planned voyage. This is a fundamental prerequisite for actual voyage optimization and makes fuel / energy savings accessible. The design contribution in this respect is that actual operational conditions are gathered and allow to produce more precise design briefs for similar or likewise ships in the future. The present system allows to feed experience gained from operation into detailed specifications for a new design brief which will be much improved by more precise weighting of different (operational) conditions and hence allow for a more specified design optimization, e.g. focusing more on the role of efficient behavior in waves, wind or other conditions which are typically considered to be "off design" at present.

### **Carl Büttner Tanker**

Within the MariData project the main application is a tanker of 183 m length overall, 32 m maximum beam, 16 m depth, a design draft of 9.50 m (scantling draft of 10.5 m) and a cargo capacity of about 45 000 m<sup>3</sup> (see Figure 1) is studied with regard to its energy consumption. The ship is an oil-chemical tanker, the CB Adriatic (called CBT for brevity), was built in 2019 after having been jointly optimized for an anticipated operational profile, i.e., for multiple speeds and drafts. The hull features an asymmetric stern, the propulsion system a tip rake propeller and the rudder a Costa bulb. Results from model tests showed a performance in the top of its class.

**Figure 1: CB Adriatic (oil-chemical tanker, IMO 9851696), operated by Carl Büttner Shipmanagement**

The project sets up a digital twin in order to compare consumptions as computed by means of simulations and as measured onboard and to suggest how to further improve energy efficiency. To this end, the ship's hydrodynamic performance needed to be simulated for many different operational scenarios, e.g. in calm water, in sea states representative of its operational profile, in both deep and shallow water, when maneuvering and when under the influence of heavy winds and current. As can be readily appreciated, this calls for suitable geometric representations of the ship hull, the propulsion system, appendages and the superstructure. Besides the tanker, also two heavy lift carriers have been equipped and investigated.

### **Data Acquisition**

One cornerstone of our investigation was the acquisition of sensor-driven ship data alongside navigational data. To do this, custom-tailored hardware has been deployed on 6 ships of two fleets, representing a range of carrier vessel usages (tankers and heavy lift / project cargo vessels). The minimum specifications included access to navigational and performance-related data, such as Speed Over Ground (SOG) and Fuel Oil Consumption (FOC). To streamline data management and accessibility, a common interface has been established using the Navis Bluetracker Suite (Kaleris, 2024). This well-established platform, combining sensor and reporting data, serves as the backbone for data integration and pre-processing. In addition to this, a proprietary high-frequency data interface has been implemented to address the additional demands of model validation and onboard route monitoring. This interface supports archiving for historical analysis and facilitates local use, providing a robust foundation for real-time decision-making and continuous improvement of the digital twin. After initial sensor deployment, the acquired data on actual trips has been verified through plausibility checks and crew feedback, ensuring the reliability and practical relevance of the information obtained from sensor and onboard systems data.

Figure 2 illustrates the data flow within our system. The Navis Bluetracker Suite (B6, Figure 2) acts as the primary conduit for information, seamlessly integrating with the proprietary high-frequency data interfaces. On the shore side, this setup is enhanced by a proprietary server for geodata (e.g., environmental and navigational data; B3, Figure 2) and routing services. This architecture ensures a smooth and efficient flow of data from onboard sensors to centralized systems and back to the onboard decision support system (B1, Figure 2), enabling comprehensive monitoring and analysis. The visualization of this data provides valuable insights into vessel navigation and performance, empowering stakeholders to make informed decisions for enhanced maritime operations. Additionally, on shore side, extensive evaluation of recorded ship parameters for both system improvements and crew training is facilitated.

## SIMULATIONS AND SURROGATES

### Components

A ship traveling through water is influenced by many factors, all of which contribute to some extent to its total energy consumption. Assuming that interactions are sufficiently small in comparison to any component's direct contribution, a superposition ought to give reasonably good estimates. For the sake of simplifying the analysis often calm-water at infinite water-depth is considered, see Figure 3a, while the actual situation at sea comprises wind, waves, current, fouling along with possible effects from shallow water and/or canals, see Figure 3b. All components need to be suitably considered. Here, only the key contributors shall be discussed in some detail, namely calm-water resistance, added resistance in waves and propeller performance.

**Figure 3: Components for which data are produced by simulations**

### Calm Water Resistance

Calm water resistance is typically the first and often foremost element of all hydrodynamic considerations. It is made up of two different components: (i) the pressure or form-related wave resistance and (ii) the viscous drag. The added resistance due to wind and waves is treated in the following section. The calm water contributions to the overall power requirements of a vessel typically amount to 70% of the overall power required on board. The pressure related component depends – besides speed and draft of the ship – on the hull form and hence is invariant over the lifetime. Viscous resistance however changes a lot over time due to increased hull roughness due to fouling. As the overall share of the viscous or frictional resistance can be large, especially for typical merchant vessel cases, this has to be taken into account not only during operational optimization but already during design as to make sure that the selected engine meets the requirements of increased water resistance over time.

For the surrogate model used in the digital twin of the CBT, a set of design predictions formed the basis. This concept follows an approach developed in the HOLISHIP project, see e.g. (Marzi, et al., 2018; Papanikolaou, 2018).

A first evaluation of the operational conditions of the tanker revealed that more draught and trim conditions than considered during design were required to cover the entire envelope. This meant that an extra set of predictions had to be performed. As the design predictions all were performed using a standard roughness according to ITTC guidelines, further analysis of additional hull roughness conditions was included in the data set which finally resulted in a model comprising more than 190 different conditions for the calm water resistance. This was considered sufficient for use during operational optimization. Predictions were performed using HSVA's in-house RANS code FreSCo<sup>+</sup> (Hafermann, 2007)

using different roughness models. An example of the calm water predictions is shown in the following figure which illustrates also the complex wave formation at the bow of the ship.

Figure 4: Example CFD prediction for the CBT – fully laden at design speed

The entire set of predictions resulted in a response surface shown in Figure 5 indicating total resistance as a function of speed and draft (even keel situation). Due to confidentiality, these and all following resistances are normalized with the calm water resistance  $R_{calm,ref}$  at a ship speed of 13 kn and a draught of 9.5 m.

Figure 5: CBT calm water resistance as a function of speed and draft, even keel

The effect of hull roughness has been accounted for using a dedicated new wall function model in FreSCo+ developed in the MariData project. This allows to choose between different wall functions and even to specify local distributions of roughness based on a sand grain equivalent. The following Figure 6 indicates the effects of different distributions of roughness on the hull of the CBT: On the left, variable sand roughness distributions on tanker hull are indicated: from bottom to top: constant fouling, positive fouling gradient, negative fouling gradient and variable fouling fraction. On the right, friction coefficients on the hull and along hull center line are shown based on the different mean (spatially constant) sand roughness.

Figure 6: Effect of local roughness distribution on shear forces

Alternatively, roughness effects can of course also be modelled using the well-known ITTC roughness model. Figure 7 indicates the respective response surface for additional resistance according to roughness as a function of speed.

**Figure 7: Added resistance due to hull roughness on CBT**

### Added Resistance in Waves

The contribution of added resistance in a seaway to the total resistance can be quite significant, depending on the ship type and weather conditions. To obtain a good estimate of the resistance, the following parameters must be considered:

- draught at aft perpendicular
- draught at forward perpendicular
- vertical position of center of gravity
- ship speed
- main direction of incoming waves
- peak period of wave spectrum
- significant wave height of incoming waves

Because of the number of relevant parameters, methods like RANSE-based simulations are not feasible to build the surrogate model. Instead, simulation methods based on potential flow theory are used. The 3D panel code NewDrift, developed at National Technical University of Athens (NTUA), was used in the scope of the MariData project to create large sets of training data. To generate penalizations for many different floating conditions, a process using the CAD environment CAESSES was set up. About half of the generated dataset of approx. 6000 points is used to train the surrogate model using a Kriging approach. The remaining points serve as control set to check the model quality.

**Figure 8: Added resistance due to seaway in  $T_p = 9.5$  s,  $H_s = 2$  m**

## Propeller Performance

Simulations were performed in the panel code panMARE (Hundemer, 2005) developed at the Institute of Fluid Dynamics and Ship Theory. A grid study resulted in a blade discretization with 20 panels in chord wise direction and 25 panels in radial direction, shown in Figure 9.

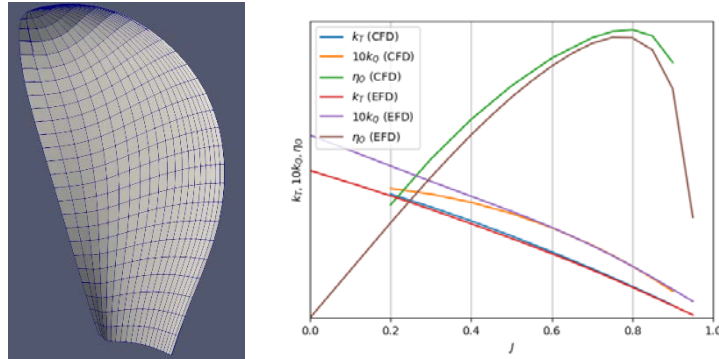

Figure 9: CBT propeller blade panel grid and open water comparison of simulated and measured results

A Sobol sequence was used for the sampling in parameter space of rotation rate and blade pitch  $\theta$ . Only operating conditions from the first quadrant were simulated until the absolute of the second statistical moment of thrust coefficient, torque coefficient and open water efficiency fell below  $1\text{E-}4$ . 736 operating conditions remained for the generation and testing of the two surrogate models under the condition  $c_{Th} < 10$ . The models are designed to determine the advance coefficient  $J$  and torque coefficient  $k_Q$  from the ship loading curve coefficient  $k_T/J^2$  and  $\theta$ , see Figure 10 for the resulting response surfaces.

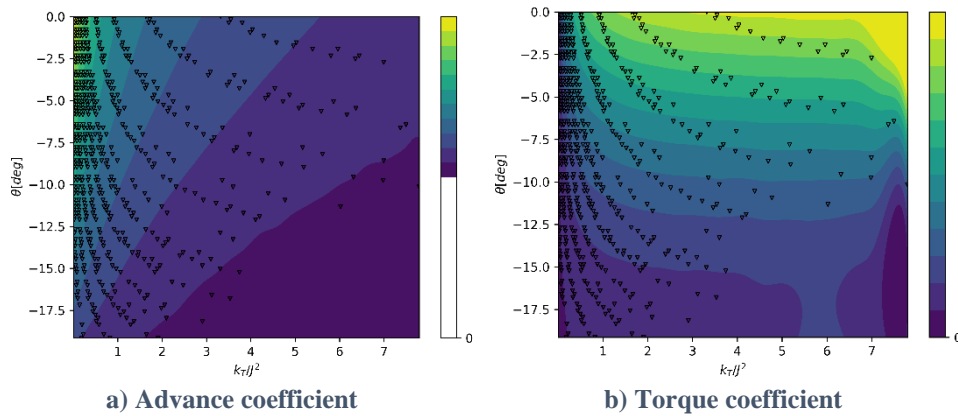

Figure 10: CBT propeller surrogate model response surfaces

## Various Additional Components

Environmental factors not only introduce parts to the added resistance but can also introduce transversal forces as well as yaw moments. The reaction of the ship to these components in form of drift motion and necessary rudder angle to neutralize yaw moments is modeled with a set of maneuvering coefficients. These also contain parts for the longitudinal force due to sway motion and rudder angle.

## Aerodynamic Resistance

For the wind influence, forces were determined through hybrid RANS/LES simulations for two geometries, a detailed geometry and a simplified one regarding deck and deckhouse superstructure. The difference in longitudinal and transversal force for the two versions in apparent wind angles of  $0^\circ$ ,  $45^\circ$  and  $90^\circ$  were between  $-5\%$  and  $8\%$  of the force on the detailed version. The surrogate model was built with a coefficient-based interpolation approach with ship speed, wind speed, wind angle, draught and material properties of the air as input parameters,

Figure 11: Air velocity distribution on midship plane for two geometry detail levels

Figure 12: CBT wind force surrogate model results for 5 m/s ship speed as a function of apparent wind angle and wind speed

### Added Resistance in Shallow Water

Simulations with the CBT hull in restricted water depths were carried out using a Finite-Volume method. The results were used as training data for a Kriging-based surrogate model, as previously published e.g. in (Harries, et al., 2019) and (Harries, et al., 2017) for the added resistance due to shallow water with the parameters water depth, ship speed and draught. Exemplary results of this model are shown in Figure 13.

Figure 13: Added resistance due to shallow water effects for CBT at T=9.5m

### Uncertainty considerations and analysis

Given the complex structure and interdependencies between different elements of the overall MariData development, it is evident that there are several sources of errors, causing uncertainty. Prominent sources of uncertainty are:

- **Simulations:** System behavior is only approximated by simulations which themselves are sufficiently converged numerical solution to chosen mathematical model that describe the physics of interest. In some cases certain phenomena are deliberately neglected to be able to undertake simulations with reasonable effort, e.g., potential theory for sea-keeping analyses in which viscous effects are not taken into account.
- **Interactions:** Assuming that various resistance components can be superimposed linearly omits any interaction between them. For instance, hull fouling not only changes calm-water resistance but might change the wake field into the propeller.
- **Surrogates:** The various components are captured by means of surrogates, i.e., meta-models that are fed with simulation data and which interpolate (or approximate) these data, yielding quantitative results for system behavior where no simulation actually took place. Previous work has shown good accuracy for surrogates representing calm-water resistance ( $\pm 1\%$  difference between the approximation and the simulations) and added resistance in waves (uncertainty of  $\pm 2.5\%$ ), see Harries et al. (2019) and Harries et al. (2017), respectively.
- **Biofouling:** This component has a huge impact on ship resistance while its assessment is often rather difficult. Without regular inspections, the amount and location of biofouling can only guessed by the crew while in port. In the present case timely and well documented hull inspections were available which allowed to determine a fairly accurate level of hull roughness increase during the periods for which historic voyages were analyzed.
- **Representation:** The geometry of various components is not taken into account as built but as designed, causing additional uncertainty in the simulation set-ups.

There are further uncertainties which are related to the weather fore- and/or hindcast as well as in the sensors installed on board. These will be briefly addressed in the sections below.

Ideally, a through analyses of the error propagation would be undertaken. This, however, was beyond the scope of the project and is certainly beyond the scope of this paper. Still, an attempt was made to develop an appreciation of the influence of uncertainty by assuming  $\pm 5\%$  of change in calm-water resistance, independent of its origin, and  $\pm 20\%$  of change in added resistance in waves. Further investigations would be needed.

## Engine Model

The main engine model was supplied by project partner AVL and predicts the fuel oil consumption based on engine operational data as shown in Figure 14.

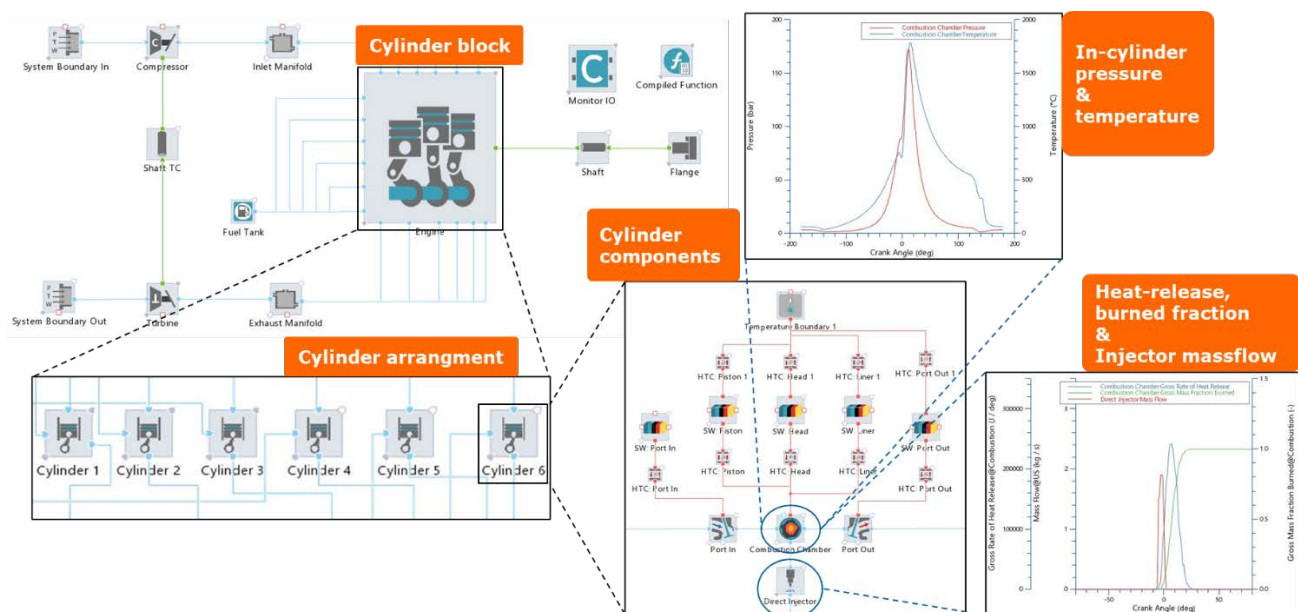

Figure 14: Detailed main engine model derived from design data

The core of the model consists of six cylinders, which in turn are divided into a combustion chamber and an integrated injector model. All geometric design parameters have already been considered in the model parameterization. The model can calculate and output both transient, i.e. time-resolved, engine variables (e.g. total engine power, fuel consumption, engine speed, etc.) and traces resolved via crank angle position (e.g. cylinder pressure curve, heat release rate, etc.). Combustion and heat release in the combustion chamber are approximated using the empirical vibe model. The calorific

value of the fuel was stored using the fuel tool integrated in the AVL CRUISE M tool and is used as the basis for calculation in combustion modeling.

The injector model receives a variable injection mass flow as a transient target value as an actuator signal and distributes the corresponding fuel quantity during the conversion between the time/crank angle domain in accordance with the stored injection profile via a working cycle. The engine shaft, which is mechanically coupled to the cylinder bank, can be operated both speed-controlled and torque-controlled. Depending on the set mode, either the applied speed or the applied torque can be applied directly as a control variable. The transient response of the motor model after the manipulated variables have been changed can be checked for plausibility using the calculated engine power, consumption, and speed. A turbocharger has been added to the main engine model, which means that charge air conditioning and energy recovery from the engine exhaust are considered in the model. A simplified representation without operating maps for the compressor and turbine was selected: the turbine component is equipped with an internal wastegate sub model, which adjusts the wastegate opening depending on the power requirement.

In addition, two auxiliary blowers were added to the main engine model. The pressure increase that the intake air experiences as it flows through the blowers is taken into account using adapted maps. These are used to maintain charge air control even at low engine loads, where the turbocharger alone cannot achieve the desired compression on the intake side. With the implementation of the turbocharger and the auxiliary fans, the gas path representation of the main engine is complete.

Due to the limited measurement data available, which does not allow a detailed comparison of the internal cylinder condition with detailed combustion curves over a working cycle, no changeover was made to a predictive combustion model with detailed, phenomenologically based parameterization. Instead, an empirical Vibe combustion model was used and its parameters were adjusted as part of the parameter variation plan so that the simulation results approximate the consumption/power and torque figures in the data sheets with sufficient accuracy. The purpose of the Vibe function is to reproduce the typical S-shaped profile of the integrated heat release of combustion engines (Stiesch, 2003). The start of combustion and the combustion duration in the cylinder were defined as load point-dependent parameters of the Vibe model. The shape factor used was also represented as a function of the load point. It was possible to achieve a high level of agreement between the simulation results and the characteristic values from the data sheets by taking the above-mentioned measures when parameterizing the Vibe model. The accuracy was examined over five stationary operating points: 25%, 50%, 75%, 100% load and then at 10% overload. Table 1 shows the resulting model reference deviation for absolute fuel consumption (FOC) and power-specific fuel consumption (BSFC). Depending on the selected operating point, the deviation ranges between 0.3% and 0.98%.

**Table 1: Deviation of the simulated fuel consumption over five reference load points**

Load Points	25	50	75	100	110
Deviation percentage FOC	0.594	0.332	0.886	0.269	0.745
Deviation percentage BSFC	0.522	0.299	0.983	0.167	0.622

## WEATHER ROUTING

### Weather Data

To evaluate the simulations – i.e. by comparison with measured data – and to perform route optimization for historical and planned routes, we need to know the physical state of the atmosphere and the ocean at the time of travel. The in-situ data from the sensors deployed on the ships are not sufficient as they do not cover all necessary variables and provide only information about the current state. Today, multiple operational forecast and reanalysis systems exist which can fill this gap. For oceanographic data we use two products, “Global Ocean Waves Analysis and Forecast” (EU Copernicus Marine Service Information (CMEMS). Marine Data Store) and “Global Ocean Physics Analysis and Forecast” (EU Copernicus Marine Service Information (CMEMS). Marine Data Store) and for atmospheric data we use the Global Forecast System (National Centers for Environmental Prediction/National Weather Service/NOAA/U.S. Department of

Commerce, 2015). The data come in different spatial and temporal resolutions. Table 2 shows an overview of those variables expected as input for our fuel consumption model.

**Table 2: Overview of the environmental variables downloaded from CMEMS and GFS**

Variable	Platform	Space	Time
Wind speed u-component <sup>1</sup>	GFS	1/4°, global	3 h, 10 days-forecast
Wind speed v-component <sup>1</sup>	GFS	1/4°, global	3 h, 10 days-forecast
Air pressure reduced to mean sea level	GFS	1/4°, global	3 h, 10 days-forecast
Air temperature at water surface	GFS	1/4°, global	3 h, 10 days-forecast
Spectral significant wave height	CMEMS	1/12°, global	3 h, -1 Y to 10 days-forecast
Wave period at spectral peak	CMEMS	1/12°, global	3 h, -1 Y to 10 days-forecast
Mean wave direction from	CMEMS	1/12°, global	3 h, -1 Y to 10 days-forecast
Total <sup>2</sup> surface sea water zonal velocity (u)	CMEMS	1/12°, global	1 h, -2 Y to 10 days-forecast
Total <sup>2</sup> surface sea water meridional velocity (v)	CMEMS	1/12°, global	1 h, -2 Y to 10 days-forecast
Sea surface salinity	CMEMS	1/12°, global	1 h, -2 Y to 10 days-forecast
Sea water potential temperature	CMEMS	1/12°, global	1 h, -2 Y to 10 days-forecast

<sup>1</sup> available at 10 m, 20 m, 30 m, 40 m, 50 m, 70 m, 100 m height above ground

<sup>2</sup> Eulerian + Waves + Tide

As the system being developed in the MariData project aims at providing decision support in real time, the focus is on actual forecast data. However, for the evaluation of the models we also need historical data. The CMEMS products include analysis data for the last 1-3 years and thus also cover the period for which we collected data on the ships. For GFS, analysis data is not available. Instead, we use the archived forecasts from the temporarily closest forecast cycle. In addition to the temporarily varying environmental data, we also use static data on water depth from the ETOPO 2022 15 Arc-Second Global Relief Model with a 30 arc second resolution (NOAA National Centers for Environmental Information).

## Routing

A variety of algorithms has been explored in the past to optimize time and/or fuel consumption during sea journeys for a given weather scenario (Walther, Rizvanolli, Wendebourg, & Jahn, 2016). Due to the large interdisciplinarity of the MariData consortium, it is not only possible to investigate the performance of individual algorithms in the project context but also to elaborate on the interplay between the respective hydrodynamic simulations for power and fuel consumption on the one hand and the weather routing tool (WRT) on the other hand. In this paper, the measured power consumptions for historical routes traveled by a CBT are compared to routes provided by the routing tool as a general proof of concept. In addition, the effect that different weights on added resistances have on the simulation of power consumption for a specific historical route as well as on the routing procedure will be investigated.

The routing algorithm which has been utilized in this paper is an ‘isofuel’ algorithm – i.e. it provides routes that are optimized for fuel consumption – based on the concept of the modified isochrone method by Hagiwara (1989). Similar to the latter, the routing is performed in individual routing steps. For every step, it is calculated how far the ship can travel in different directions with a fixed amount of fuel considering the respective weather conditions and properties of the environment. All environmental variables listed in Table 2 are considered in this process. Tides are only considered as part of the overall ocean currents. Water depth is assumed to be static based on bathymetry data. At present the ship is assumed to sail at constant speed and fore and aft draught for the full route. Adaptations will be considered in the next step. Weather conditions are considered to be constant for every individual routing step.

The optimization is achieved by grouping routes according to their courses and selecting only the route segment per group for the next routing step that maximizes the travel distance. Using this concept, a wide angular range is scanned systematically for optimal routes as it can be seen in Fig. 15. The algorithm considers constraints by landmasses and shallow water by eliminating routes that cross the latter from the optimization process. Thereby, shallow waters are defined as areas with a water depth below the sum of the ship’s draught and an under keel clearance of 20 m.

Due to the nature of the algorithm choices in an early routing step might lead to an overall worse fuel consumption later. This is partially mitigated by scanning a large number and wide range of angles and by using many groups in the

selection process thus keeping a sufficient number of segments for the subsequent routing step. In the future, it is planned to evaluate algorithms which consider always the complete route like genetic algorithms.

### Uncertainty of environmental data

Further uncertainties in the model evaluation and the route optimization are related to the environmental data. The reanalysis and forecast data used to feed the power and fuel consumption models represent average values for a coarse grid where one grid cell covers an area in the order of tens to hundreds of square kilometers and time periods from 1 to 3 hours. In contrast, a ship experiences conditions at a specific position in space and time which might vary significantly from the average values. Moreover, the reanalysis and forecast models come with their own uncertainties.

**Figure 15: Visualization of route segments at an intermediate routing step of the Isofuel algorithm for a CBT traveling in the Bay of Biscay**

## SYNTHESIS AND SHIP OPERATIONS

### Synthesis

It would be rather resource-intensive – if not prohibitively expensive – to compute the performance of a ship by means of direct simulation, i.e., by computing the behavior of all components at full-scale and bringing them into the correct balance of total resistance encountered and thrust delivered, providing the engine power and fuel oil consumption for any given speed in any environmental condition. As shown in Fig. 2 the approach taken here is to subdivide the overall system into manageable components. This follows the approach developed in HOLISHIP (Papanikolaou, 2018), and used for design synthesis. Based on (many) upfront simulations, realized via Design-of-Experiments, the various contributions are captured in surrogates that provide quantitative results within split-seconds for any condition of interest.

A python module called mariPower was implemented that connects all described surrogates for (added) resistance components and propulsion to consider every factor during the power and fuel consumption prediction. It takes loading conditions along a route specified by a discrete trajectory and ship speeds and determines the encountered weather from a forecast or hindcast for all points along the route. Then, it iterates the unknown ship motion parameters (propeller rotation rate, drift angle and rudder angle), continuously updating the surrogate model results as their inputs change. After convergence or the maximum number of iterations is reached the fuel oil consumption is estimated from the resulting engine power and rotation rate.

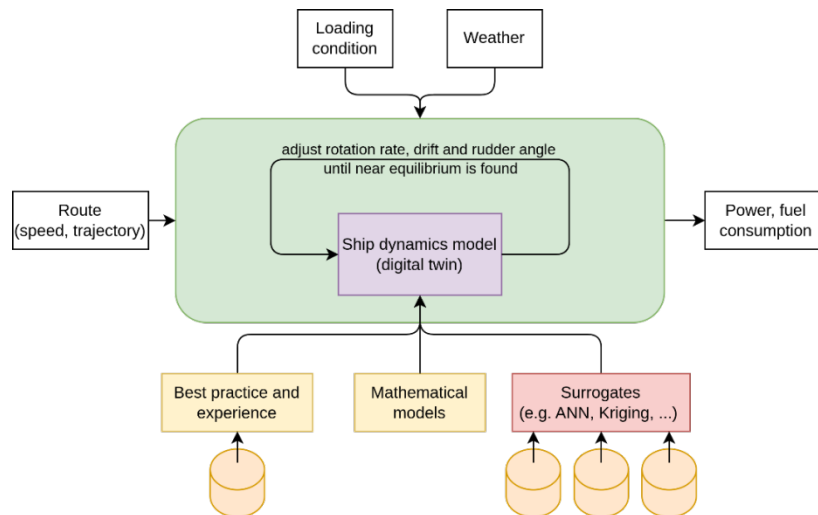

Figure 16: Process flow within mariPower

## Ship Operations via mariPower

The described module mariPower was implemented as a general framework to take into account various environmental factors in the prediction of necessary engine power. In the current state, it is able to consider additional forces due to wind, seaway, fouling and shallow water. In the latter three cases also wake fraction changes can be included. The base class in the module implements the functionality to iterate the ship and engine motion state. It updates the added forces in longitudinal and transversal direction as well as the yaw moment of all available sources iteratively and estimates a drift and rudder angle to keep its course based on maneuvering coefficients. The total required thrust and forward velocity through water are used as inputs to the propeller model which predicts the resulting rotation rate and torque. This continues until an equilibrium of longitudinal forces is found or the maximum number of iterations is reached. Its child classes allow the connection to individual user-defined surrogate models for the added forces and wake fraction changes due to each of the described environmental factors. Those only need to comply with the defined input and output parameters and units. The code uses vectorized functions where possible to increase efficiency.

## STATISTICAL ANALYSES

### Data Lake

Within the research project MariData extensive measurements of onboard data with high sampling rate were performed. Those data were used to find predominantly encountered weather conditions as well as periods where the operating conditions were steady with a certain tolerance.

For the latter, the sensor data was synchronized first and resampled to a frequency of 1Hz to ensure a shared time stamp before filtering with a minimum ship speed and several other conditions regarding draught and engine load to remove sections before and after berthing. This combined data was then separated into voyages whenever a pause of more than two hours was found. Since this could also happen due to technical issues with the sensors, the endpoints of resulting routes are not necessarily near ports of call. Each voyage data is then evaluated regarding the standard deviation on rolling windows of 30 minutes compared to an individual tolerance for each sensor. If all tolerances are met, the window is marked as steady. In a second step, the slope of this evaluation result is calculated to determine starts and ends of steady intervals. Finally, all values in between stops and starts are marked as unsteady as well as those values between starts and stops where the time difference is less than the window length. The results are then resampled to a period of one hour and enriched with hindcast weather data.

To determine the representative operating conditions used in the following chapter, histograms were calculated from the operational data and manually analyzed.

## Representative Operating Points

Two representative weather situations were picked from available operational data of seven months. For a ship speed of 6 m/s (11.7 kn) at a draft of 9.5 m on even keel the calm water case was selected having a low wind speed of 2 m/s with the rough weather case set at 12 m/s wind speed. Since no onboard wave measurements were available the seaway was approximated using a Pierson-Moskowitz spectrum for the two wind speeds (see Table 3). Water and air temperature were chosen as 293 K and the air pressure at 101350 Pa. The roughness of the hull was assumed to be hydraulically smooth in this case.

**Table 3: Wind and seaway conditions for representative operating points**

Weather	calm	rough
Wind speed	2 m/s	12 m/s
Significant wave height	0.09 m	3.25 m
Peak period	1.5 s	9 s

## INFLUENCES IN REPRESENTATIVE OPERATING POINTS

### Resistance Components

The digital twin was simulated in both weather conditions from all directions. In calm weather, the added resistance due to seaway is almost zero. The wind forces cause some yaw especially for crosswinds while the added resistance is highest for the frontal wind directions. Still, the maximum total added resistance is only around 3% of the calm water resistance. For rough weather, the added resistance due to seaway causes a drastic rise of the total added resistance, contributing 50% and more of the calm water resistance. The wind forces cause maximum drift angles of around 4° while increasing the total added resistance in head wind by another 30% to a total of 80% of the calm water resistance.

**Figure 17: Added resistance components and drift and rudder angle in calm condition (forces normalized by calm water resistance)**

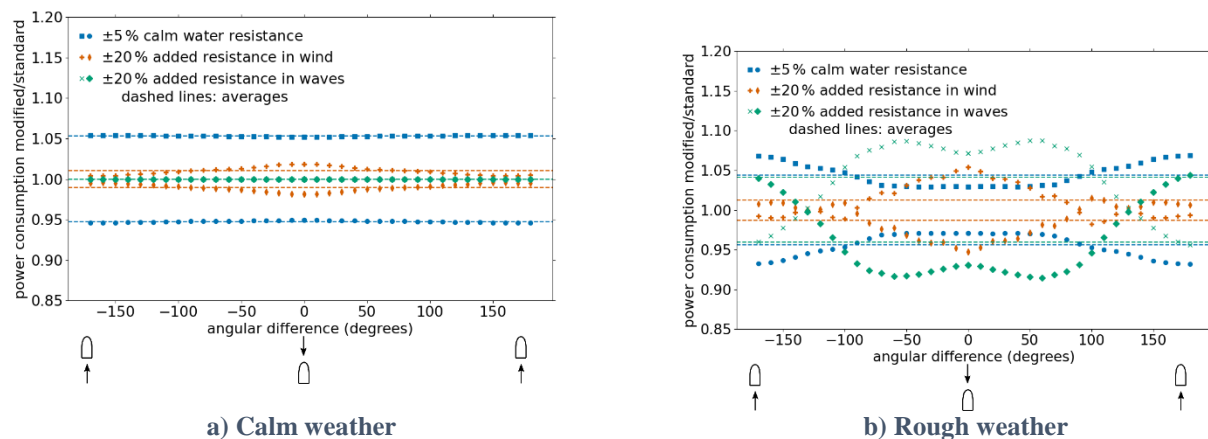

**Figure 18: Added resistance components and drift and rudder angle in rough condition (forces normalized by calm water resistance)**

## Hypothetical Variation of Resistance Components

In the following, the effect of adding weights to the calm water resistance as well as the added resistances for waves and sea state on the power consumption is investigated. By these manipulations, it is possible to mimic imperfect hydrodynamic simulations and study the respective differences of the power prediction. As in the previous paragraph, angles between wind and waves on the one hand and the ship's course on the other hand are scanned in steps of ten degrees for two weather scenarios. The ratio of the power consumption calculated for the modified resistances over the results for the original settings is visualized. The results for changing the calm water resistance by  $\pm 5\%$ , the added resistance for wind by  $\pm 20\%$  and the added resistance for waves by  $\pm 20\%$  can be seen in Figure 19.

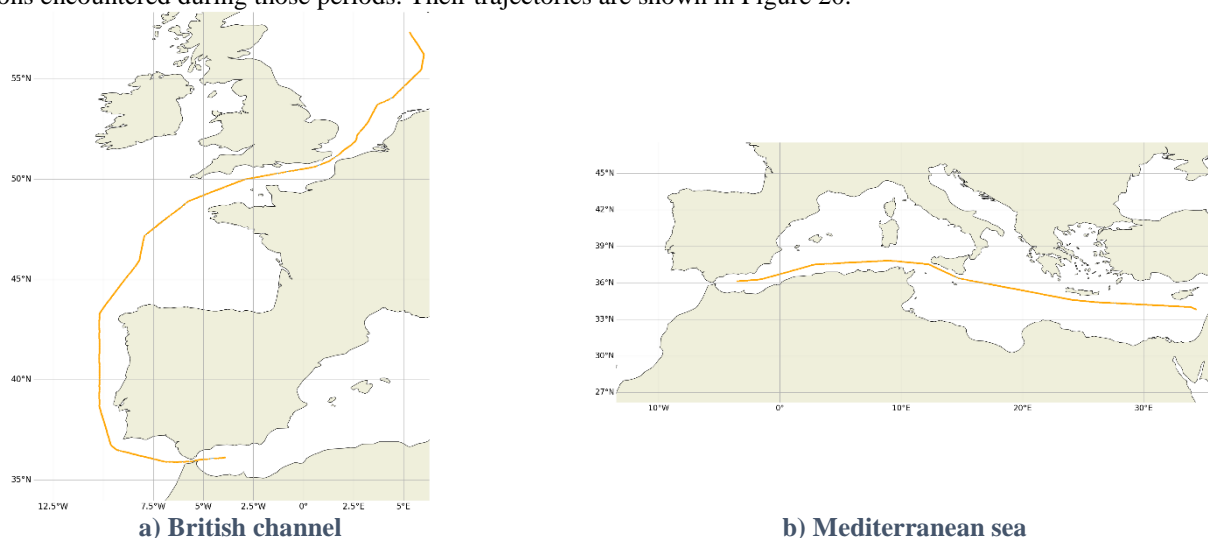

For the calm-weather scenario, the effect of the modifications for the added resistances for wind and sea state are negligible while a  $\pm 5\%$  modification of the calm-water resistance directly translates into a  $\pm 5\%$  deviation for the power consumption. For the rough-weather scenario, the effect of the modifications for the added resistances for wind and sea state are most significant if wind and waves are coming from the front. In these cases, a 10% deviation for wind and 5% deviation for waves is reached. Due to the significant contribution from the added resistances for wind and sea state in this scenario, the modifications of the calm water resistance have a smaller effect ( $\sim 3\%$ ) on the overall power consumption if wind and waves are coming from the front.

**Figure 19: The ratios for simulations of the power consumptions for manipulated resistances over those for standard settings in dependence of the angular difference between the CBT's course and the directions of winds and waves in ideal weather**

## INFLUENCES IN REAL CONDITIONS

Two routes have been selected from the analyzed operational data of one of the tankers in 2023. They were chosen based on long periods of quasi-steady ship motion and operation as well as being different regarding the severity of the weather conditions encountered during those periods. Their trajectories are shown in Figure 20.

**Figure 20: The historical routes traveled by a CBT which have been selected for investigations on the simulated power consumption in real weather conditions**

## Comparison of Operations and Simulations

When comparing predicted and measured engine power in Figure 21 the surrogate models clearly are able to predict the power with a certain error (RMS error across all routes in 2023 was 6.5%). Correlation coefficients showed that the main cause for the apparent fluctuations in the predicted power between all input parameters was the speed through water with a correlation coefficient of -0.657. The measured propeller pitch was usually above 98%, so the error due to predicting the propeller operating point for the maximum pitch only is assumed to introduce little error. Since the response surfaces of all surrogate models shown in previous chapters are continuous, we suspect the measured speed through water or the engine power to have some kind of measurement error.

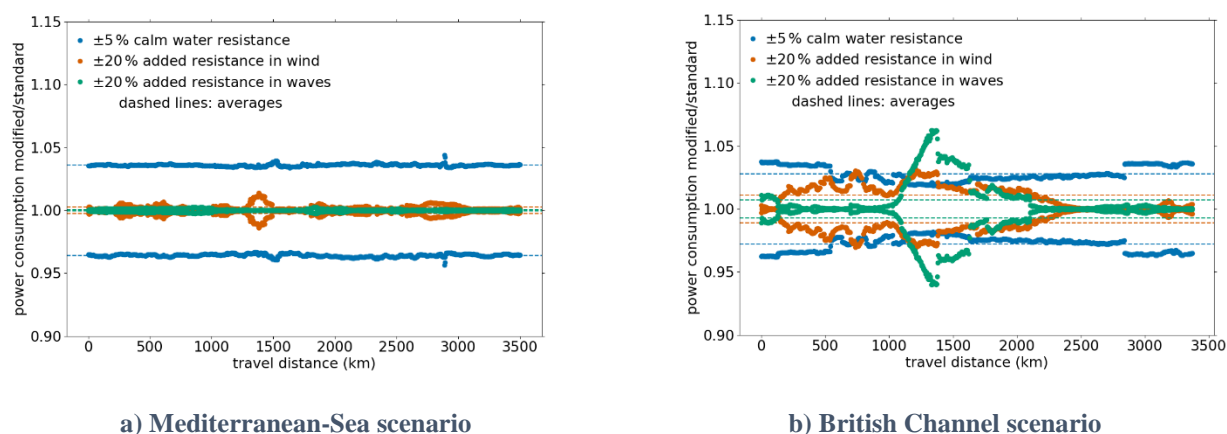

**Figure 21: Predicted and measured engine power along “Mediterranean sea” route**

## Hypothetical Variation of Resistance Components

To investigate the effect of manipulated resistances on realistic routes, the power consumption has been simulated for historical routes traveled by a CBT under real weather conditions. In addition to the simulations for the standard settings, the calm water resistance as well as the added resistances in wind and waves have been varied by the same values as for the previous investigations for the representative operating points. The routes that have been selected pass the Mediterranean Sea as shown in Figure 20a and the British Channel as shown in Figure 20b. While the weather conditions

are mild in the Mediterranean Sea, the route through the British Channel traverses a low-pressure region roughly at the middle of the full travel distance.

The results for both routes are provided in Figure 22. It can be found that for the rough weather conditions in the British-Channel scenario, the modifications of the added resistances for wind and waves have a more significant effect than for the calmer conditions in the Mediterranean-Sea scenario. In contrast, the effects of the manipulations of the calm water resistance are more significant in the Mediterranean-Sea scenario than in the British-Channel scenario.

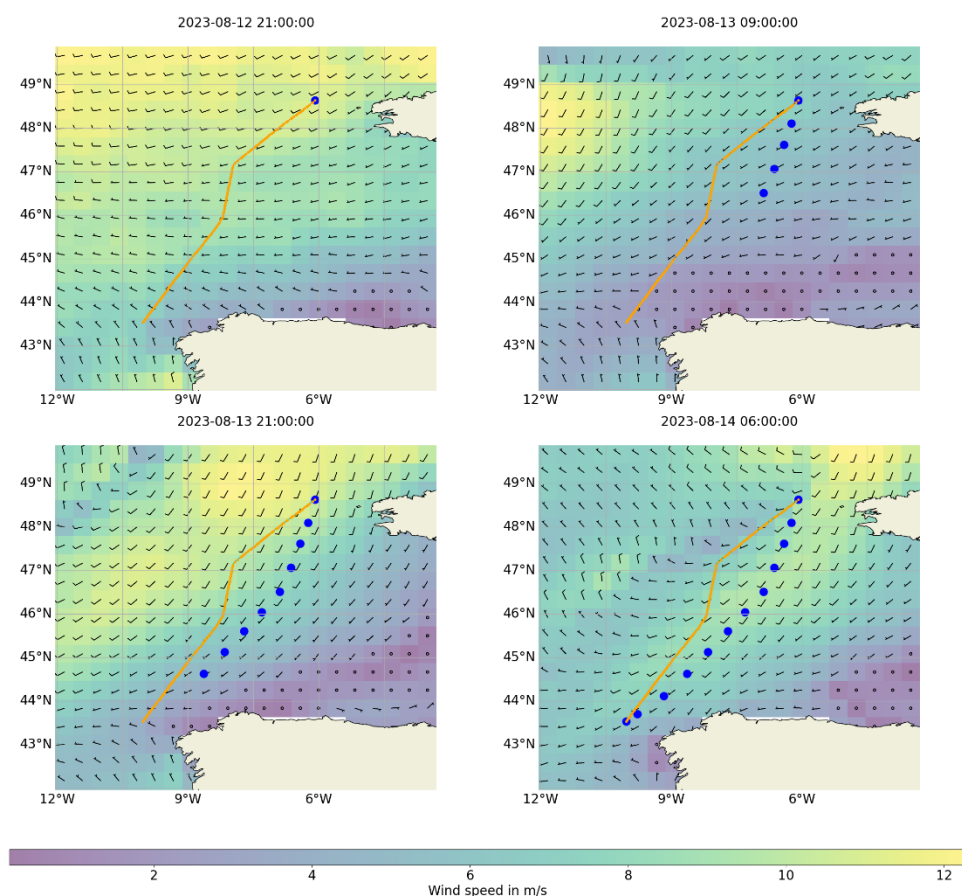

**Figure 22: The ratios for simulations of the power consumption for manipulated resistances over those for standard settings in dependence of the travel distance for historical routes traveled by the CBT**

## Routing in Actual Weather

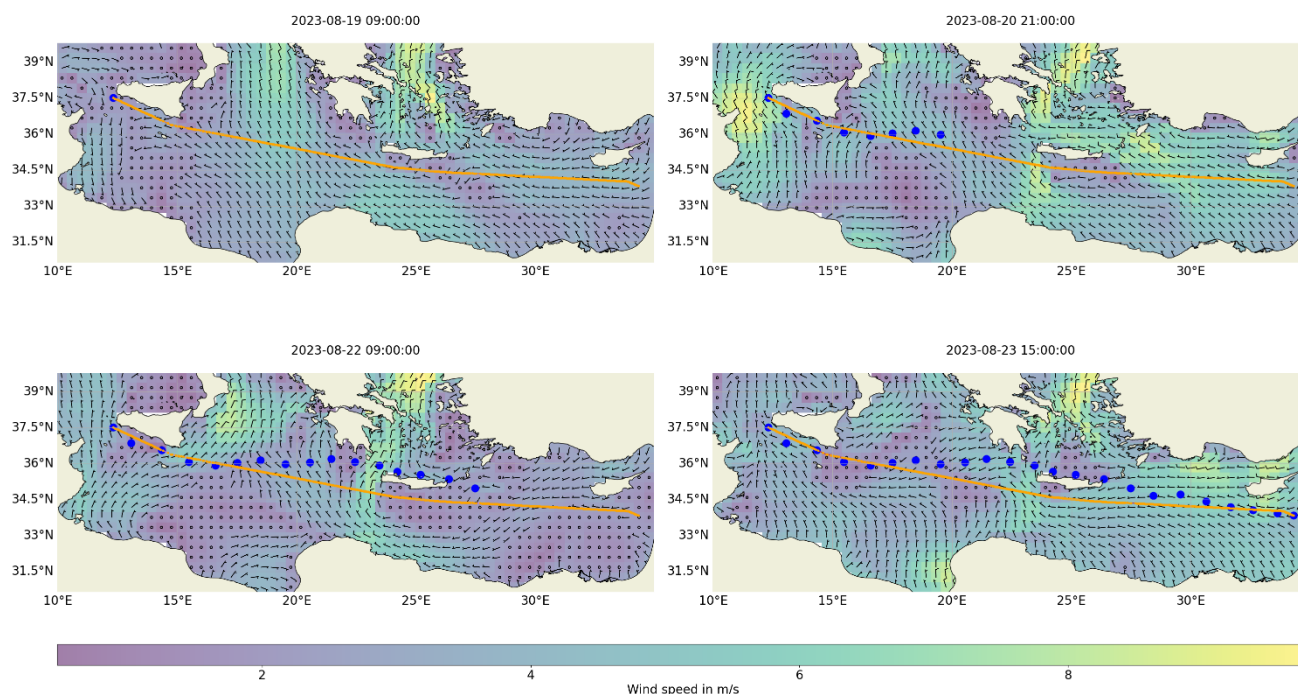

In this section, it shall be demonstrated that the WRT of the MariData DSS provides alternatives to historical routes that reduce the overall fuel consumption. In addition, the effect of manipulations of the resistances on the routing procedure will be elaborated.

Naturally, the effect of the routing will be most significant in regions where restrictions like water separation zones or danger areas are rare. This is why two segments from the Mediterranean and the British-Channel scenario that meet these conditions have been selected for the investigations. The corresponding areas are displayed in Figure 23 and Figure 24 and shall be referred to as the Biscay and the Crete scenario.

For the routing procedure, the constant speed of the tanker is set to the average speed of the historical route. The inputs for fore and aft draught are averaged over the full historical route. In addition, the settings for the hull roughness are adapted to those which were found to describe the measured power consumption best (see Sec. 21).

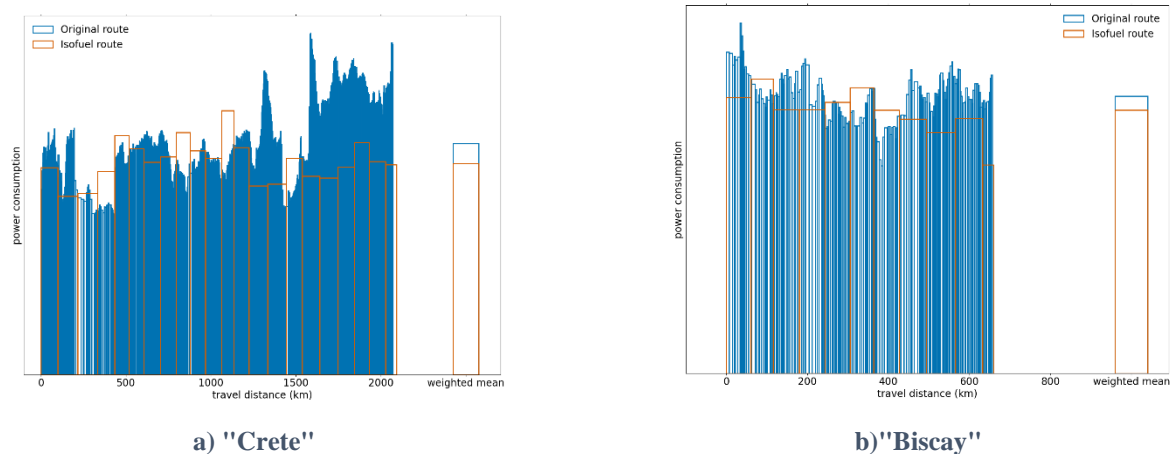

**Figure 23: Trajectories of reference (orange) and optimized (blue) routes in the Biscay scenario for four snapshots. The background map shows wind speed and wind direction as heat map and wind barbs.**

**Figure 24: Trajectories of reference (orange) and optimized (blue) routes in the Crete scenario for four snapshots. The background map shows wind speed and wind direction as heat map and wind barbs.**

The alternative routes for both scenarios are compared to the historical routes in Figure 23 and Figure 24. The differences between the historical routes and the routes from the WRT are significant. In the Biscay scenario, the WRT tanker travels

farther east than the historical route and in the Crete scenario, the WRT tanker passes by Crete on the northern side, while the historical CBT is traveling on the southern side. Looking at the corresponding weather conditions, these differences are plausible as in both scenarios, the wind speed and wave heights are more suitable for the routes selected by the WRT. In particular, both wind speed and wave heights are decreasing from west to east in the Biscay scenario making routes that reach farther to the east more fuel-efficient. In the case of the Crete scenario, the WRT tanker traveling on the northern side of Crete experiences stronger tail wind than the original CBT tanker traveling on the southern side.

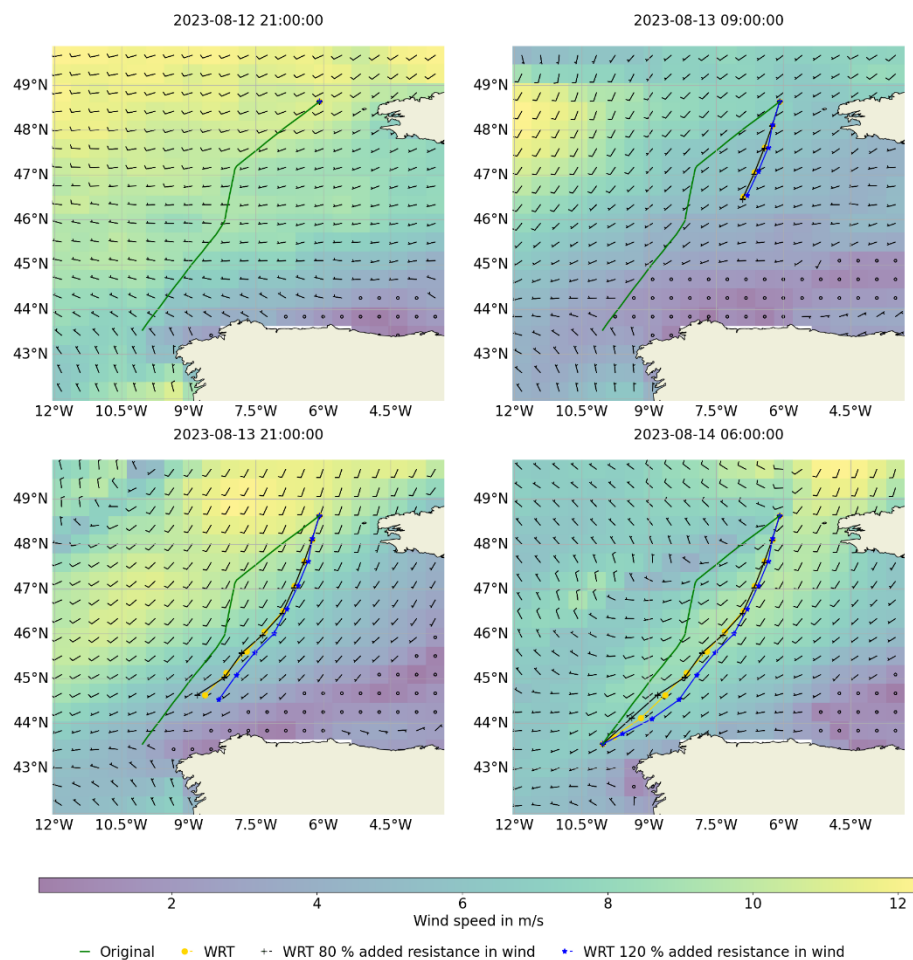

**Figure 25: Power consumption of reference and optimized routes in two scenarios**

Figure 25a and Figure 25b compare the resulting power consumptions for the historical and the WRT routes. For both scenarios, a smaller mean power consumption can be observed for the WRT routes which, in particular, results from a significantly smaller power consumption towards the end of both routes. Considering the absolute values and differences with respect to the historical route for travel time, travel distance and fuel consumption provided in Table 4 and Table 5, the WRT routes tend to be slightly longer, they reach the destination in roughly the same travel time (differences are smaller than an hour) and they spare about 8.7 % (Crete scenario) and 6.4 % (Biscay scenario) of the total amount of fuel that has been consumed for the historical routes.

Similar to the previous sections we investigate how a variation of individual resistances influences the routing process. We selected only the Biscay scenario as the effects are more significant here due to rougher weather. Figure 26 shows how the proposed routes differ geographically for variations of added resistance in wind. Table 4 and Table 5 summarize the key characteristics of travel distance and time and accumulated fuel consumption for both routes. Here, also values for variations of added resistance in waves and calm water resistance are included.

Generally, it can be observed that with a higher resistance ships can travel less far in each routing step and vice versa for lower resistances. Higher and lower resistances also naturally result in a different accumulated fuel consumption along a given track. However, the optimized routes also tend to travel in different areas to the originally proposed route without variation. If the added resistance in wind is 20 % higher, the ship can save fuel by traveling farther in the east where wind speeds decrease. For the last few waypoints, the opposite effect can also be observed when resistance is 20 % smaller. The specific behavior of the routing algorithm depends on a multitude of factors, so one has to be cautious with drawing specific conclusions from the given examples. In particular, the temporal evolution of the weather conditions can smear definite effects by the resistance variations. As a general conclusion, varying resistance components can not only change the overall consumption but also the track proposed by a routing optimization tool itself.

**Figure 26: Trajectories of optimal routes found by varying the added resistance in wind by +-20 %**

**Table 4: Key characteristics of the routes in the Crete scenario**

Route	Fuel consumption difference	Travel distance	Travel distance difference	Travel time	Travel time difference
Original	-	2071 km	-	4 days, 03:14:36	-
WRT	8.7 % less	2092 km	21 km (1.0 %) more	4 days, 04:10:15	00:55:39 (0.9 %) more

**Table 5: Key characteristics of the routes in the Biscay scenario**

Route	Fuel consumption difference	Travel distance	Travel distance difference	Travel time	Travel time difference
Original	-	657 km	-	1 day, 7:35:23	-
WRT	6.4 % less	660 km	3 km (0.5 %) more	1 day, 7:35:07	00:00:16 (0.0 %) less
WRT (120% Wind)	4.6 % less	670 km	13 km (2.0 %) more	1 day, 8:06:09	00:30:46 (1.6 %) more
WRT (80% Wind)	10.1 % less	660 km	3 km (0.5 %) more	1 day, 7:37:31	00:02:08 (0.1 %) more
WRT (120% Wave)	4.1 % less	661 km	4 km (0.6 %) more	1 day, 7:38:53	00:03:30 (0.2 %) more
WRT (80% Wave)	10.5 % less	659 km	2 km (0.3 %) more	1 day, 7:33:57	00:01:26 (0.1 %) less
WRT (105% Calm)	3.4 % less	661 km	4 km (0.6 %) more	1 day, 7:38:16	00:02:53 (0.2 %) more
WRT (95% Calm)	11.3 %	665 km	8 km (1.2 %) more	1 day, 7:49:58	00:14:35 (0.8 %) more

## NAVIGATIONAL SUPPORT

Defining the relevant operational points is critical for custom-tailored ship design as currently practiced. According to our research, there is a high variance in how these operational points are defined. Making a digital twin of the prototype available at design time, we want to engage in a discourse on the differentiation of an optimization project or making compromises transparent and discussable at the design stage. The role of virtual prototyping (VP) and related concepts in ship design has been identified as crucial in the highly individualized field of ship design, with even sister ships having significant design variations (Hassani, et al., 2016). Effective VP requires an interdisciplinary effort, covering hydrodynamics, machinery and power systems, structural engineering, navigation, and control. Current contributions in the field focus on methodological innovation in the design processes (Dodero, Bertagna, Braidotti, Marinò, & Bucci, 2022), the discourse on Human-Centered Digital Twins (Preuss, et al., 2023), and review the “clean” integration of Digital Twins (DT) in Marine Engineering (Mauro & Kana, 2023) or industry in general (Sharma, Kosasih, Zhang, Brintrup, & Calinescu, 2022). This paper aims to contribute to and expand upon the framework relating virtual Prototyping/Digital Twins and Ship Design.

Our goal is to provide early-stage information to operators on how a ship might behave in future scenarios and inform ship design by how operators will actually conduct the vessel—and in which typical range of environmental conditions. On one hand, we used this constant comparison of virtual ship operation and actual journeys to inform and validate model construction. On the other hand, having the DTs and actual environmental data available during design-time enables designers and operators to compare the performance of design variants, including current ships, all performing under the same conditions. In this project, we derived actual typical operational points from previous journeys, combined them with actual trips and environmental conditions encountered, and enabled operators to drive the digital representations of existing ships and prototypes in a highly realistic ship simulator in identical conditions, e.g., actual weather data. Repeated with design variants, this enables a much more detailed look into, e.g., added resistance (e.g., wind, wave and even hull fouling effects), resulting in requirements analysis of unprecedented depth, matching the custom-tailored approach to carrier vessel design aimed for today to ensure peak energy efficiency.

Ship design is always a compromise. Designers today already account for added resistance, but can seldom base calculations on detailed data of, e.g., how often a ship will actually face specific conditions. In this project, a broad parameter space is explored, including the analysis of a crew’s decision-making between avoiding and confronting weather situations in simulator runs where, on historical routes with actual weather data, and equipped with a next generation energy efficient operational decision support system developed in this project, future operators determine the sweet spots informing design decisions. Gathering these data during design time enables addressing operational aspects

during simulations (e.g., prioritizing cargo space upfront in the ship, even if it negatively impacts seakeeping resistance). Additionally, our system allows for the detailed exploration of future propulsion systems, such as diesel-electric drives, with the ability to connect multiple engines to an electrical power supply, and its design implications, when existing ships on established routes are to be replaced.

Supporting this virtual prototyping and test-driving, a novel Onboard-Decision Support System (DSS) for navigational and operational support was designed and implemented (Schwarz, et al., 2023), enabling differentiated control over route optimization processes. A novel module allows for the inspection of simulation data quality (i.e., uncertainties), pertaining to chart accuracy, up-to-date weather, and model fitness for the current operational point, among others. This digital-twin powered tool also enables logging and evaluating user actions (Zoubir, et al., 2023), again driving the optimization process in the ship design phase. Factors considered in the DSS include Requested Time of Arrival as multiple distinct windows (i.e., encouraging slow steaming to match external conditions in tide waters, ship lock operational times or port arrival time frames), CO<sub>2</sub>e emissions, and energy efficiency, enabling the analysis of crew decisions in specific contexts. The DSS hereby interacts with the DT for route optimization, realistic simulation, and simultaneously feeds and optimizes the DT. Insofar, the DSS functions as both a research vessel and an outcome.

## FEEDBACK FOR DESIGN

Ship operational patterns have changed drastically over the past decades. On the one hand enhanced digital systems on board support the crew in operating the vessels leading to a large amount of data which are often only used for optimizing part of the operation. Often based on purely data driven and machine learning algorithms these are also prone to errors resulting from erroneous data collection and sensors if not properly validated. On the other hand, vessels are – still – often designed for a limited range of operational conditions while in practice they encounter all conceivable conditions during their life-cycle often not considered during the early stages of vessel design. This is often due to the fact that a number of operational constraints are not known a priori and may change over time. This may have economic, environmental or even political reasons which are barely predictable at the beginning of a 25 + years lifecycle of a new ship. Present striking examples being the situations around the two major canals, Suez and Panama which call for significant changes of operational patterns, due to different causes but having similar effects. A digital twin in turn which uses all available information from design stages onwards helps to optimize operations and provides valuable feedback to ship design in that collected data will both improve the quality of design data and will form the basis for more holistic considerations of future designs.

During design, predictions of operational and environmental performance are traditionally based on a forecasted, limited range of environmental conditions. Due to limited resources, a design team always needs to decide where to put a focus and hence resources for further improvements and where an existing solution would be sufficient. Similarly, it is important to understand if an improvement at design stage will actually show during operations and to which extent. In

the present example for a medium-size tanker all components which contribute to resistance at representative trim and draft conditions and in specific weather conditions so as to maintain certain speeds were studied. The composition of total resistance followed the classic approach in naval architecture of superposing calm-water resistance, added resistance in waves, wind resistance, resistance due to fouling, resistance when sailing with (small) yaw angles at non-zero rudder angles while keeping the course and, finally, resistance increases in shallow and/or restricted waters. It was generally assumed that secondary influences are negligible, for instance, that mean wind resistance does not change with ship motions in heavy seas. Furthermore, added drag due to openings such as bow thrusters, sea chests, sacrificial anodes, potential asymmetries from production etc. were not accounted for.

There are several findings that this study suggests, some of which are not surprising while others may indicate that further attention should be given in the future:

- Calm-water resistance, unsurprisingly, is the governing component. A decrease or increase of resistance yields similar improvements or drawbacks, respectively, provided the propulsive efficiency is not determinately affected. At least for the tanker design at hand and for the routes considered any improvement – independent of where it comes from – leads to reductions in fuel oil consumption to almost the same extent.
- The increase of resistance due to hull and propeller fouling has very tangible effects. While maintaining good conditions is controlled by the operator the design team may be able to contribute to the ease of cleaning the wetted surface.
- Wind resistance turns out to be a component that deserves more attention. Even though air is considerably less dense than water (factor around 800) the air resistance is non-negligible and should be considered when designing superstructures for higher energy-efficiency.
- Added resistance in waves naturally also contributes to overall resistance. However, tangible increases lead to less severe drawbacks in fuel oil consumption and, vice versa, tangible decreases – while being hard to realize when keeping the main dimensions constant – also do not show considerable effects.

While these findings are based on the current example it is evident that the concept of a design based Digital Twin for energy efficient operation can yield equivalent conclusions also for other ships and ship types. Using the complete design information collected in the surrogate models introduced in the Resistance chapter, the Digital Twin allows analyzing the effect of any special focus in form of a “What if?” analysis once weighted changes to either factor influencing the performance are introduced. This feedback will allow designers to more efficiently decide on the focus for further improvements. In the future this will particularly apply to so-called green ships, for which the use of alternative fuels or energy sources (e.g. wind propulsion) introduces additional constraints not addressed in traditional design processes.

## CONCLUSIONS

The MariData project developed a simulation based digital twin for improved energy management of ships, based on available design information which was further enhanced using the same concepts as during design to cover the broader range of operational conditions encountered during the life-cycle so far. As an example, a medium sized tanker was investigated in a white-box approach for its major resistance components and its propulsion system, comprising the propeller, the rudder and the main engine. All components were simulated with appropriate and validated numerical methods for large sets of representative conditions. The data were captured in dedicated surrogates equivalent to those already applied during design optimization for a fast and repetitive look-up. Subsequently, a simulation tool was established that takes environmental conditions – wind, waves, currents and bathymetry – along with the ship’s loading – draft and trim – into account and computes the fuel-oil consumption for any given speed. Uncertainties in each of the modelling and simulation steps have been considered, This allows running routing optimizations in which all important contributors are considered. For each leg along a certain route the simulation tool thus determines the expected FOC.

Comparing onboard measurements for several routes, primarily along Europe’s Atlantic coast and in the Mediterranean, with the white-box simulations fed with the weather and bathymetry encountered and the speed (through water and over ground) measured on the ship has shown realistic accuracy. Nevertheless, some erratic differences which are visible when comparing simulated and measured engine power could not be resolved yet. The question whether these relate to the reliability of acquired sensor data from onboard measurements needs to be solved in the final phase of the project. An uncertainty is also introduced in the comparison of simulations as local weather phenomena could still have been slightly different to the hindcasts interpolated from the European weather grid. The surrogates which represent the digital twin of the ship are smooth and, therefore, cannot be held responsible for higher frequency variations of the solution. While the simulations may not always yield results that are accurate in absolute terms, they indicate clear tendencies. Looking at the relative FOC for various routes gives confidence that the major elements which determine overall energy consumption were well captured. The system combining weather routing and FOC was further utilized to check sensitivities regarding hypothetical changes of various resistance components. Those changes are representative of two scenarios: (i) What should a design team focus on when spending resources on improving a ship and (ii) which components need to be captured accurately to yield reliable suggestions for safe, economic and environmentally friendly routes. To this end,

hypothetical changes to three resistance components were undertaken: (i) What if calm-water resistance, i.e., the lion's share of resistance, could be improved by 5% and vice versa. This is typical of many hull form optimization campaigns that often yield three to seven percent of improvements over good baselines. (ii) What if added resistance in waves is under- or overestimated by 20%. Of course, added resistance in waves cannot be influenced so easily at the design stage, save for modifying main dimensions which, however, are often more or less fixed. Yet, for routing, unless a rather high-fidelity seakeeping code is employed, the accuracy of the predictions, at least in many routing routines, might only be within that range, see Harries et al. (2023). (iii) What if the estimate for wind resistance is  $\pm 20\%$ , wind resistance not being considered often at the design stage with more than reasonable estimates.

As expected, though not often shown, changes in calm-water resistance are fully apparent, i.e., any improvement leads to a reduction in energy consumption of almost the same amount. Added resistance in waves and wind resistance often being substantially smaller than calm-water resistance do not influence the FOC to the same extent. Yet, they affect the optimal route by avoiding detrimental and by taking advantage of favorable conditions. Therefore, it appears questionable if a routing algorithm can produce reliable predictions for energy savings if the underlying models are too simple, e.g., if calm-water resistance is merely taken from series data via the input of a handful of main dimensions, see Harries et al. (2022) for additional discussion.

Consequently, for design work it seems fair to still focus on calm-water performance as has been done in the past. However, aerodynamics should no longer be simply estimated. While this might be obvious for ships that should be retrofitted with wind-assisted propulsion systems (WASPs) or new buildings that shall benefit from WASPs from the start this may well be worthwhile to consider for ships in service and for new buildings, especially in view of retro-fit options which can offer reductions in aerodynamic resistance for a range of vessels (Voß & Marzi, 2020).

While here a white-box model for the simulation of FOC was used it should not be forgotten that there are black-box models, too. They are trained on data measured onboard a ship over considerable periods of time without building on any physics-based simulations or using low fidelity models. Black-box models may potentially be more accurate regarding actual FOC, in particular when applying machine learning on large data sets. However, from black box models it is likely more difficult to understand which components contribute how much to the overall performance, making them less valuable for designers. In the future, a hybrid approach may show benefits, i.e., as suggested in the synthesis model presented here, see Fig. 2, the major contributors are determined from a white-box while deviations could be captured from a black-box. This, however, is subject to additional research. Based on the experience made here, one should be cautious with data from onboard measurements. They should not be used without supervision and intelligent filtering.

Naturally, it needs to be kept in mind that the study presented here only covers a single ship. It stands to reason, however, that similar influences could be seen for other ships. For smaller ships, for instance, the effect of added resistance in waves might be more important since they experience larger motions. For ships with sizeable loads on and above deck, meanwhile, the impact of wind resistance might have greater importance. Additional work is needed to quantify which components show an especially strong influence on both energy consumption as considered at the design stage and routing recommendations as made for efficient ship operation.

# Industry 5.0: Transforming ship design through human-centered approach

Ludmila Seppälä<sup>1,\*</sup>

## ABSTRACT

*Industry 5.0 heralds a paradigm shift by reinstating the significance of human centricity alongside technology. Incorporating human collaboration into the design methodology aligns with general project management methodology and addresses the imperative of facilitating sustainable goals in the industry. Focusing on human skills and aspirations offers a viable path to expedite the adoption of new technology into the mainstream, aligning with the evolving needs of the shipbuilding industry and green targets of society development. The article delves into the implications of the Shipbuilding 5.0 paradigm to design process and methodology, the potential changes it brings, and the potential benefits it can offer to the evolution of the shipbuilding industry.*

## KEYWORDS

Shipbuilding 5.0; Human aspects of technology; Digital transformation; Design methodology

## INTRODUCTION

The ship design process is often perceived as a primary engineering discipline focused on functionality. There are numerous methodologies and approaches to managing and organizing this process and many forums where such topics are discussed. A recently introduced concept to the shipbuilding world is Industry 5.0. Initially developed by the EU (European Union Publications, 2021), it takes the previous idea of Industry 4.0 to the next level. The levels of the Industrial Revolution are conceptual simplifications capturing the core changes in the social-technology landscapes and related processes understanding. These levels should not be interpreted as an assessment of the technology use, readiness, or advancement in digitalization, as these only indicate the industry's transformation stage and a conceptual framework.

Changes described in Industry 5.0 can be reflected in the evolution of the shipbuilding industry and ship design process. This article explores what changes in ship design can be expected in the context of Industry 5.0. It starts by providing an overview of the Industrial Revolution concepts focusing on ship design and shipbuilding, identifying impact areas, examining each area in detail, and offering a framework approach for considering the human-centricity perspective.

## SHIP DESIGN METHODOLOGIES AND HUMAN CENTRICITY

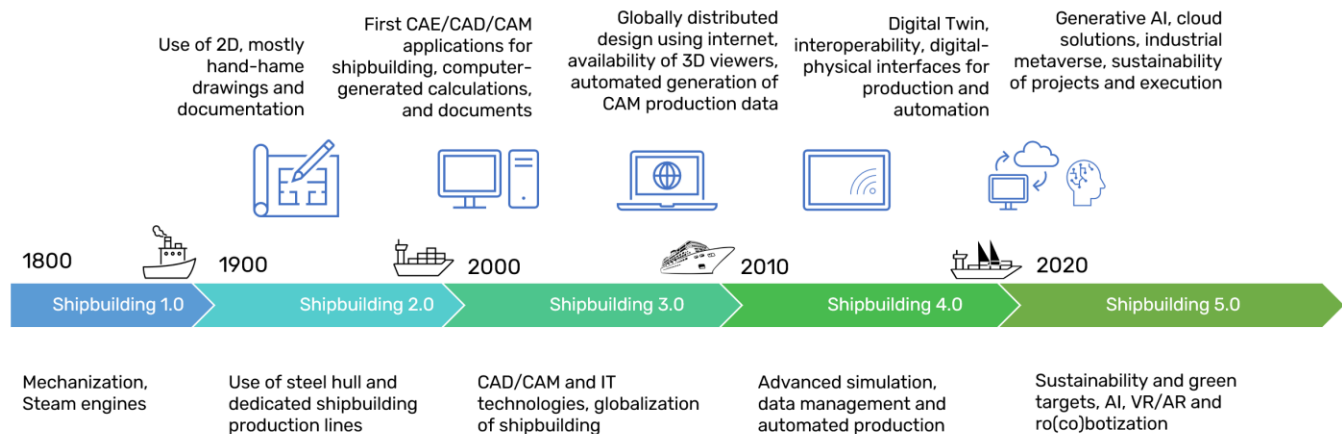

The slow evolution of the ship design activities and methodology development reflects the society and technology development process. Figure 1 presents a very simplified version of the main changes in shipbuilding, primarily triggered by industrial evolution. From sailing ships to steam engines and steel hulls, these changes directly impacted the designs and purposes of vessels. It enabled longer sailing routes and larger cargo holds, and it is impossible to say what the cause and the reasons were

---

<sup>1</sup> CADMATIC, Turku, Finland

\* Ludmila.seppala@cadmatic.com

- the desire for stronger vessels or the enablement of longer sailing due to more reliable ships. Later, CAE/CAD/CAM technology enabled more complexity and opened the doors to robotized production processes. This process is still ongoing; however, hardly any ship design is performed without the involvement of IT technology. Now, we witness the next leap forward with data management systems, advanced simulation, and a human-centricity finding its space in the IT technology serving shipbuilding. The latest stage of evolution, Shipbuilding 5.0, is expected to focus on placing human needs and capabilities at the heart of intelligent IT to take cyber-physical systems to the next level.

**Figure 1: Evolution of concepts towards Industry/Shipbuilding 5.0 and main driving forces behind the concept levels and ship design technology.**

For the ship design process, these steps can be described as a change from manually made design to technology-creating design based on human input. Only 30 years ago, it was a mainstream practice to do calculations and prepare all documentation using pen and paper or a calculating machine at best. Some 20 years ago, the first applications for engineering calculations were employed for ship design. At about the same time, the first CAD application provided the possibility to create a digital model and 3D model to evaluate engineering decisions and generate semi-automated output. There are technical possibilities to present the design model in Virtual Reality (VR), use simulation to assess hull forms and propulsion alternatives, and involve any expert anywhere in the world in the design process. These are undeniable advancements of the change that affected the ship design process due to technology and societal evolution. Industry 4.0 emphasizes a connection between digital models and physical products, while Industry 5.0 adds a human-digital-physical layer of complexity. Considering the latest stage, Shipbuilding 5.0, expectations are high with generative AI applications popping up in all areas, the industrial metaverse making its first steps into the industry, and co-bots and robots being employed in many shipyards for various tasks. What makes it unique is its overall focus on sustainability and resilience. It can be expected that the ship design process will be affected by these changes, and the following sections outline some of them.

## AREAS OF SHIP DESIGN WHERE HUMAN-CENTRIC APPROACH CAN INFLICT CHANGES

The primary goals of shipbuilding lay in large-scale transportation, with various goals in rivers, sea, and ocean exploration. There are numerous purposes for waterborne transportation and human activities on and underwater. These goals are often substituted in ship design with derived imperatives, such as "delivering value for owners and operators" and ensuring the safety of operations. We must return to the origin and address the initial question - why does society need waterborne transportation and exploration of the rivers, seas, and oceans? While the response to these questions might be obvious, the presentation of the question in this form opens the core of the Industry 5.0 concept, placing human intentions and interests at the core of all processes. Focusing on the core of the initial reason provides a key to evaluating how to fulfill the request. This way, the discussion is taken from the context of shareholders, such as the owner or operator perspective, into a more comprehensive background of stakeholders, such as society goals, regional differences in communities, and people who will operate and use the vessels. This is a primary shift towards human-centricity, which should be performed before functional requirements.

The shipbuilding industry is different from other transportation industries. There are many explanations for this, ranging from the narrow specific expertise required for naval architecture to the complexity of projects closer in scale to onshore production facilities, such as power plants. Additional differences can be found in the methodology approach - product versus project. While most similar industries refer to the end product as a product and hence apply product design and management

methodology, shipbuilding often refers to vessels as projects. It is even sometimes said that shipbuilding projects are similar to the R&D process. However, there is no mainstream discussion about applying methodologies from the R&D approach, such as software development, to ship design processes. As a separate industry focusing mainly on shipbuilding-specific needs, there is little cross-dissemination with other industries and practices. On one side, this helps to facilitate a significant amount of complexity and stay in one direction, but on the other hand, this deprives shipbuilding of experiences in similar industries and technologies, as well as general management practices.

To summarise, ship design has the following differentiators: rapid advancement to the functional approach, lack of connotation with other industries, and approaches to design. The next part presents a more detailed discussion about the areas with the most potential to evolve under the concept of Shipbuilding 5.0.

### **Change of focus from shareholders to stakeholders**

The purpose of building vessels should primarily focus on the intention of its use and, consequentially, on human intention. Therefore, decisions made during the design stage should be verified against the design's intended purpose. One might say that ship technical specifications outline all these intentions and purposes, and indeed, this is the expected flow of information—the ship owner would describe in a relatively detailed manner the main expectations and limitations for the future vessel. Ideally, it should incorporate the expectations of people who need to "keep vessel at seas" and those who "need to make it functional" onboard. However, the technical specifications are often copied from previous vessels and projects, and requirements are significantly affected by personal preferences or beliefs. It is a very human way, but unfortunately, such misconceptions placed in the first steps of the design process significantly affect the later stages.

Two examples of the early identification of the end user need tackled early in the process are twin x-stern by Ulstein and double-acting technology (DAT) by Wärtsilä. In both cases, identification of the primary intentions of the vessels and expected operations in the early stages led to an entirely new design. In the case of Twin X-stern, a step away from traditional thinking with one stern, they proved maximum maneuverability and fuel savings, especially for offshore operations requiring a ship to remain in position in rough weather (Ulstein, 2021). In the case of DAT, the new design was identified during tests, leading to a whole new class of designs optimized for bow performance in open water and stern designed to break the ice (Warsila, 2024). Another similar example is a barge and pusher or puller combination, initially created to address the challenges of inland shipping and insurance requirements for unmanned vessels. Instead of having a manned vessel, having an unmanned barge and a pusher tug operating alongside is a more economically feasible solution.

The examples illustrate how addressing human centricity at the very early stages of the design can change the course of the design process and challenge standard practices or intentions to reuse previous project practices. Changing the focus from the shareholders' perspective of the ship owner to stakeholders of the future vessel, such as the primary purpose of the new-build project, its goals, and expectations, might significantly affect the design outcome and the later design stages.

### **Future use of ships and how to address unknowns**

A typical lifespan of commercial vessels is about 20 years, and the navy fleet might be extended to 30 or more years. This means that many unknown and unpredictable factors exist when defining the main characteristics of future designs. Such concerns are repeatedly addressed in the methodology research, and a comprehensive overview is presented in IMDC 2022 (Erikstad, 2022). The questions brought to the discussion are uncertainty when designing for the future and the needed flexibility to meet this uncertainty. Some industry design companies experience the same concerns and look for a methodology to tackle these design aspects (Yrjänäinen, 2023). The approach proposed revolves around a typical engineering approach – to account for the changing factors, such as technologies, regulations, and environmental changes, and integrate these into the operational scenarios accounted for in the design. This approach is propagated to the simulation of operations, and while being a viable alternative, it exercises a linear approach to a complex design problem. One may argue that similar problems are addressed in variant management for a typical PLM approach and scenario-building technique in general and strategic management.

A possible approach to tackling this area would be to employ one or several approaches from other fields of study or industries. The shipbuilding industry often dismisses experience from other fields as distinctively different from its own. However, there might be a suitable methodology for approaching complex projects with high uncertainty levels and multi-stakeholders. This approach can be taken from general project management, where many similar or even more complex organizational, process, and methodology issues are actively researched and tested in industrial settings. A more specific methodology, such as agile development principles (Rigby, 2016), can be adopted, similar to the design spiral approach in an iterative nature of incremental development to handle complexity and uncertainty. Considering the ship design project from a typical research and

development perspective, the process outcome changes along the project's progress, and external factors may significantly change the scope and outcome.

Systems thinking (Forrester, 1961) (Ford, 2009) offers yet another way to look at ship design methodology. Currently, it is often applied in a way that limits the scope of functional systems of the ship and system architecture. A broader perspective can be taken to look at a future vessel as a part of the system of stakeholders, such as owner, operator, transportation, or research systems - as a part of the system of shipyards, suppliers network, technology providers, etc. It can offer a more holistic view of design and address human centricity in a large context, leading to innovations, sustainable factors accounted for early, and greater flexibility compared to a standard approach, which gets into the specifics of functional design very early.

An additional way of tackling uncertainty would be to employ futures studies methodology. Futures studies is a field of science that researches the uncertainty and complexity of futures. A classic example of this methodology is scenario building, which offers a way to structure unknowns and include unexpected factors. One of the main principles of future studies is to involve stakeholders in the discussion and, through this discussion, to identify possible, probable, and plausible paths. This approach was presented in the research (Jokinen, 2022), where the influence of creativity shaping long-term futures for decisions made about ship design was examined using foresight methods. Looking at the ship design problem as a task to create a design that serves in the future is a novel perspective to ship design methodology.

### **Change of design process elements: workforce, expectations, tools, and expertise**

The third area of the transformation is the process elements affected by a change of perspective. These elements are workforce, expectations, tools, and expertise. The first one is the change in the workforce, which the industry and academia have witnessed already, and these changes are expected to accelerate in the future – changes in the workforce involved in the design process. Generations XYZ engineers gradually replace the stereotypical image of the past with experienced engineers solving challenges and striving for the best outcome. New generations of engineers expect technology to serve their needs and facilitate a significant part of the design process, including encapsulated best industry practices and tacit knowledge to be embedded in the tools. One aspect of this change is accessibility and user experience of the technological tools interactions – instead of the laborious process of creating 2D drawings to use interactive AI-assisted Mixed Reality (MR) headsets and generate engineering output automatically. Software providers continuously fostered this shift of the paradigm process, and expectations often exceeded reality in this area and sometimes even created unrealistic expectations of technology solving all imaginable problems, which remain unsolved for now.

Expectations are another area that can be affected by incorporating human perspective. Based on the human perspective, marketing promises and sometimes science fiction publications often elevate expectations, creating an image from limitless possibilities. Managing the expectations early enough can help allow a realistic approach and leave space for innovation. It requires a conscious and systematic effort to manage this process instead of considering it taken care of by itself.

Tools are arguably the fastest-evolving element of the design. The tools refer to various ship design packages for modeling, simulations, etc. Within the last decade, only the advancements in hardware and software alone have gone that far to take designers from 2D reality with paper drawings into Mixed Reality, where design can be created and designed full scale with immersing experience in 3D. Digital Twin concepts are enabled by the possibility of handling large and increasingly complex amounts of data and connectivity. The original vision of a unified Digital Twin was gradually substituted with a more practical Digital twin for a particular purpose and now slowly moves into the direction of a digital thread or backbone, enabling the storage and use of Digital Models and Twins for specific purposes. Software developers increasingly place User Experience (UX) at the center of the software development process and recognize the importance of technology adaptation instead of focusing on functionality exclusively.

In the previous wave of evolution, Industry 4.0, the main focus was on the connectivity of digital models and the physical world to enable manufacturing and automation. Blurring the borders between the digital and physical worlds provided numerous applications to send ship design data directly to production or machinery. It became mainstream to use general cutting and welding programs automatically based on 3D data and created many automated interfaces and applications for robotic assembly in the industry. Now, attention from the software development teams is dedicated to the usability of the data, tools, interfaces, and user experience. Therefore, the focus is no longer on the tool's functionality; a human-centric perspective is gradually incorporated, addressing the previously described challenges: workforce and expectations. Fully robotized production lines remain a vision for shipbuilding while using co-bots, and AI-generated planning and scheduling are a reality enabled by advanced ship design technology.

Expertise or skills is the last element of the change process. It refers to specialized expertise required for ship design and knowledge management systems facilitation of organizational knowledge management. Modern shipbuilding's complexity

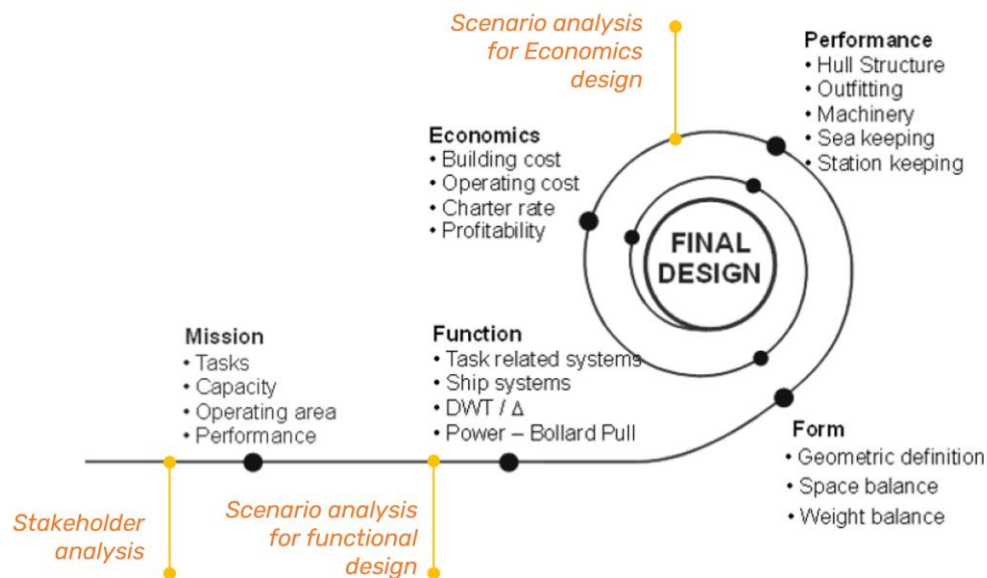

exceeds a single person's capacity to handle all aspects or disciplines, elevating the need for expertise management, different teams' involvement, and tacit knowledge facilitation. Newer generations of shipbuilders expect technology to store and offer embedded knowledge, skills, and expertise that previous generations needed years to acquire. Here, technology plays an even more critical role as a storage and facilitator of knowledge.

## IMPACT ON SHIP DESIGN PROCESS METHODOLOGY

Based on the discussion from the previous part, the following additions can be suggested to the system-based ship design process methodology. Conceptually, these additional additions are presented in Figure 2 as a development for Levander's illustration (Levander, 2006).

Adding the human-centricity aspects calls for additional points in the "design spiral". These points allocate the space in the design process for analyzing stakeholders, building scenarios for functional design as a representation of alternatives, and similarly for the project's economic feasibility. These might be already accounted for in the other stages of the design process; however, making these steps explicitly visible provides a more comprehensive view of the methodology. It highlights three points where the human-centric approach has the most significant impact and can change the course of the whole design process. Figure 2 shows these additions: stakeholder analysis, scenario analysis for functional design, and scenario analysis for economics design.

**Figure 2: Adapted system-based ship design, a leading figure from (Levander, 2006), additional points for stakeholder analysis, scenario analysis for functional and economical design points added based on the proposal from the proposal in the article.**

Stakeholder analysis is suggested as a first step of design activities. Before defining the mission parameters, the initial question should be how and who will benefit from the future vessel. This way, the focus will shift from stakeholders to stakeholders. Analyzing stakeholders can provide insights into the differences between involved groups and potential conflicts of interest among these groups. It would help to map potentially conflicting expectations and also identify sustainability characteristics. As in the examples used above, it can lead to innovative designs and more tailor-made solutions where challenging stereotypes or previous designs have significant potential to offer radically new approaches to design. Such analysis can be arranged as one or several workshops, including as wide a range of shareholders as possible. Ideally, it should include ship owners, naval architects, building yard representatives, and any other potential stakeholders, such as local authorities or local communities that will exploit the potential of a new build.

Scenario analysis (Ramírez, 2016) for functional design is another step after the main characteristics are defined in the two previous steps – stakeholder analysis and mission identification. It should precede the functional design stage and can serve as a foundation for developing several alternative design variants. There are many possible techniques to perform scenario building and analysis. It can be an elaborated process with several workshops, steps, and a thorough study of alternatives, or it can be a simple identification of the central axis for differences and main different scenarios. For example, one axe can be GHG emissions (extremes can be a traditional heavy fuel engine and methanol engine), and another axe can be the shape of a bow

affecting cargo capacity and stability. The natural objection here would be that typically, in the design, there is a multitude of parameters and variations significantly exceeding 2 or 3 extremes, which would lead to the exponential growth of a number of scenarios – 4 in the case of 2 axes, 16 in the case of 3 axes, and so on. To avoid this unnecessary complexity, previous steps from stakeholder analysis and mission clarification can help identify the most valuable criteria for design and focus on these. The outcome of this activity would be a set of distinctively different scenarios for discussion and selection of 1-2 for further development. It can provide a structured way to manage innovation and avoid opinion-influenced decisions.

Scenario analysis for economics design, similar to the functional analysis scenarios, economic scenarios can be built to evaluate the financial feasibility of the project. It can be performed for one functional design or for a set of designs and can include known economic characteristics and future.

Both of the previous steps offer not only a framework to consider different variants and specs of the designs but, most importantly, a tool to address uncertainty in the future. Scenario building is a method in strategic management and futures studies that facilitates the exploration of alternative futures by constructing plausible and consistent narratives of potential developments (Schwartz, 1991). It helps to think systematically about uncertainties, test assumptions, and consider the implications of different future contexts. All of these can enhance design decisions and help avoid design mistakes by providing a structured way of evaluation in complex projects. Along with the scenario methodology, many other tools, such as systems thinking and foresight techniques, can be employed. These can offer a more holistic setting to address the growing complexity of ship design projects, uncertainty of future requirements and regulation changes, and provide a sustainability focus to the maritime industry.

The overall change of the perspective based on human centricity impacts the whole design process. The steps discussed above are explicit actions that can impact the methodology. Besides the methodology, the overall process and its parts are gradually changing. Societal and technological changes impose a significant impact on these. Slow changes from a hierarchical management style in organizations give way to a more flexible way of working, which impacts how decisions are made and how innovations are fostered, allowing the creation of new designs and unleashing human imagination and creativity. Society's goals change from continuous economic growth to sustainability and green targets, giving a prevailing imperative to all activities. Generations of designers change and bring differences in how work is done and what parts are perceived as the most critical. Technology develops fast, allows us to benefit from the digital twin, and opens possibilities for the use of virtual possibilities in simulation, harvesting operational data, and creating an immersive experience in visualization. The whole separate area of potential development is related to Machine Learning (ML) and Artificial Intelligence (AI) applications for ship design and digital twin data management. In addition to the above steps, the design process itself evolves. The management process for ship design as a project, the effect on tools UX or expertise management, including HR aspects or knowledge management systems in organizations—all of these changes will take place gradually in the future and result in updated methodology and, hopefully, the enablement of better designs.

As discussed above, the influence of human-centricity on design process management provides an exciting area for research and application. Ship design methodology can benefit from adopting selected practices from project management – agile methodology, stakeholder and impact analysis, systems thinking, and foresight techniques. This cross-use of methodology from other fields can enrich the narrowly focused ship design process with human-centricity and a broader interpretation of stakeholders' intentions and tackle the uncertainty of future changes. An alternative possibility for such an approach is a service design methodology, with the first research of its application presented (Kim, 2024).

## CONCLUSIONS

This article reviewed some aspects of the evolution of the ship design process and methodology based on the framework of the Shipbuilding or Industry 5.0 concept discussion. Without being exhaustive, the main paradigm shift for human centricity was presented as an influential factor in ship design, and possible results of such a shift were discussed. The main areas where the changes can be expected are a change of focus from shareholders to stakeholders, the inclusion of the future uncertainty element in the design decisions, and a change of several aspects of the process: workforce, expectations, tools, and expertise management. Possible impacts on the ship design methodology are identified as three additional steps in the commonly used methodology based on design spiral – stakeholder analysis, scenario analysis for functional design, and scenario analysis for economic evaluation. The expected implications are identified as a structural approach for uncertainty, innovations, and expectations management. The potential benefits include a higher degree of alignment between stakeholders and with the society goals, expectations of new designs and applications of waterborne transport in maritime industry.

The future is not carved in stone, and while some of the implications of human centricity appear most likely, some might take a completely different turn or unexpected directions. While predictions were never the intended outcome of this article, the discussion about Shipbuilding 5.0 and its effects on the ship design process should positively impact the industry overall.

# A novel usage of rough sets in design of data fusion systems

Brendan Sulkowski<sup>1,\*</sup> and Matthew Collette<sup>2</sup>

## ABSTRACT

*Design changes for crewless vessels are unexplored compared to the maritime design processes that have been utilized and updated for hundreds of years. This paper presents an exploration into how autonomous and unmanned systems can impact maritime design, specifically focusing on how well they can fuse multiple types of information. Currently, formal and informal communication onboard crewed vessels between various departments is critical in constructing a view of the vessel's current health and future capability. A major focus area is determining whether utilizing data classification techniques can replace these human-centered decision processes, and what the design implications of losing the human synthesis will be. This paper proposes a mechanical spring-mass-damper system with base excitation using real-world ocean data to be used to perform analyses. Rough Set Theory (RST) is a data classification technique that can be used for the characterization of a set of objects, finding dependency between attributes, and creating rules for making decisions. RST is compared with other data classification techniques to determine where each classifier succeeds and how they can generate information useful in design. By integrating the results of these analyses, this paper identifies ways to begin fusing multiple information types and how this will impact marine design in the future of crewless systems.*

## KEY WORDS

Digital Twin; Machine Learning; Design Uncertainty; Wave Forecast; Safety Prediction

## INTRODUCTION

As human safety becomes increasingly more important in every aspect of life, the desire for crewless platforms grows in the ground, air, and marine domains. However, the necessity for operating crewless platforms for weeks to months is a challenging endeavor that separates the naval world from many other domains using autonomous or human-less systems. Designers currently lack guidance on which types of systems may be successful for these long-term applications. While a range of machine learning approaches have been proposed in the computer science literature, it is not clear how these methods could help the overall design process. This work compares a Rough Sets based approach to two conventional classifiers, looking at both accuracy and how the classifiers generate design-relevant information.

Collette et al. (2022) interviewed human crew members who had served or were serving on several types of ships and were involved in different roles both on and off the vessel. Crew members discussed that they were still deeply involved with making sure ship systems were healthy and functional even though there are preventative maintenance systems and sensors

onboard that work without humans constantly in the loop. Through years of experience, humans can sense when or where there may be an issue even if it is not noted by a fault sensor or other component. Therefore, a major issue with crewless platforms is exposed – how will we be able to predict failure? This is imperative both in the design phase of a vessel and across the vessel's lifespan.

Remaining Useful Life (RUL) is an estimate of how long an item, component, or system can operate and fulfill its intended purpose before repair or replacement becomes necessary. Gebrael et al. (2004) developed neural network models around bearing parameters and a parameter-updating algorithm that computed bearing failure time predictions. Liao et al. (2006) present a proportional hazards model and a logistic regression model in predicting the RUL of an individual unit. They also use a bearing test to demonstrate their proposed approach. Li et al. (2018) proposed a data-driven approach for prognostics using deep convolution neural networks. They then used their approach to perform and cross-compare an experimental study with NASA's C-MAPSS Dataset with other approaches. Cai et al. (2020) contributes a hybrid physics-model-based and data-driven remaining useful life (RUL) estimation methodology of structure systems considering the influence of multiple causes by using dynamic Bayesian networks. Finally, Aivaliotis et al. (2017) present an approach to try and provide a satisfactory solution for calculating RUL of machines in a production plant through PHM technique, leading to the idea of using a Digital Twin (DT).

A digital twin is a dynamic virtual representation of a physical object, person, system, or process that absorbs data and replicates processes to predict possible performance outcomes and issues. It will last the entire life of its physical twin, can be updated from real-time data, and can aid in the decision-making process of its twin. Kritzinger et al. (2018) provided a thorough review of DT in manufacturing at that time and showed that development was still relatively new but increasing in effort. Zhao et al. (2020) described a modeling method using DT for a manufacturing process, proposing a hierarchical model and mapping strategy for generating DT data, and Liu et al. (2023) proposed an updating method for DT knowledge based on a memorizing-forgetting model. On the maritime side, Raza et al. (2022) conducted research for applying DTs for autonomous vessels, and stated that DTs can be used to optimize path planning models using real world data such as sea charts and wave disturbance estimates. Mauro and Kana (2023) review the present-day status of DT research, and they state that the shipping industry is a few years delayed compared to other industry sectors, especially manufacturing. Finally, Kinaci (2023) discusses the need for DT for full autonomy in the seas, using a maneuvering math model to represent a physical ship. They developed a digital twin environment for a model ship and tested a control algorithm for sailing automation. Collectively, the prior research on digital twins contains several component examples, but digital twins are not discussed thoroughly from a design perspective, especially regarding autonomous vessels.

Failure prediction will be one of the most important aspects of autonomous vessels, especially in the design phase. These are platforms that do not have the experience of human crews and do not have enough underway data to learn from themselves yet. This work outlines a proposed system model which can be used to model component degradation. Several different classifiers are used on data generated from the model to predict failures and are compared with each other. Finally, rough sets was used to classify and analyze the data to be looked at from a design perspective. Background information on rough sets is included in the machine learning classifiers subsection of the next section.

## SYSTEM SETUP AND CLASSIFIERS

Studying vessels designed for long-term autonomy is challenging, as full-scale prototypes are only in the early stages of development. Based on the literature review above, a model system was created to stand in for the autonomous vessel. The model system should have multiple interacting components whose health could be assessed in differing ways and a single output parameter to stand in for the capability of the overall vessel. The model system should also allow realistic weather forecasts and uncertainty to be included in the system. After some discussion, a spring-mass-damper system, excited by stochastic wave systems, was selected. The spring, mass, and damper can be modeled as degrading components; as the value for each change, the overall response of the system also changes. By setting a maximum allowed displacement on the system, an equivalent of a safety threshold, dependent on the health of all three components and the weather prediction, can be modeled. This section introduces the spring-mass-damper system, ocean wave parameters, and the overall setup of the simulation. The parameters used for each trial are described, and the machine learning classifiers are also introduced

and detailed in this section.

## Spring-Mass-Damper System

A spring-mass-damper system was developed to model component degradation and is composed of a mass block, a stiffness component, and a damping component, as well as using an ocean wave input as base displacement. The system can use different input parameters such as significant wave height and peak frequency to excite the dynamic system and track its response. Figure 1 is a physical drawing of the system. In the figure,  $y$  represents the base displacement,  $x$  represents the mass displacement,  $m$  is the mass component,  $k$  is the stiffness component, and  $c$  is the damping component.

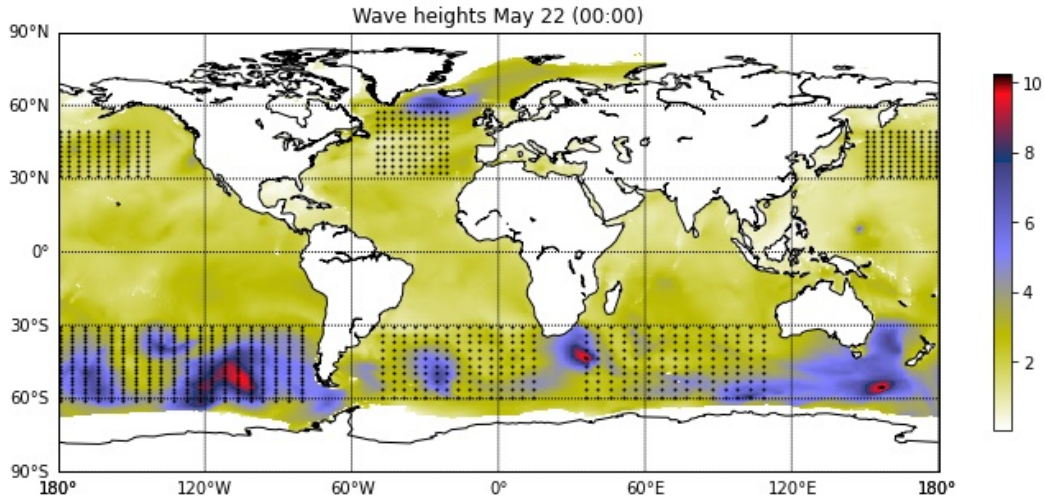

Figure 1: Spring-Mass-Damper system diagram

## Simulations using Ocean Weather Data

Using the correct system model and setup is critical for accurate, reusable, and scalable results. The weather data, i.e. the significant wave heights and peak periods used to model the base excitation, were taken from the European Centre for Medium-Range Weather Forecasts (©2023 European Centre for Medium-Range Weather Forecasts (ECMWF) ECMWF (2023)). This data is published under a Creative Commons Attribution 4.0 International (CC BY 4.0).

The ECMWF has open weather data containing wave data from across the Earth, and the ECMWF provides “global forecasts, climate reanalyses, and specific datasets”. The data used for this project is five predictions for one specific time on one specific date, which was the 00:00 hour on May 22, 2023. Data was collected at 1000 points distributed across the world’s oceans in order to collect a range of different significant wave heights and peak periods. The five different datasets are the real-time data from May 22, and weather predictions from 24, 72, 144, and 240 hours out. Figure 2 displays the significant wave heights at the 00:00 hour on May 22. The regions on the map filled with black markers are the coordinates where weather data was collected for this project.

The mass and stiffness values were chosen to generate a certain range of natural frequencies, which can be converted to natural periods. The periods were selected to correlate with the peak periods seen in the ocean data. The mass, stiffness, and damping values were generated using Latin Hypercube Sampling (LHS) with three dimensions and 1000 data points for each component. LHS distributed  $m$ ,  $k$ , and  $c$  values between the selected minimum and maximum for each component, which are shown below in Table 1. The Bretschneider ocean wave spectrum was used to create the wave spectra used for the base excitation. Equation 1 displays the equation used for the Bretschneider wave spectra. This equation comes from the textbook *Offshore Hydrodynamics* (Journée (2001)).

**Figure 2: Significant wave heights for 00:00 hour on May 22, 2023 with data collection regions overlaid**

**Table 1: Minimum and Maximum values for mass, stiffness, and damping components**

	Mass (kg)	Stiffness (N/m)	Damping (Ns/m)
<b>Minimum</b>	1	1	0.1
<b>Maximum</b>	10	9	9.5

$$S_{\zeta}(\omega) = \frac{173 \cdot H_{\frac{1}{3}}^2}{T_1^4} \cdot \omega^{-5} \cdot \exp\left(\frac{-692}{T_1^4} \cdot \omega^{-4}\right) \quad (1)$$

$$T_1 = 0.772 \cdot T_p \quad (2)$$

Using the mass, stiffness, damping, and wave data values, the average maximum displacement of the mass was calculated for each of the 1000 data points. Equation 3 shows the amplitude for the vibration of a base-excited spring-mass system, and then, using the square root of the moment, multiplied by 3.85, the greatest response amplitude expected on 1000 independent observations is generated. An arbitrary threshold value was selected such that a mix of maximum displacements both exceeded the threshold and remained below the threshold. If the maximum displacement exceeded the threshold, the trial result was considered a ‘failure’, and if it remained below the threshold, the result was a ‘pass’.

$$x = \frac{Ky(1 + (2\zeta\omega/\omega_n)^2)^{1/2}}{((1 - \omega^2/\omega_n^2)^2 + (2\zeta\omega/\omega_n^2))^{1/2}} \quad (3)$$

The first set of trials looked at how failure prediction accuracy changed with decreasing weather forecast accuracy. For these five trials, the exact m, k, and c values from the LHS results were used. For the base excitation, all 5 weather forecasts were used to determine how prediction accuracy is affected between the real-time zero-hour data and the 240-hour predicted weather data.

## Simulations using Alternate Parameters

A major part of the Collette et al. (2022) report revolved around the human interviews with crew members. They reported that human crew members onboard marine vessels are deeply involved in the preventative maintenance process to the point that they are sometimes able to notice a fault or failure before a sensor or machine can report it. However, especially in the design space of autonomous vessels, human inspection will not exist and sensors will be necessary for sensing component health. This puts on the designers the need to choose sensors, sensor accuracy, and decision methods that will use the sensor data. However, very little guidance exists in this space right now.

Therefore, an additional column was added to the data table utilizing a ‘visually inspected’ spring. The stiffness values were taken from the LHS generations, and using three levels of accuracy, given a label. Results were labeled ‘healthy’, where the spring is in a healthy and optimal state, ‘worn’, where the spring is well-used but still functional, and might not work as optimal as in the ‘healthy’ state, and ‘failed’, where the spring is no longer operational. For a crewless vessel, this could correlate with an onboard imaging system or periodic human inspection between voyages. A trial was conducted using the visually inspected stiffness results, the same LHS results for mass and damping, and the zero-hour weather data to see how decreasing stiffness component knowledge accuracy affected the prediction accuracy.

## Machine Learning Classifiers

Ultimately, a crewless vessel will need to be able to make its own assessment of safety, given its current understanding of its health and the forecasted weather. Collette et al. (2022) noted that this process was highly human-dependent at the moment, with extensive discussion among senior crew members used to arrive at integrated, vessel-level assessments. In designing a crewless vessel, this process will need to be automated. As a first approach, a machine learning classifier could be used to integrate component health information and weather forecasts to assess if the system is safe. In this work, three machine learning data classification techniques were applied to these test cases. Support vector machines (SVM) are supervised learning methods used for classification and regression, and this work features SVM from scikit-learn in Python with the default SVC method (Pedregosa et al. (2011)). An advantage of using SVM is that it uses a subset of training points in the decision function (called support vectors), so it is also memory efficient. SVMs are adaptable and can manage high-dimensional data and nonlinear relationships, however, they are black-box models and the method of finding the final product may not always be understood. In Adadi and Berrada (2018), the authors discuss how black-box models do not disclose anything about internal design or structure, meaning users are finding results without thorough knowledge of how the model is working. On the other hand, glass-box models are completely exposed to the user from start to finish, so users have full knowledge of how the model works.

The second technique is a Decision Tree, which is a glass-box supervised learning method that makes predictions by learning simple decision rules from data features and previous data. A decision tree is a flowchart-like tree structure where internal nodes denote features, branches denote rules, and leaf nodes denote the results of the algorithm. This work uses the `DecisionTreeClassifier` from `sklearn` to predict outcomes. It is used for both classification and regression problems, and because decision trees are glass-box models, they present options that allow for informed decisions to be made. For the design phase of the vessel, such rules are useful as they indicate to the designer which parameters and values are most important to understand. However, decision trees can be less accurate than SVM and other black-box models, depending on the problem.

Finally, Rough Set Theory (RST) was also compared. RST can be used for both classification and to give a deeper understanding of the problem and decision space, which is attractive for use in a design setting. RST was originally proposed by Polish scientist Zdzislaw Pawlak and is a technique for identifying and learning on common patterns in data, especially in the case of uncertain and incomplete data (Pawlak (1982)). The mathematical foundations of this method are based on the set approximation of the classification space. The theory allows for a description of objects to be used which can contain information about various features. The precision, or amount of detail in the description can vary based on the knowledge of the feature and other limitations. RST uses indiscernibility relations to recognize and discover attribute relations. Therefore, it needs data to be in a discretized form to properly function, so the input data for rough sets was sorted into bins for

the data analysis and performance accuracy test.

Also in RST, two approximations are developed: The upper approximation is the set of objects which possibly but do not definitely belong to the target set, and the lower approximation is the set of objects which positively belong to the target set. Objects that fall between the lower and upper approximation are said to be in the boundary region. If the boundary region is non-empty, the set is said to be rough, otherwise it is a crisp set and all cases can be classified without fail.

Large volumes of data can be difficult to classify into specific categories through visual inspection, and RST can discern and classify objects in large data sets. RST uses the indiscernibility relations and lower and upper approximations to characterize and express an information system, and therefore does not require additional parameters to extract information. Rough Sets results were generated in this paper using the RoughSets package in R (Janusz et al. (2020)). The process for performing the data analysis in R begins with taking in the dataframe with the simulation results and converting it into a decision table. Then, the indiscernibility relation is computed and utilized with the decision table to compute the lower and upper approximations. Like with the SVM and decision tree classifiers, the data was split into training and testing sets, and the classifier was then able to compute the predictions for the test set, determine the overall accuracy of the predictions, and generate a list of rules.

Assessment Approach

From the 1000 data points, 700 were used for training the classifiers and 300 were used for the testing phase. The overall accuracy of the predictions was the main focus point for each classifier in comparing them to each other and is defined as the percentage of test trials where the predicted outcome matches the true outcome. The results and comparisons between classifiers are given in the following sections.

RESULTS AND DISCUSSION

The results from the simulations were used with the previously described data classification approaches to predict possible failures. Two different approaches were simulated, the first being the case where the mass, stiffness, and damping values all come from the Latin Hypercube Sampling. These are run with each weather data-set out to 240 hours to see how each classifier handles the changing weather uncertainties. The results are shown in Table 2, with the classifiers bolded in each row, the trial bolded in each column, and the table filled out with the accuracy percentages.

Table 2: Table of prediction accuracies (in percentage) for each classifier in each trial case

	<b>0-hour</b>	<b>24-hour</b>	<b>72-hour</b>	<b>144-hour</b>	<b>240-hour</b>
<b>SVM</b>	95.28	95.28	94.85	93.06	90.66
<b>Decision Tree</b>	91.50	91.50	90.72	88.55	85.74
<b>Rough Sets</b>	91.95	91.95	89.70	86.30	84.20

The results show that overall, SVM outperforms the other two classifiers in prediction accuracy. Rough sets performs similar to but better than the decision tree for the 0 and 24 hour trials, but worse than the decision tree for the other three weather prediction cases. In the case of SVM and decision tree, the prediction accuracies remain similar from the 0 hour trial to the 72 hour trial, and then the accuracies drop significantly as the weather prediction becomes increasingly inaccurate. Rough sets performs similarly, except it loses its accuracy at 72 hours instead.

When thinking about how these results can be thought of in the design space, the drop off in accuracy as the weather knowledge weakens should be the main focus point. It emphasizes how designs need to focus on not only overall vessel safety, but also the unpredictability of the oceans. On crewed vessels, humans have the ability to make decisions based on their past experiences and knowledge of how well their ship can handle a certain weather obstacle. On uncrewed vessels however, the vessel itself may need to make the decision on whether to change its mission or remain on course. Being able to

do this from 72 to 144 hours out is much more optimal than only having 24 hours to make a well-informed and accurate decision.

The second approach involves using the same mass and damping component values, but using a ‘visually inspected’ stiffness component to emulate the findings from the human crew interviews mentioned in Collette’s paper. The prediction accuracy results for this approach are shown in Table 3 along with the initial result from the first trial.

**Table 3: Table of prediction accuracies (in percentage) for each classifier in the trial case with a visually inspected stiffness component compared to the original test case. The new trial case also uses the 0-hour weather data.**

	0-hour	Visually Inspected
SVM	95.28	93.67
Decision Tree	91.50	90.17
Rough Sets	91.95	91.90

The 0-hour result from the first trial is included and compared to the visually inspected trial results because that case contains the most knowledge about the system. The results show that the SVM and decision tree results drop in accuracy by about 1.6 percent and 1.33 percent respectively from the 0-hour, full data case to the 0-hour, visually inspected stiffness component case. However, the rough sets prediction accuracy remains about level with only a drop of 0.05 percent.

The decrease in accuracy is expected with less knowledge about the system as a whole, but rough sets holding its accuracy was unexpected. Again, rough sets prove to be better than the decision tree at this stage and slightly worse than SVM, but closer than before. Rough sets also provides other options for data analysis as opposed to SVM and decision tree, which is detailed in the following section.

IMPACT ON DESIGN

While Rough Sets may not have outperformed the SVM and decision tree classifiers in terms of failure prediction accuracy, it also provides other information that can be more useful in design. The boundary region was defined as being the area between the lower and upper approximation, where the lower approximation was the set of objects that positively belonged to the target set.

The accuracy results show that from the real-time data to the 72 hour prediction data, there is not much of a drop in accuracy. However, there is a significant drop in prediction accuracy when moving to the 144 hour weather prediction data. Therefore, we looked at how the boundary region changes while using Rough Sets from the 0 hour case to the 144 hour case. Six different bin sizes were used for each case, with the bin sizes meaning how knowledgeable the system is on component accuracy. The number of bins ranges from 3 to 20, where the number of bins means that the exact numeric values of mass, stiffness, and significant wave height data have been placed into the corresponding number of bins between their minimums and maximums to discretize them. Such binning is also related to the accuracy of potential sensors for each component.

The trial used for this test case is the visually inspected spring component, along with the bin values in place of the previous mass, damping, and significant wave height components. Table 4 shows the number of cases (out of 1000) that were placed in the boundary region for the different number of bins in each trial.

**Table 4: Number of test cases in the boundary region for differing numbers of bins**

# of Bins	3	5	7	10	15	20
0h Trial	542	261	143	29	4	8
144h Trial	609	303	150	45	8	10

Looking at the table, the number of bins and the number of cases in the boundary region are clearly related. With a lower

number of bins, such as 3 or 5, there are more cases in the boundary region than at 10 or 15 bins. This shows that the number of bins affects our knowledge accuracy. As we begin knowing more about the system and can better differentiate between data, we can place them more accurately where they belong.

This can be related to design in looking at things such as sensor fidelity. If a sensor can only offer 3 or 5 different knowledge states about a part or product, it might not be worth selecting over one that offers 10 knowledge states. This is especially relevant in autonomous vessels, where knowing the difference between a component being healthy, worn, or failed may make the difference between a successful mission and a lost or compromised asset. However, at the extreme right hand side of the table, a different story is shown. Here, there is little advantage in selecting a sensor accuracy corresponding to 20 bins over one with 15, at least in terms of how well the data can be classified into sets.

Also being compared was the 0 hour trial to the 144 hour trial. The immense fall-off in prediction accuracy for the 144 hour case allowed for analysis in this situation as well to see if a similar pattern developed. While there was not an exact pattern, the superior knowledge of the 0 hour trial outperformed the 144 hour trial at every number of bins. Some cases, such as 7 bins and 20 bins did not have much difference, but with 10 and 15 bins, the 144 hour trial had 66 percent more cases and twice as many cases in the boundary region, respectively. This difference shows how more accurate knowledge about one aspect of a system, in this case the weather component, can allow for better design choices to be made.

Being able to visualize the impact on classification via the size of the boundary region is an important advantage in using a system like rough sets. Compared to black-box classifiers, whose performance may change with hyperparameter settings and the pipeline used to build the model, the boundary region is a fixed property of the engineering data set used to describe the problem. It provides a second way of looking at the potential for classifiers to work on the base problem that is quickly humanly understandable. Differing sensor accuracy and real-world uncertainty can also be examined.

## CONCLUSION

This paper presented a system that was used to model component degradation and knowledge degradation. The spring-mass-damper system was combined with real-world ocean data to excite the system and 1000 test cases were simulated. Different machine learning classifiers were used to predict operational successes and failures and were compared to each other based on their accuracies. Support vector machines (SVM) was the best classifier in the sense of prediction accuracy, as compared to decision tree and rough sets. However, Rough Sets provided opportunities to look at the system in different ways, specifically how we can use it to think about design.

Rough sets have the ability to not only predict results from learning on training data, they also can perform other operations. Here, rough sets was used to look into how changing knowledge accuracy about a system or component can affect design knowledge. We saw that as we increased our sensor fidelity, the number of cases that could be positively classified increased immensely. This has design implications where rough sets can be used to determine which configurations or components can be considered in an optimal design region, or if they might need to be worked on further to narrow down the feasible design space.

# Human digital twins to inform ship design

Nicole Catherine Taylor<sup>1,\*</sup>, Anriëtte Bekker<sup>2,\*</sup> and Karel Kruger<sup>3</sup>

## ABSTRACT

*A key building block of digital twin solutions is a virtual counterpart for an asset that can be coupled to the asset throughout its lifecycle – predicting an asset's potential performance at design and providing insight into operation during service. This paper presents the development of human digital twins that integrate human factors into conventional ship design procedures, particularly focussing on seakeeping performance assessments. A novel method for incorporating human-centric performance criteria in seakeeping analyses is proposed and initial validation thereof is detailed. Human digital twins are seen to provide a platform for informing the ship design process using data captured during vessel operation.*

## KEY WORDS

Digital Twins; Ship Design; Human-Centred Design; Seakeeping; Motion Sickness

## INTRODUCTION

A visible rise in research interest is evident in reviews of digital twins in the maritime domain. Digital twin solutions comprise of virtual counterparts linked to assets and communication between the coupled digital and physical entities. This is not to be confused with geometric models that mimic the structural components of assets, particularly in the case of ships. Ship digital twins are recommended to be created at the inception of the physical ship lifecycle, at the beginning of design, to be coupled with the physical asset through production and operation to retirement. (Mauro and Kana, 2023; Madusanka *et al.*, 2023)

The most recent International Marine Design Conference state-of-the-art report on ship design methodology identified exploiting operation data from digital twins as an emerging development that will become an intrinsic part of future design processes (Erikstad and Lagemann, 2022). It is likely that a digital twin of an asset will contribute design data to the design stage of its coupled asset, shown by arrow (a) in Figure 1 for Ship 1. However, it is unlikely that a digital twin of an asset will contribute operation data to the design stage of the asset, as the design precedes the operation of the asset. It is more likely that digital twin of an asset already in operation may inform the design of next-generation or new, similar assets, as shown in Figure 1 for two ships, particularly by arrow (b).

**Figure 1: A Digital Twin in Operation Informing the Design Stage of Another Asset.**

It is evident that data should be exchanged between the digital and physical entities within a digital twin solution throughout the physical ship lifecycle, represented by arrows labelled (c) in Figure 1 (Madusanka *et al.*, 2023). However, a gap in information flow from digital twin solutions that capture data during ship operation and send data to a new ship's design stage is highlighted in literature, represented by arrow (b) in Figure 1 (Fonseca *et al.*, 2023). The objective of the work presented is to propose information feedback from digital twins used during vessel operation to aid the ship design stage.

In maritime literature, as presented until now, digital twin developments are typically referred to for ships. However, human digital twins are the focus of attention in the work presented. Where a ship digital twin is coupled to a vessel, a human digital twin virtually mimics the identity, condition and behaviour of a person.

A human digital twin for a seafarer, called Mariner 4.0, was developed and trialled on board the SA Agulhas II (Taylor *et al.*, 2023a). Mariner 4.0 facilitated the study of motion sickness in real time during ship operation on a research expedition. Subjective feedback was captured from vessel occupants through a mobile application and sensor readings from a full-scale motion measurement system. The human digital twin developed personalised motion sickness criteria that can aid the diagnoses of motion sickness incidence (MSI), an estimate of the percentage of individuals in a group that may vomit on board (O'Hanlon and McCauley, 1974), using the motion sickness dose value (MSDV), a human-weighted metric of a level of ship motion that is known to induce motion sickness (ISO 2631-1, 1997). An MSDV can be calculated with Equation 1,

$$\text{MSDV} = \int_0^T a_w(t) dt, \quad [1]$$

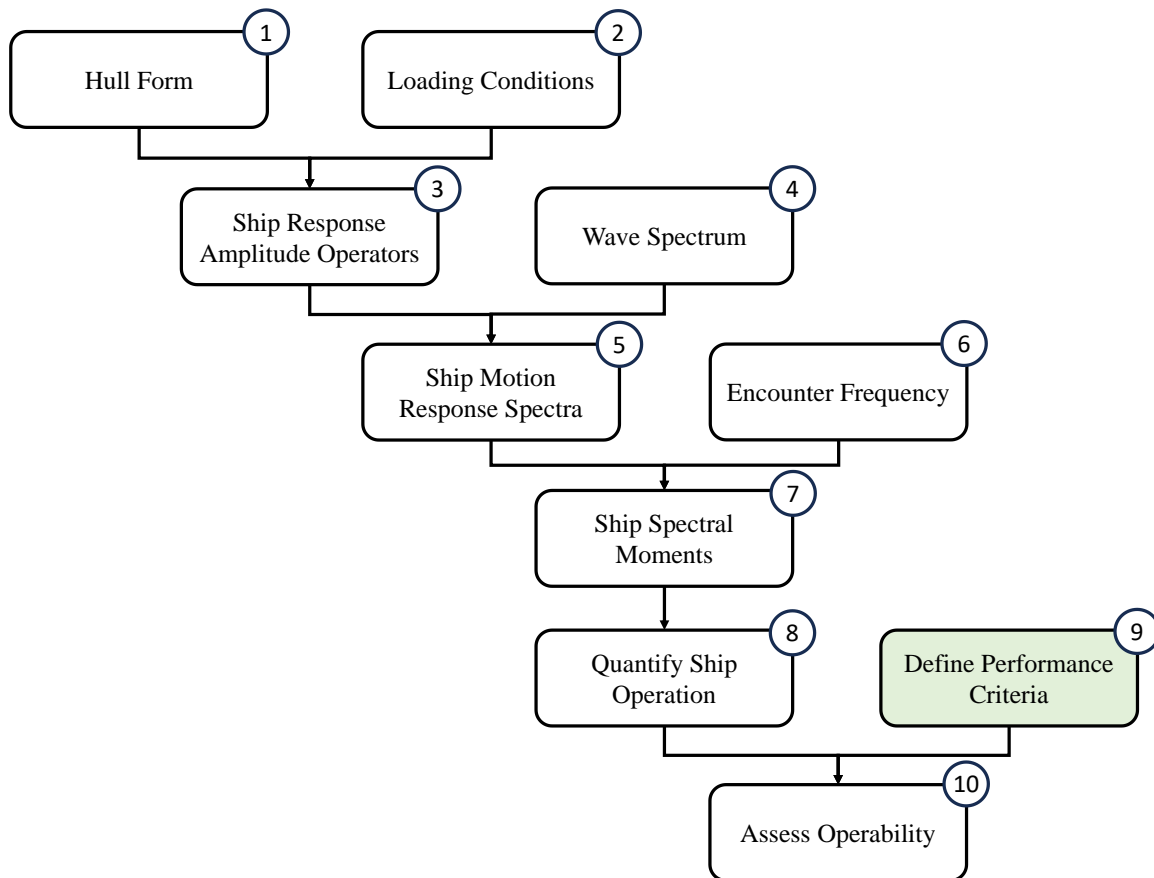

where  $a_w$  is the frequency-weighted acceleration measured by z-oriented accelerometers and  $T$  is the duration of exposure in seconds (ISO 2631-1, 1997). The z orientation is vertically aligned with the heave motion of a ship, but comprises additionally of roll and pitch components.

The work presented starts with a description of a baseline method to assess seakeeping performance that contextualises the proposed means for constructing an information loop from ship operation to design through human digital twins. A Mariner 4.0 deployment and results are detailed as an illustrative use case of the method for informing ship design using human digital twins. Thereafter, potential benefits and drawbacks of integrating human digital twins in ship design procedures are discussed.

It is envisioned that human digital twins will venture out to sea with their seafarer counterparts, returning to land with human-centric insight gained from ship operation that is of value for seakeeping assessments typically conducted in ship design.

## SEAKEEPING PERFORMANCE ASSESSMENT METHODS

It is common practice to define the specifications that a ship should achieve or criteria that a ship should not exceed during missions it is designed for, irrespective of the methodology selected for ship design (Erikstad and Lagemann, 2022). Performance criteria are selected to assess ship seakeeping, typically through forming operability envelopes (Tezdogan *et al.*, 2014). Figure 2 presents a foundational procedure for applying conventional seakeeping performance methods. The work presented does not intend to amend the extensively used procedure shown in Figure 2. Instead, the focus is on Step 9, which incorporates the development and selection of human-centric performance criteria.

**Figure 2: Basis of Conventional Seakeeping Performance Methods (adapted from Tezdogan *et al.*, 2014; Scamardella and Piscopo, 2014; 2015).**

## DEVELOPMENT OF HUMAN-CENTRIC PERFORMANCE CRITERIA USING HUMAN DIGITAL TWINS

Taylor *et al.* (2023b) proposed that seafarers each be coupled with a unique virtual representation of their state and behaviour, which describes their condition of well-being while performing tasks on board. The virtual representations are human digital twins devoted to acquiring and managing data related to the seafarers they are coupled with during ship operation. The core functions of human digital twins are to acquire data, process data and provide information to support decision making. Data acquired could be related to a seafarer in particular, such as their heart rate measured by a wearable sensor, or their environment, such as rigid body motion of a ship that a seafarer is exposed to, measured by sensors installed on the ship structure. Information that human digital twins should inform seafarers of should be related to seafarers' virtual representations. For example, a seafarer could be notified if their vibration exposure associated with a task that they have scheduled will go above a safety threshold for whole-body vibration when completing a dangerous task. Thresholds in the work presented are values for metrics

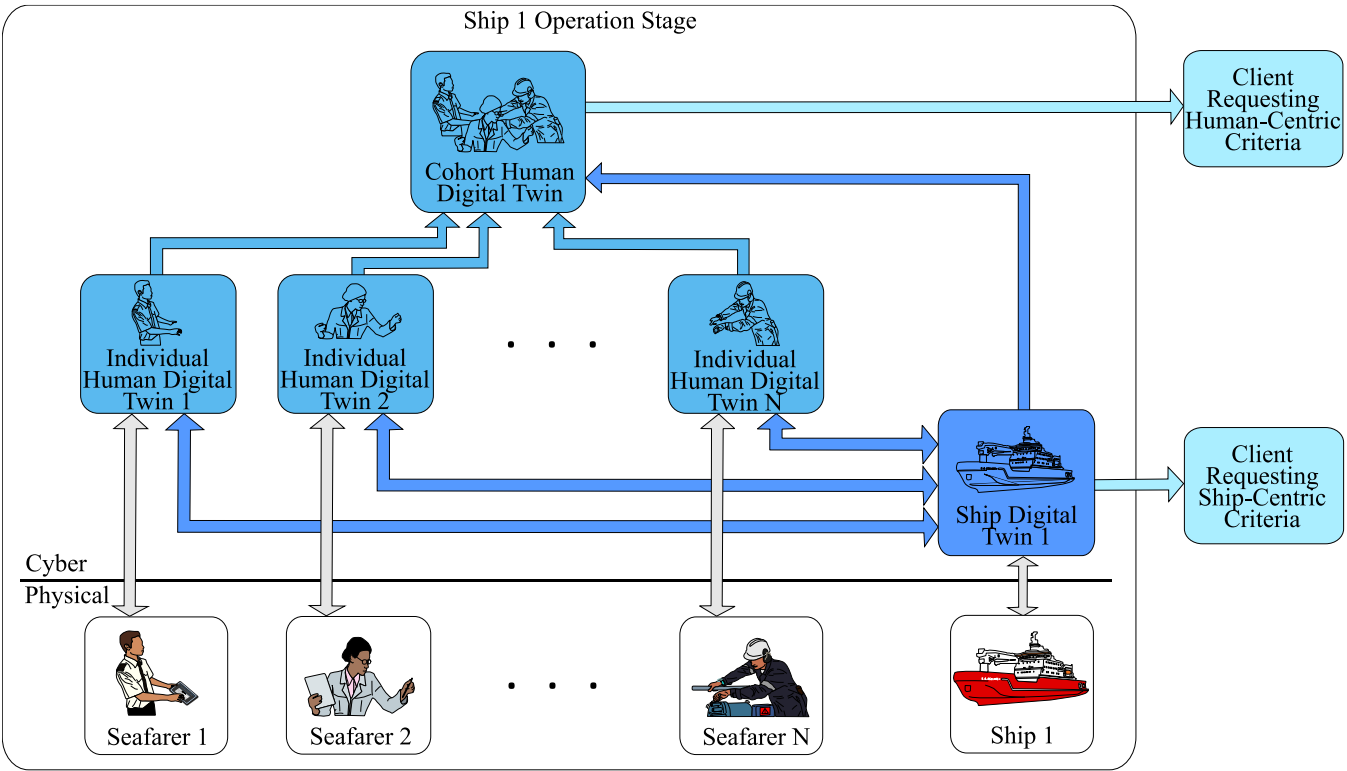

that quantify ship performance above which ship operation would be deemed unacceptable (NATO, 2000). If the task does exceed the safety threshold, then rescheduling to when the vibration of the ship is more acceptable would be advised.

Individualised data analyses can be conducted by each human digital twin in such a way that thresholds are determined to aid prediction of human response incidences, such as motion sickness (Taylor *et al.*, 2023a). It is common practice that a threshold is qualitatively selected or, more rarely, estimated from experiments (NATO, 2000). The work presented proposes the development of human-centric performance criteria during ship operation to capture invaluable real-world experiences that are not present during structured experiments traditionally performed at sea trials (NATO, 2000). This incorporates phenomena encountered during the full duration of a voyage into criteria development, such as adaptation to motion. Furthermore, criteria can be tailored to specific voyage scenarios and missions, including various durations of assessment.

Human-centric performance criteria are best developed for seafarers at an individual level that is associated with attributes unique to each seafarer, such as their age or previous seafaring experience. Thresholds are not strictly to be linked to the ship(s) a seafarer lives and works on, but rather metrics of ship operation. Hereby, seafarer-specific collections of human-centric performance criteria developed through human digital twins can be generated so that stakeholders can extract thresholds relevant to their ship or voyage missions. For example, a cruise ship designer may prefer to select characteristics of individuals that best describes an unadapted cohort. Comparatively, naval ship designers would be more inclined to work with thresholds of seafarers that are more tolerant to vessel motion.

**OBTAINING AND IMPLEMENTING SEAKEEPING PERFORMANCE ASSESSMENT METHODS THROUGH DIGITAL TWINS**

Service-oriented architectures based on digital twins have been developed for maritime solutions (Erikstad and Bekker, 2021). The development and servitisation of the diagnostic motion sickness criteria through human digital twins is recommended, additionally motivated by service-oriented approaches being widely accepted (IEC, 2017). The architecture that displays the interactions between digital and physical counterparts to generate and use diagnostic motion sickness criteria is presented in Figure 3.

**Figure 3: Architecture Displaying the Interactions Required for the Development and Use of Diagnostic Human-Centric Performance Criteria Through Human Digital Twins.**

In Figure 3, the individual human digital twins are each coupled to unique seafarers, which generate personalised thresholds. Hierarchically, the thresholds from individual human digital twins are aggregated at a cohort level. The Cohort Human Digital Twin acts as a service provider that offers clients relevant human-centric thresholds.

Clients in the work presented could be any entity that is interested in retrieving a human-centric threshold based on seakeeping methods conducted for the purposes of performance assessments, which is recommended to be included in the functionality of Ship Digital Twin 2 shown in Figure 1. Moreover, full-scale ship measurements are managed by Ship Digital Twin 1, which provides information regarding the state and behaviour of the vessel, such as rigid body motion while travelling through open water during a voyage, or ship-centric criteria.

The work presented does not focus on automated control of the seafarer, but rather on informing stakeholders of relevant information at the appropriate time for making decisions. For example, the Cohort Human Digital Twin could provide the average motion sickness level of passengers to the navigating officers in a ship's Bridge via a user interface, which may be used to inform their next actions, such as adjust the ship speed and course.

## ILLUSTRATIVE USE CASE

Motion sickness is focussed on in this illustrative use case as it is a prevalent natural human response to ship motion. Symptoms can include nausea, vomiting, tiredness and bouts of depression in severe cases, none of which are conducive to comfort or productivity aboard (Stevens and Parsons, 2002; Mansfield, 2005). The effects of motion sickness on passengers and crew are sought to be minimised through seakeeping in ship design, which is detailed as a conventional means of motion sickness assessment. A proposed method of enhancing human-centric performance criteria development is then described, followed by a real-world deployment to showcase human digital twins in operation, working towards exploiting operation data to inform ship design.

### Conventional Motion Sickness Assessment

The MSI is widely adopted in seakeeping performance assessments (Tezdogan *et al.*, 2014; Scamardella and Piscopo, 2014; 2015). Criteria for the MSI that are reported in literature include:

- 5 % at 0.5 hours of exposure for naval crew (Baitis *et al.*, 1994);
- 10 % of general passengers (ABS, 2021);
- 20 % of naval crew at 4 hours of exposure (NATO, 2000);
- 35 % over 2 hours (Tezdogan *et al.*, 2014).

The MSI can be computed from the second and fourth ship spectral moments. The MSI is related to absolute acceleration shipboard as described by Equation 2,

$$MSI = 100 \cdot \frac{1}{\sqrt{2\pi}} \int_{-\infty}^z e^{\left[-\frac{1}{2}x^2\right]}, \quad [2]$$

which expresses a cumulative distribution function using the standard normal distribution, where  $z$  is given by Equation 3,

$$z = \frac{\log_{10} \bar{a} - \mu}{\sigma}, \quad [3]$$

and  $\sigma$  and  $\mu$  can be determined empirically, and  $\bar{a}$  is the absolute acceleration (O'Hanlon and McCauley, 1974; McCauley *et al.*, 1976). McCauley *et al.* (1976) found that  $\mu$  is suitably estimated by Equation 4,

$$\mu = k_1 + k_2 \cdot \log_{10} \left( \frac{1}{2\pi} \sqrt{\frac{m_4}{m_2}} \right) + k_3 \cdot \left[ \log_{10} \left( \frac{1}{2\pi} \sqrt{\frac{m_4}{m_2}} \right) \right]^2, \quad [4]$$

where  $k_x$  are constants to be resolved empirically,  $m_2$  and  $m_4$  are the second and fourth ship spectral moments described by Equations 5 and 6, respectively,

$$m_2 = \int_0^{\infty} \omega_e^2 S_z(\omega_e) d\omega_e, \quad [5]$$

$$m_4 = \int_0^{\infty} \omega_e^4 S_z(\omega_e) d\omega_e, \quad [6]$$

and are functions of the encounter frequency,  $\omega_e$  (Lloyd, 1998; Scamardella and Piscopo, 2014; 2015). The absolute acceleration,  $\bar{a}$ , in Equation 3 can further be defined in terms of the fourth ship spectral moment (Lloyd, 1998). Only vertical ship motion is considered in recommended motion sickness assessments, hence the z subscript in the ship motion response spectra symbol,  $S_z$  (ISO 2631-1, 1997).

Contrastingly to seakeeping performance assessments conducted in ship design, the MSI computed with the MSDV is adopted in international standards for the evaluation of motion sickness performed during vessel operation, such as full-scale sea trials, using Equation 7 (ISO 2631-1, 1997; Lawther and Griffin, 1987),

$$MSI = K_m \cdot MSDV. \quad [7]$$

$K_m$  is a constant that can empirically be determined for a specific seafaring group or be used as 1/3 for a mixed population of male and female adults that are unadapted to motion (ISO 2631-1, 1997). The MSDV can be computed with sensor measurements, using Equation 1, or seakeeping methods, using Equation 8,

$$MSDV = \sqrt{m_{4w} T}, \quad [8]$$

where  $T$  is again the duration of motion exposure and  $m_{4w}$  is the weighted fourth ship spectral moment.  $m_{4w}$  is denoted by Equation 9,

$$m_{4w} = \int_0^{\infty} \omega_e^4 S_z(\omega_e) G^2(\omega_e) d\omega_e, \quad [9]$$

where  $G$  is the frequency weighting function (Scamardella and Piscopo, 2014).

## Proposed Motion Sickness Assessment

The presented method suggests developing diagnostic motion sickness criteria using real-world sensor measurements and feedback from seafarers through human digital twins. Then, the results are to be integrated into seakeeping methods conventionally performed in ship design. The operational and design methods of computing the MSDV are associated with the knowledge that the MSDV in Equation 1 can equivalently be computed using Equation 10,

$$MSDV = \sqrt{T} \cdot a_{wRMS} \quad [10]$$

and that the square root of the weighted fourth ship spectral moment equates to the root mean square value of the weighted time signal of vertical ship acceleration,  $a_{wRMS}$ , measured over duration  $T$  in seconds (ISO 2631-1, 1997; Lloyd, 1998).

It is observed that the relationship between the MSI and MSDV is not strictly linear or necessarily proportional with a 3:1 ratio for all cases. Factors, such as age and sex, influence susceptibility to motion sickness (ISO 2631-1, 1997). A criterion of 30 m/s<sup>1.5</sup> for the MSDV is reported (ABS, 2021), considering Equation 6, however Taylor *et al.* (2023a) suggest that a cumulative distribution function, using a normal distribution of MSDV thresholds, provides a more relevant fit for relating the MSI and MSDV. This suggestion aligns with findings of the relationship between MSI and vertical ship acceleration in literature (O'Hanlon and McCauley, 1974; McCauley *et al.*, 1976). Linking the MSI and MSDV through a cumulative distribution function enables the development of diagnostic motion sickness criteria, as shown in Figure 4 with 95 % confidence intervals for an exposure duration of 6 hours.

**Figure 4: Cumulative Distribution Function with 95 % Confidence Intervals Serving as Diagnostic Motion Sickness Criteria.**

Novel motion sickness criteria such as this can be used to estimate the MSI for a cohort of seafarers from ship motion predicted using seakeeping methods. The proposed method recommends computing the MSDV using Equation 8 and estimating the MSI from the generated diagnostic motion sickness criteria. The estimated MSI can then be assessed against the desired criterion for seakeeping performance. Alternatively, an MSI criterion could guide the selection of the associated MSDV threshold if there is a preference for working with the MSDV.

## Human Digital Twin Deployment During Ship Operation

Human digital twins were deployed on board the SA Agulhas II to monitor the motion sickness of participating passengers (Taylor *et al.*, 2023a). A mobile application deployed on participant cell phones collected subjective feedback from seafarers that indicated whether they experienced any motion sickness symptoms or not (MSI) and tracked their location as they moved throughout the ship using near field communication (NFC) technology. In parallel, ship motion was measured by a full-scale measurement system, which computed an MSDV at all NFC tag locations over consecutive 5-minute durations.

Each seafarer human digital twin integrated the seafarer's present location with MSDV's in real time, computing an equivalent MSDV over 6 hours every 5 minutes that represented their extended motion exposure on a 3-week long research voyage. The human digital twins additionally fused the subjective feedback with the equivalent MSDV's to analyse the measurements of motion exposure against subjective observations. Individual MSDV thresholds, which were unique to each participating passenger, were computed using receiver operating characteristic curve analysis.

The individualised thresholds were used by a human digital twin that represented the motion sickness state of the cohort to generate a cumulative distribution curve with a normal distribution, which linked the MSI and MSDV metrics. In this way, the Cohort Human Digital Twin enabled the determination of a cumulative distribution curve within a real-world contextual environment, managing the evolution of the curve throughout the voyage. The equivalent MSDV computation duration was extended to accommodate durations from 0.5 to 6 hours in 0.5 intervals. A unique final cumulative distribution curve was generated for each duration, as shown in Figure 5.

**Figure 5: Diagnostic Motion Sickness Criteria Over Various Durations of Motion Exposure (adapted from Taylor *et al.*, 2023a).**

The use of diagnostic motion sickness criteria managed through the Cohort Human Digital Twin was validated. The validation procedure included requesting the MSI from the Cohort Human Digital Twin each time a new mean equivalent  $\text{MSDV}_{6\text{hr}}$  was computed based on the individually tracked locations of participating passengers. The procedure was run over the course of the 3-week research voyage to show that the latest cumulative distribution curve was accessible throughout the expedition.

Results of the estimated and observed MSI values are presented in Figure 6, of which the Spearman correlation was found to be 0.78 (Taylor, 2023). In Figure 6, MIZ is the marginal ice zone in the Southern Ocean. Ship motion in the MIZ was marginal compared to open water transits, hence the smaller values of observed MSI for participating passengers. Moreover, the MIZ separates the first and second open water voyage legs, such that adaptation to motion was observed by personnel having smaller MSI values (both estimated and observed) after the MIZ than at the start of the voyage.

**Figure 6: MSI Estimated (Objective) versus Observed (Subjective).**

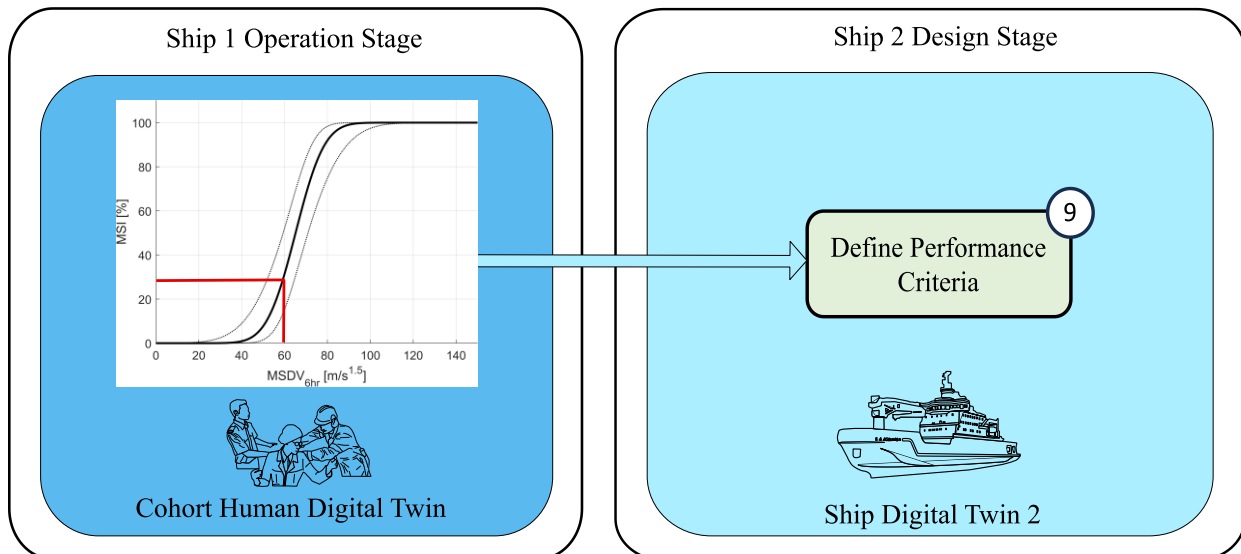

## DISCUSSION OF BENEFITS AND DRAWBACKS FROM THE INTEGRATION OF HUMAN DIGITAL TWINS TO INFORM SHIP DESIGN

Human digital twins for seafarers trialled in situ during a research voyage were seen to be effective systems for human-centred data acquisition and analysis on board a ship. The human digital twins enabled the development of diagnostic motion sickness criteria throughout the voyage, evolving with newly acquired data from both a full-scale ship measurement system and participating passengers.

The motion sickness criteria development was driven by data acquired from seafarers based on their actual experiences on board through a mobile application installed on participant cell phones. Therefore, the human digital twins tailored motion sickness criteria to a unique cohort based on individual responses. In this way, more detailed information is gathered about the MSI in relation to a human-centric ship motion dose metric (MSDV) than typical human response studies, which report using daily metrics acquired through paperbound questionnaires (Taylor, 2023). Moreover, the duration of motion sickness assessment can be tailored to specific voyage or vessel scenarios with periods ranging from 0.5 to 6 hours (see Figure 5). Motion sickness criteria identified in literature are applicable to a single duration only or do not provide related exposure times, which the MSDV computation is dependent on.

The diagnostic motion sickness criteria provided MSI estimates that were positively associated with the observed MSI, excluding the time in the MIZ. Here, a single participant stopped participating with their MSI showing a false positive while in the MIZ. The estimate of MSI is, therefore, more strongly associated with the observed MSI. The customised functionality of the human digital twins is considered beneficial for better understanding the real-world experiences of seafarers on board specific vessels, which could transpire motion sickness diagnoses. For example, the cruise industry could characterise customer satisfaction levels for their fleet.

It is envisaged that the best benefit of operational digital twins for informing design would be for fleets that operate with similar vessels, such as in the cruise and naval sectors. Human digital twins enabled production of data and results from analyses, which can provide access to results beyond a single operational voyage or the operational service of a vessel. Information flow could be facilitated from one voyage to the preparation phase of the next expedition, or from the service of one ship to the design of its or similar successors, as presented in Figure 7. The Cohort Human Digital Twin could make the cumulative distribution function accessible to Ship Digital Twin 2, which would need to define performance criteria for completing a seakeeping performance assessment. The motion sickness criteria provide an artefact of operation data acquisition and analysis that quantify the real-world experience of seafarers for informing ship design when defining performance criteria.

**Figure 7: Cohort Human Digital Twin in Ship 1 Operation Stage Informing Ship Digital Twin 2 in Ship 2 Design Stage.**

It is noted that the human digital twins require at least one deployment to incorporate real-world data. Results could be generated from simulations prior to a debut voyage, but would have to omit the inclusion of the actual experience of seafarers. The latter would provide the same results as seakeeping analyses performed previously. The human digital twins facilitated a quantitative,

empirical means of generating human-centric diagnostic criteria, compared to qualitative results readily employed during conventional seakeeping performance assessments. Such a system can be regarded a form of real-world seakeeping trials, which capture invaluable data for rare operational occurrences in situations beyond that of controlled, systematic seakeeping trials (NATO, 2000). The implication for ship design is an increase in information about ship operability that is captured during operation, which can be made available and used to guide strategic decisions. Nonetheless, it is noted that ship design is inherently complex, and the work presented provides evidence of a proof of concept that requires further development to comprehensively construct an information pipeline from ship operation to design.

## CONCLUSIONS

Constructing information feedback from data acquired and analysed during ship operations to the design stage has been proposed through digital twins for people and a ship. Human digital twins captured feedback from participating passengers, which allowed the automated generation and use of diagnostic motion sickness criteria that link the MSI and MSDV. A ship digital twin that implements seakeeping performance assessment procedures acted as a client of a cohort human digital twin to integrate the diagnostic motion sickness criteria. A real-world validation of the use of diagnostic motion sickness criteria was offered, highlighting that data managed through human digital twins can be made accessible beyond the scope of an operational voyage. Human digital twins are regarded as beneficial for integration with ship digital twins during vessel operation aiming to inform decision making throughout the lifecycles of seafarers and ships, but particularly back into ship design. In this way, human digital twins refine the practical understanding of operational situations at the time of ship design through data-driven artefacts produced during ship operation.

Future work includes using the proposed seakeeping performance methods with weather forecasts to predict ship motion and human motion sickness responses for a voyage. Results could be compared with in-situ, full-scale ship motion measurements and observed human responses over the duration of the same voyage. Moreover, MSDV thresholds extracted from the diagnostic motion sickness criteria are to be used to generate novel MSDV operability envelopes for comparison with results of real-world ship operation measured through ship and human digital twins.

## DATA ACCESS STATEMENT

Research data used to generate the plotted results is publicly accessible in an institutional repository (Taylor *et al.*, 2023c).

## CONTRIBUTION STATEMENT

**NC Taylor:** Conceptualisation; data curation; methodology; writing – original draft. **A Bekker and K Kruger:** Conceptualization; supervision; writing – review and editing.

## ACKNOWLEDGEMENTS

The financial assistance of the National Research Foundation (NRF), through the South African National Antarctic Programme (SANAP Grant No. 110737), towards this research is hereby acknowledged. Opinions expressed and conclusions arrived at are those of the author and are not necessarily to be attributed to the NRF.

The crew and managers of the SA Agulhas II, AMSOL, and vessel owners, the Department of Forestry, Fisheries and the Environment of South Africa are thanked for providing access to the ship and their significant research support during voyages. The passengers that participated in the human response research activities are greatly appreciated and thanked for their contribution.

Prof Martin Kidd is thanked for his guidance and assistance with statistical data analyses.

## ABSTRACT

*The aim of this paper is to illustrate the process of identifying the 'best compromise' solution for an all-electric destroyer at the concept design level. The design strategy reflects a paradigm shift from a sequential approach towards a holistic multicriterial approach. The destroyer is required for an extensive range and endurance, fully operable in rough sea states. A mathematical design model (MDM) that includes a set of metamodels, is implemented to evaluate the overall performance of feasible, then non-dominated designs. The power corridor concept is integrated into the MDM to optimize the location and functionality of the individual units of the power train. The fuzzy sets theory is used for normalizing and weighing incommensurable properties of candidate designs, so resolving many of the ill-defined requirements and criteria. The final result of this study is a top-level specification for the destroyer with enhanced performance and reduced power demand.*

## INTRODUCTION

The modern destroyer, born in response to the threat posed by torpedo boats to larger fleet vessels at the end of the 19th century, has evolved into a highly versatile and heavily armed surface unit. It is capable of escorting naval groups and merchant convoys, conducting anti-submarine operations, and engaging in air and surface combat with missiles, electronic warfare, and counter missions. Despite the vague classification between frigates and cruisers, destroyers often represent the most dominant surface units in the fleets of major navies.

In recent decades, there has been a steady increase in the size of naval vessels, and destroyers are no exception. Displacement and length have surpassed 10,000 tons and 160 meters, respectively, with vessels like the Zumwalt of the US Navy reaching 14,564 tons and 182.8 meters. This growth is driven by the escalating power demands of new sensors and onboard systems, as well as by the anticipated introduction of disruptive technologies such as direct energy weapons and railguns, currently under development or testing by several navies. These advancements underscore the heightened focus on the onboard electric power system, its architecture, and its arrangement. Specifically, there are increased requirements for safety, redundancy, and modularity to enhance ship survivability and facilitate retrofits and upgrades throughout the ship's operational lifespan, especially on full-electric ships.

To face these challenges, the main scope of this paper is to develop an innovative design approach for an all-electric destroyer where the integration of a power corridor plays a fundamental role in concept design and decision-making processes. This poses increasing challenges to naval ship design, which has to find new solutions and arrangements to cope with the increasing space and power demand (and thus, installed power, amount of fuel, etc.).

Destroyers are fast warships intended to escort larger vessels and equipped for antisubmarine warfare, with missiles for surface and air combat, as well as for electronic warfare. The new destroyer will have to guarantee high-level operability from the conceptual design phase, taking into account the following basic factors:

- the hydrodynamic quality of the ship hull, and the interaction of equipment, subsystems, and military installations between them and the ship body;
- the hull-environment interaction in rough sea states
- a set of crisp and soft criteria to be satisfied which respect all requirements of physical and normative nature.

To include simultaneously all these factors, it is necessary to change the paradigm in the ship design process. A multicriterial approach in ship design is the best answer for overcoming heuristic approaches such as the classic design spiral. In particular, more than the multiobjective design method, the multiattribute decision-making approach was found to be the most suitable for the concept design (Triantaphyllou, 2000; Trincas, 2001; Trincas et al., 2018). The theory of fuzzy sets was incorporated into the decision-making procedure to provide a simple mathematical tool to handle uncertainty and imprecision in the concept design phase.

Decades of experience on naval ships have shown that the order of importance to attach to the various hydrodynamic disciplines is seakeeping first, then stability and control both in the vertical plane and in maneuvering, then propulsion, and finally resistance. To respond to this scale of priorities right from the concept design, it is necessary to develop seakeeping metamodels to rapidly evaluate responses in a seaway while ensuring ship safety.

To define the new compartmental configuration with a deck dedicated to the power corridor with systems and equipment it contains, reference is made to the seminal papers of Nehrling (1985) and Cort & Williams (1987).

The paper has seven main sections. Section 2 illustrates the concept design strategy based on the principles of the multiattribute decision-making process. Section 3 describes the main feature of the power corridor designed to satisfy the destroyer's overall energy requirement. Section 4 describes the main modules that make up the mathematical design model. Section 5 deals with the decision support system where the attributes' outcomes are fuzzified. Section 6 develops the design of the baseline destroyer as an anchor point for competing designs. Section 7 contains the two phases of the multiattribute decision making process: generations of feasible designs and selection of the preferred design. Finally, section 8 draws some conclusions.

## **METHODOLOGY**

### **Ship Design Methods**

Successful engineering design, including ship design, is mainly a matter of fast and efficient decision-making in a conflicting environment. This is especially worthwhile for concept design, which is the most important phase of the global design process since it gives the highest opportunity to influence the overall efficiency and effectiveness of the ship a long way ahead. Even though evaluation of design alternatives requires rational decision-making, so far the usual way is still to reduce target complexity by using a heuristic approach in order to arrive at final technical decisions. Major weak points and ineffectiveness of still popular design methods mainly relate to the poor integration of different subsystems and the lack of mutual influence of design responses to different requirements.

Design theory has evolved to evaluate design alternatives in an integrated shell rationally, where multiple conflicting requirements, external environments, and mandatory rules are to be tackled simultaneously. This limit was overcome by the development of the multiple criteria decision-making (MCDM), which was also the name of the first conference on the subject held at the University of South Carolina in 1972. The basic concepts (optimization, satisficing solution, compromising set, ideal solution) of the MCDM can be found in the fundamental work of Zeleny (1982).

A profound debate conducted in the 1990s between naval experts and researchers, especially during IMDC and PRADS conferences, led to the distinction between multiple attribute decision-making (MADM) and multiple objective decision-making (MODM), different in application scope and underlying mathematical approach. The generally accepted conclusions were that the MADM approach is more suitable for the concept design phase (where analytical mathematics is generally used), while the MODM approach is recommended in the preliminary/contractual design phase when it comes to optimizing ship systems and subsystems. Trincas et al. (2018) summarized the impossibility of applying MODM methodologies in the concept design stage, also supported by the conclusions of recognized naval field MODM experts: Campana et al. (2007) among others. Therefore, the aim of this work is not to confirm the validity of the MADM methodology in developing a concept ship design, but to use it to propose a feasible project of an innovative all-electric naval vessel based on the power corridor concept.

### **Concept Design Modeling**

Many design teams forego a concept design altogether and proceed directly to the preliminary design phase. They usually follow the iterative design spiral procedure although mostly not in a formal way. Firstly, main dimensions are determined on a statistical basis; then a lines plan is developed and the general arrangement plan is fitted in. Hydrostatics and stability assessment, overall power estimate, engine selection, strength evaluation, seakeeping and manoeuvring qualities then follow from the analytical/numerical procedures applied to the single lines plan. A tedious trial and error process brings the relevant features of the design in balance. Such a design process is time-consuming, as no complete definition of the ship exists before a balance is reached at each turn of the design spiral.

The concept design is not a substitute for the traditional preliminary design; rather, it should precede it, yielding a top-level specification based on the primary characteristics and performance requirements of the preferred design. This early design stage has the aim of avoiding a redesign in a later stage, as often is necessary with descriptive methods (Trincas et al., 1994; Hubka and Eder, 1996) in ship design. The concept design is conceived as a new paradigm where the key words are selection, concurrency and multidimensional design space. The early phase of the ship design process requires reliable and fast time decisions, allowing the design team to explore a wide range of feasible solutions and offering increased assurance for benefits throughout the ship's lifetime. Such a demand requires that several fundamental features, normally associated with later phases of the design process, should be anticipated at the level of concept design. In the present study, one of these features is the

integration of the power corridor into the general arrangement plan and evaluation of its effect on the optimal choice of the main characteristics of the destroyer (ship dimensions, general plans, hydrodynamic properties). The concept design process follows a prescriptive model (Andreasen, 1992) that is broken down into three basic interrelated activities:

- *design analysis*: random generation and performance assessment of a large number of design alternatives that have to meet the required targets subject to crisp and soft constraints; this activity is performed by executing the mathematical design model so many times as to fill the design space enough;
- *design synthesis*: filtering the feasible designs (i.e., designs not eliminated automatically by crisp constraints); creating the set of non-dominated designs that constitute the Pareto frontier;
- *design selection*: based on different metrics and multiple attribute decision-making techniques, aimed at selecting the preferred design from the ones in the Pareto frontier.

The quality and accuracy of the *design analysis* is crucial, since it dramatically affects the target of obtaining a successful ship. Unfortunately, at concept design stage the design team is often faced with imprecise information on the functional requirements and uncertainties in the ship performance, as well as with the significant interaction and interconnectivity of the main ship design disciplines. All these aspects make ships complex systems that requires highly evolved decision tools to handle this high degree of complexity. Since it becomes impractical to rely on simulation and numerical codes for the purpose of concept design, a preferable strategy is to use approximation models, which are referred as metamodels as they provide a ‘model of the model’ (Kleijnen, 1987), to replace the expensive detailed simulation models. A metamodel-based approach (i.e., artificial intelligence applied to ship design) is the solution also to limit uncertainties across the predicted performance, functional requirements, building costs, and so forth (Derelöv, 2009), while reducing the computational expense and the design cycle time, and providing quick tradeoff for evaluation. Evaluation (*design synthesis*) and decision making (*design selection*) are key parts of the design process. In conventional ship design they are generally poorly structured and depend significantly on designers’ own perceptions, which often imply a subjective (and thus suboptimal) assessment as a result. To improve on the latter, the Authors propose an evaluation strategy that combines a MADM approach (Trincas et al., 1994; Pahl et al., 1996) with different techniques (feasibility judgement, ELECTRE method and Pareto frontier), to reduce the number of candidate solutions (Ulrich and Eppinger, 2007).

## POWER CORRIDOR

Cooke et al. (2017) introduced the concept of Power Corridor: a single entity incorporating distribution, conversion, isolation and storage of main bus power throughout the ship. The aim was to introduce significant advantages in terms of higher level of survivability, a simplified general arrangement plan of the ship as well as reduction of building and life-cycle costs.

Thanks to the on-land construction of the power corridor modules, and the subsequent easy onboard assembly, the cost of initial construction and repair (and future modernization) of the power corridor will be reduced compared to standard onboard power plants. Advantages in terms of standardization in modules’ production (e.g., power electronics converters based on the Power Electronics Building Blocks – PEBB – concept) and the possibility to de-risk new modules in the factory are also present. Thus, a reduction in production, installation, supply chain, and training costs is expected. The use of identical pieces of hardware and control interfaces rather than many bespoke units also provides improved maintainability.

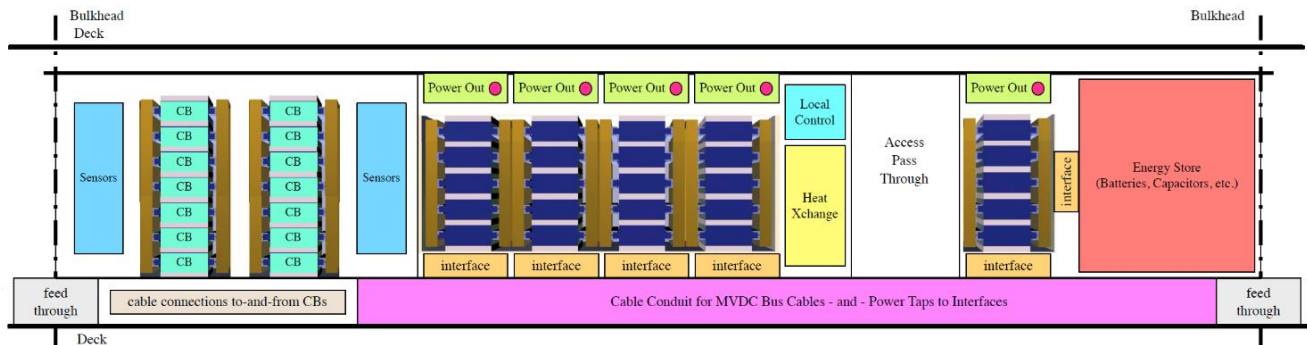

The installation of two redundant power corridors, installed onboard in separated locations, together with the centralization of the distribution, isolation, and energy storage functions, provides improved survivability. The interchangeability of the power corridor modules enables fast and easy replacement of faulted elements during service (without requiring ship docking).

The definition of a single entity dedicated to most of the functions related to electric power generation, distribution, and utilization, provides advantages in terms of quality of the ship design. In fact, the onboard arrangement can benefit from the Reserved Space approach, where the length and volume dedicated to the power corridor can be defined in the early phases of the ship design (Chalfant, 2015). This simplifies the process of allocating onboard the power system components, leading to the possibility of considering the power system design of an all-electric ship much earlier in the ship design process, enhancing the design results. This is because it encourages the ship’s design team to consider the power system as an integral part of the ship design, optimizing it dually in relation to the overall ship. The use of uniform modules also aids in this regard.

A representation of the Power Corridor is depicted in Figure 1. It is composed of the following main components:

- bus cable and conduit (magenta)
- power converter stack (dark blue and brown)
- interface junction box (orange)
- energy storage (salmon)
- circuit breaker or disconnect (teal)
- bulkhead penetration (gray)

The details about the Power Corridor concept can be found in Cooke et al. (2017).

**Figure 1: Modular integrated power corridor (Cooke et al., 2017)**

The Power Corridor concept briefly presented above is here used as a key point in the design process. Thanks to its modular nature, it enables the integration of critical components of the power system directly into the concept mathematical design model, thus expanding its capabilities. The expected result is the definition of a set of feasible ship designs, evaluated considering not only the usual ship design parameters and constraints, but also the electrical related ones (power, space, weight, cooling, etc.).

## MATHEMATICAL DESIGN MODEL

Ship properties that are likely to influence the identification of viable alternatives and their selection must be determined and analyzed as early as possible, that is, at the concept design phase. In fact, the success of the decision-making process in the concept design depends on how effectively the mathematical design model (MDM) simulates the real performance of the ship taking into account a sufficient number of primary properties (attributes). The MDM yields a large set of alternative solutions that have to be feasible in terms of the selected attributes. The candidate designs are randomly generated employing an adaptive Monte Carlo method. The structure of MDM is modular to allow the design team to vary or include different sets of analytical formulations and data to model the problem at hand with the greatest possible accuracy. It contains various design relationships for calculating areas, volumes, sizes, weights, electric power, stability, and so forth.

The MDM employs relationships based on practical design skills, scientific-based methods and metamodels based on statistical analysis of databases of similar ships, e.g. destroyers. It is written in Fortran 90 language.

### Structure of the Model

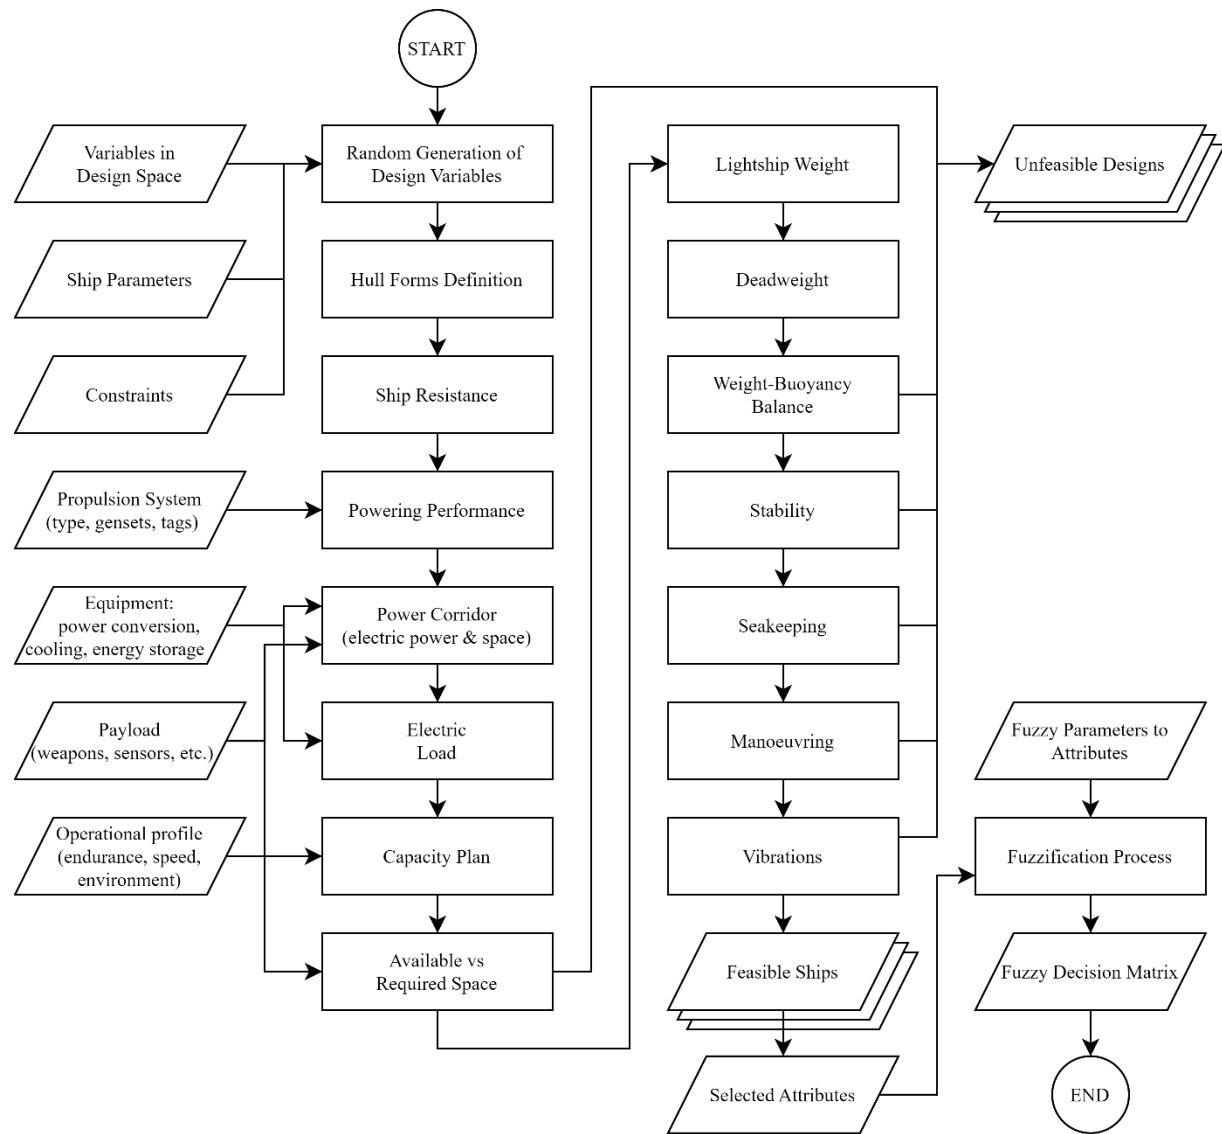

The general structure of the MDM for destroyers, denoted as DESMAD and described in Figure 2, evaluates the attributes by a number of analytical modules, some of which consist of metamodels.

Unlike other mathematical models developed by various naval design centres, DESMAD does not include any iterative process except in the hull steel weight module. The approach adopted is non-compensatory: if a candidate design does not overcome any crisp constraint of geometric, physical and/or regulatory nature, it is immediately discarded. Only the designs in which both primary and secondary attributes overcome the constraints are feasible and are stored in the decision matrix.

### Hullform Definition

This module selects the hull dimensions and relationships, which determine the technical requirements and capabilities of the candidate designs. The choice of appropriate form parameters has to comply with many constraints, mainly related to main dimensions and longitudinal prismatic coefficient. One crisp constraint is to have a natural roll period higher than 10 seconds to avoid the installation of large anti-rolling devices. As capability to sustain medium-high speed in rough weather and good ride quality are desired targets, a slender hullform is mandatory. The design waterline must have an entrance half-angle below 10 degrees. V-shaped sections are recommended even if at the expense of a slight extra building cost. In order to reach high efficiency at high speeds with minimum pressure pulses against the hull from the propellers, a hull/tip clearance not lower than 25 percent of the propeller diameter is imposed.

In each generation, some geometrical characteristics, such as  $C_B$  and  $C_{WP} = C_B/C_{VP}$  are immediately derivable from the independent variables. For this purpose, starting from four basic hulls and using the Box-Behnken four-level design DoE technique (Myers et al., 2016) a database of one hundred hulls was constructed whose geometric characteristics of interest ( $BM$ ,  $BML$ ,  $KB$ ,  $WS$ ,  $LCB$ ,  $LCF$ ) were determined by statistical analysis with the Response Surface Methodology (RSM).

**Figure 2: Flowchart of the mathematical design model**

## Ship Resistance

The still water resistance is evaluated by summing the bare hull resistance and the added resistance due to appendage as:

$$R_{CW} = R_{BH} + R_{APP} \quad [1]$$

**Bare Hull Resistance.** The resistance module estimates the resistance of the ship in calm water as well as in sea states 4, 5 and 6, at speeds ranging from 10 to 33 knots. Values of added resistance due to wind and hull roughness of 18 months are evaluated too.

The resistance in calm water is calculated following the DTMB methodology, where the residual resistance component is evaluated according to the algorithm of Fung (1991) that is statistically based on experimental measurements made on destroyer models with large transom sterns. The added resistance due to hull roughness and fouling is taken into account adding the allowance correlation according to formulas proposed by Townsin et al. (1981).

**Appendage Resistance.** A set of empirical formulas (Kirkman et al., 1979) are used to calculate separately the added resistance of each appendage, such as bilge keels, propellers, rudders, and shaft lines. The area of the bilge keels is taken as 2.5% of the waterplane area at the design draft to make more effective their contribution to roll damping. The sonar dome is considered as a part of the hull so contributing to the frictional resistance component of the bare hull. Added resistance due to steering is estimated using approximate formulas given by Norrbin (1972).

**Added Resistance due to Wind and Waves.** The added resistance in an irregular sea is based on the superposition principle for the components of the wave, motion and resistance spectra as well as on the assumption of linearity for the ship response. In a wave spectrum, the mean added resistance in regular waves is then calculated from

$$\bar{R}_{AW} = 2 \int_0^{\infty} \frac{R_{AW}}{\zeta_a^2}(\omega_e) \cdot S_{\zeta}(\omega_e) d\omega_e \quad [2]$$

where  $\zeta_a$  is the wave amplitude,  $\omega_e$  is the encounter frequency,  $S_{\zeta}$  is the spectral value.  $R_{aw}$  is determined using the formulation of Lang and Mao (2020) in unidirectional head regular waves:

$$R_{AW} = \frac{1}{2} \rho g \zeta_a^2 B B_f \alpha_T (1 + \alpha_v) \left( \frac{0.19}{C_B} \right) \left( \frac{\lambda}{L_{PP}} \right)^{Fn-1.11} \quad [3]$$

where  $\lambda$  is the wave length,  $B_f$  is the bluntness coefficient of the design waterline,  $\alpha_v$  is the speed correction factor depending on Froude number (Liu and Papanikolaou, 2016), and  $\alpha_T$  is the draft correction factor (Kwon, 2008). Calculations are performed at SS4, SS5 and SS6, which correspond to significant wave heights of 1.875, 3.250, and 5.000 meters according to the WMO. They account for a frequency of 43% in the North Atlantic. The resistance due to wind is calculated for head wind as:

$$R_W = 0.5 C_X \rho_a V_R^2 A_T \quad [4]$$

where  $V_R = V_S + V_W$ ,  $\rho_a$  is the air density, and  $A_T$  is the transverse ship area exposed to wind. The wind resistance coefficient in the longitudinal direction,  $C_X$ , given by the Isherwood formula (1973). The wind speed is correlated to the significant wave height as follows:

$$V_W = 6.851 \sqrt{H_{1/3}} \quad [5]$$

## Powering Performance

This module calculates the power developed at the speeds of interest in the required operating conditions, and determines the fuel consumption for each speed. The ‘design point’ of the fixed-pitch propeller is selected at the combat speed in a given sea state in order to take into account the increased loads the propeller will encounter over the years.

When a ship sails in a rough sea, the quasi-propulsive performance,  $\eta_D$ , decreases compared to calm water, since the open-water propeller efficiency decreases much more than the increase in hull efficiency. Minsaas et al. (1983) provided the following approximations for the reduction of thrust and torque coefficient because of lower propeller submergence due to waves and ship motions:

$$K_{T\beta} = \beta \cdot K_T \quad K_{Q\beta} = \beta^{0.8} \cdot K_Q \quad [6]$$

where  $\beta = 1 - 0.675[1 - 0.769 h/R]^{1.258}$  for  $h/R < 1.3$ , while the hull efficiency increases slightly due to the increase in the wake fraction and the irrelevant variation of the thrust deduction factor.

Change in the effective wake fraction due to hull roughness is estimated by applying a modified version of ITTC-1978 formula for full-scale wake prediction. Losses in propeller efficiency due to roughness and fouling are evaluated as proposed by Townsin (1983).

## Power Corridor

In DESMAD, the power corridor keeps its width and height constant for each generated ship, whereas its length varies depending on the ship length and its subdivision. These values dictate the allocation of dedicated volumes and areas for each design alternative within the required space module. By determining the total power requirements for payload, propulsion, and other non-vital loads through the Electric Load and Powering Performance modules, the volume required by all modules positioned in the power corridor can be assessed. Assuming a standard-sized cabinet within the power corridor (1.60 m wide, 2 m high) and employing a volume-to-power conversion for all main components, the occupied length in the power corridor can be calculated and compared to the available length. In this way, non-feasible solutions can be excluded and free length in

the power corridor reserved for future upgrades can be assessed. If a zonal distribution system is implemented, the available, required and free lengths are defined zone by zone to ensure proper accommodation of all components.

### Electric Load

The electrical load module assesses the maximum electric load in the winter cruise condition, including margins, since it is associated with the highest fuel consumption. The electric power value is obtained from the gensets, where a factor 0.91 is introduced to transform mechanical power into electrical power. The latter is the sum of payload electric power and non-payload functional electric load, including auxiliaries, outfitting, crew accommodations, heating, ventilation, and air conditioning (HVAC). In particular, the HVAC electric load power value is a function of the net volume of the ship, which is calculated by subtracting from the total volume of hull and superstructures the volumes of the engine and auxiliary rooms, the fuel tanks, the fore and aft peaks, the lavender water and grey water tanks, the trunks for aspiration and exhausted gas, as well as the volumes occupied by the military system. The payload electric load is considered an input, whose power value is determined by summing all the electric loads that are required to be installed onboard for performing the ship-specific missions (e.g., weapon systems, sensors, etc.). The non-payload electric load is automatically evaluated based on the ship's propulsion and manoeuvring performance, the number of crew members, and so on. All formulas introduced in this module are empirical. A margin is added to compensate for voltage fluctuations.

### Capacity Plan

To assess the required volume of tanks, first the fuel consumption required for the generators shall be assessed. Since it is the sum of the propulsion and electric consumptions, it turns out to vary significantly with different speeds, with the electric load associated with each operating condition, and with the demand of the military equipment (weapons, sensors, cooling).

In this respect, we deem that at the concept design level it is useless to try to make the gensets operate at the optimal load, i.e. the one with the lowest consumption. This strategy has the advantage of ensuring that the range constraint at cruising speed is respected with a safe margin. The fuel amount for the gas turbines is the same for all designs, whilst for the gensets the fuel rate is a function of the delivered power for the low, cruise and endurance speed, and of the power demand not satisfied by the gas turbines at combat and top speeds.

Fuel tanks must have sufficient volume to guarantee the range required at endurance speed. Other tanks are needed for lubrication oil, fresh water, ballast water, sewage, waste oil, and helicopter fuel. The volume of these tanks is calculated by means of simple empirical formulas.

### Available vs Required Space

The space balance of a ship has an overriding importance on the overall ship's effectiveness. Arrangement of spaces in the general arrangement plan is evaluated concurrently with hullform selection. Design whose available spaces (areas and volumes) are lower than required, are discarded immediately.

The subdivision scheme considers constraints on the location of machinery spaces, the need to have a discrete number of subdivisions of at least minimum length, as well as safety considerations. Subdivision arrangement and compartment arrangement follow the requirements of RINAMIL (2017a). The Available vs Required Space module evaluates available space within the hull against power corridor volume, machinery arrangement and tankage requirements based on length, height, and volume of machinery spaces for the required propulsion plant and auxiliary machinery. Tankage volume is validated against the required endurance fuel. Available ship areas and volumes are calculated for payload items and a variety of ship functional purposes. The superstructure and deckhouse above the main deck are specifically sized to meet design requirements for the remainder of the required payload, crew, and ship functions.

### Lightship Weight

The destroyer employs an all-steel construction. The components of the lightship weight (*LSW*) are classified by the US Navy Ship Work Breakdown System (SWBS). *LSW* is divided into six main groups, consisting of groups 100 through 600. Assessment of the hull steel weight (group 100) requires an iterative process since the weight of foundations can be determined only after having calculated the weight of the groups from 200 to 600, with due accuracy for 200-machinery group, 300-electric plant and 500-auxiliaries. A weight margin factor of 7.5 percent is added to the computed *LSW*; it includes 2.5% for future growth.

The longitudinal centre of gravity is assumed to coincide with *LCB*, whilst *KG* is increased with a margin of 3 percent.

The hull structure is divided into three primary components: longitudinal structures, transverse structures and super-structures. The weight of each component is calculated using the metamodels obtained from the statistical analysis of the results obtained from the structural calculations on the hundred ships in the database. All other weights in *LSW* are evaluated using empirical formulas as a function of the ship's main dimensions and coefficients.

## Deadweight

The deadweight (*DWT*) is the sum of the consumables (fuel weight, lubrication oil weight) and payload. It also includes the ballast water for trim adjustment through a compensation system.

The payload is mostly determined by the military payload in Group 400 and the entire Group 700, which consists of a fixed payload and a variable payload. The latter includes weights of the crew, provisions and required stores, which depends on the crew size and the required stores period, as well as on the helicopters, JP-5 fuel, missiles and ammunition. The fixed payload is basically the combat system weight (vertical launch system, railgun, weapons handling, etc.).

## Weight-Buoyancy Balance

The balance between the ship buoyancy and ship weight is assured through applying a crisp constraint. In detail, the relative difference between full load displacement  $\Delta_{FL}$  and the total ship weight  $W_{FL}$  shall be within 2.5 percent. This condition is stated as:

$$\frac{|\Delta_{FL} - W_{FL}|}{\Delta_{FL}} \leq 0.025 \quad [7]$$

## Stability

The general intact stability criteria of naval ships (RINA, 2017b) to be fulfilled for the righting lever curve are more stringent than the IMO criteria for merchant ships. Intact stability criteria are verified using empirical formulas for calculating cross curves of stability, as outlined by Degan et al. (2021). Subsequently, the righting lever curve is evaluated at the design draft to ensure compliance with stability criteria. A further criterion for intact stability is the feasibility range of the ratio  $C_{GM/B}$  between the metacentric height  $GM$  and ship beam at the design waterline  $B_{WL}$ . According to values assumed for the DDGx ship model, it can be expressed as:

$$0.090 \leq C_{GM/B} \leq 0.135 \quad [8]$$

Damage stability compliance is evaluated by determining the geometric floodable length using regression equations, following the approach of Mauro et al. (2019). These floodable lengths are then utilized to guide bulkhead allocation, as described by Braidotti & Prpić-Oršić (2023).

## Seakeeping

First of all, the module calculates the natural periods of heave, pitch and roll, subject to two crisp constraints: i) the natural roll period must be higher than 10 seconds; ii) the double heave and pitch periods must be quite different from the roll period.

For seakeeping assessment, various tools are available such as linear numerical codes based on "strip theory", completely reliable for single-hull ships up to Froude numbers equal to 0.35, nonlinear numerical codes, experimental tests on physical models and nonlinear numerical simulations. As stated above, the strategy underlying the concept design does not involve any direct calculation. Therefore, several metamodels were built at the University of Trieste (*UT*) where many ship responses were evaluated for the hundred ships generated with the DoE. Calculations were performed for the annual average significant wave height in the North Atlantic ( $H_{1/3} \approx 2.450$  m) at endurance speed. The sea was described by the two-parameter Bretschneider spectrum. The metamodels refer only to the root-mean-square (RMS) of motions and effects induced in the vertical plane in head sea. This hypothesis is entirely consistent with what was stated by Bales (1980): "It was further assumed that both the index and the relationship could be adequately quantified using analytically-based results for long-crested, head seas. The implications of this assumption are that rolling motion can be adequately controlled by subsequent appendage design, and that coupling effects from the lateral modes at oblique relative headings and/or in short-crested seas will not significantly alter trend identified under the relatively simple conditions evaluated".

The valued responses are heave, pitch, vertical acceleration at the bridge, relative motion and relative velocity at the propeller tip at 12 o'clock, relative motion at helideck, relative motion at sonar dome, vertical acceleration at railgun foundation, slamming and deck wetness. Corresponding metamodels may be expressed in functional terms as:

$$MS = f\left(\frac{BM_L}{L}, \frac{L}{B}, \frac{L}{T}, \frac{B_{tr}}{T}, \frac{LCB - LCF}{T}, C_{WP}, C_{VP}\right) \quad [9]$$

The operability limits for naval ships are given in Table 1. The more stringent ones are selected as crisp criteria in the mathematical design model. The *RMS* responses of the metamodels are unified in the seakeeping measure of performance (*MOP*) after weighing each seakeeping characteristic using the AHP method (Saaty, 1980).

**Table 1. Seakeeping criteria**

Recommended and Default Criteria	NATO STANAG (2020)	NORDFORSK (1987)	RINA (2017c)
Pitch (RMS)	1.5 deg		
Vertical acceleration at bridge (RMS)	2.0 m/s <sup>2</sup>	2.75 m/s <sup>2</sup>	
Motion sickness incidence (MSI)	20% in 4 hrs		35% in 2 hrs
Slamming		3% probability	20/hr
Deck wetness		5% probability	30/hr
Propeller emergence			90/hr

### Manoeuvring

As with the other properties of the destroyer, in the ship concept design a quick computation is required to assess the ship's maneuverability. This module predicts the attributes of course keeping, advance and turning ability, quantified by the tactical diameter, using the metamodels built on the basis of results obtained by calculations on ships of the destroyers' database, carried out with a code (Nabergoj, 2000) made available to UNITS. The code integrates the manoeuvring nonlinear equations by means of a fourth-order, variable step Runge-Kutta method. It uses hydrodynamic derivatives calculated using the formulas of Yoshimura and Masumoto (2011). The manoeuvring model is applied only in calm water.

To evaluate the path keeping, the evolution index of Norrbin (1971) – the so-called P-number -is used.

Maneuverability criteria for merchant ships are generally not applicable to the special requirements of naval ships. The attributes are subject to rules established by RINA (2017c). A bounding value of 3.5 ship lengths is applied for a minimum tactical diameter, whereas the P-number is required to have a minimum value of 5.0.

### Vibrations

The module calculates the first four natural frequencies of vertical hull vibration mode based on regression analysis of a large number of full-scale measurements, made available to UNITS. Then, the risk of unwanted resonance is estimated by comparing these hull natural frequencies with three excitation frequencies, i.e. engine second-order frequency, propeller imbalance and propeller blade frequency. An averting membership grade function is used to assign aspiration level to avoid the worst case of resonance between the excitation and hull natural frequency.

## DESIGN OF THE BASELINE DESTROYER

### Technical Specification

The technical specification is a more stringent variant than that formulated by the Italian Navy regarding the operating conditions. The military payload is that assumed for the USA Notional Ship (Chalfant et al., 2015; Chalfant 2017). The destroyer is required to operate in the wider Mediterranean Sea, the Arabian Gulf, and the Red Sea, as well as in the Atlantic, Indian and Pacific Oceans.

The ship must be capable of carrying out its functions for at least thirty years, in which operation must be guaranteed for at least 70% of the time, assuming as a reference employment away from national basins periods of up to 8 months (6 in the area and 2 for transfer). It must ensure compliance with MARPOL TIER III regulations, ensure transit of 1000 miles at a minimum speed of 12 kt and stay in port for 7 days in ECA zones.

The ship propulsion system shall be based on a conventional twin propeller/rudder solution, powered by electric motors, realizing an all-electric ship. The onboard gensets have to supply both propulsion and onboard loads, exploiting an integrated power system.

The crew is assumed to have 26 officers, 25 non-commissioned officers, 78 sergeants, 80 troops, plus 21 additional accommodations. The standard reference for living spaces on board, food storage and waste treatment is the SMM-100 regulations of the Italian Navy (Marina Militare Italiana).

The ship shall be characterized by logistical autonomy of at least 45 days and must be energy efficient neutral, e.g. green plus notation. It must be able to retain black and grey water on board for at least 7 days. Regarding military payload, the ship is required to include (Chalfant, 2017):

- 1 x railgun (impulse of 10 MW)
- 1 x laser gun
- 2 x 76/62 naval gun
- 2 x machine guns close-in weapon system

- 2 x multipurpose rocket launcher
- 3 x fixed face radar in both S and X bands
- 2 x integrated topside array
- 2 x 48-cell Vertical Launching Systems (VLS)
- 1 x sonar in the bulbous bow

## Power System Design

As the ship is all-electric, it is required to supply full power by means of electric generators, through a suitably sized integrated power system. The Power Corridor concept described above has been selected for this ship, and the Zonal Electric Power Distribution System (ZEDS) of Figure 3 has been defined. This solution offers significant advantages in terms of survivability and flexibility a ZEDS provides (Sulligoi et al., 2020) and is capable of managing large power level variations due to direct energy systems (Bosich et al., 2023), which are even more important for naval ships. The electrical zones follow the subdivision of the ship into Main Vertical Zones, and each can operate separately from the rest of the power system (provided that sufficient electrical power is available in the zone for the installed loads). Each load group is interfaced to one or both the power corridors by means of suitably sized power electronics converters, which have multiple functions. First, they step-down the voltage to the level required by the loads; second, they convert the DC voltage of the main buses in AC, if required by the loads; third, they manage the power flows in and out of the power corridors. Some of the loads (i.e., the chillers and the railgun) have no dedicated converter installed on the power corridor, because they either require specifically designed power supply systems (it is the case of the railgun), or they are supposed to already integrate conversion phases to perform their expected functions (it is the case of the chillers).

In relation to the onboard electric loads listed above, the definition of the interface converters' power has been made as follows:

- the 10 MW railgun requires a 17 MW power supply (Chalfant, 2017), which can be fully powered by either power corridor; the power supply is integrated into the railgun subsystems, thus interface converters are not required.
- the 300 kW laser requires a 0.5 MW interface converter, and can be fully powered by either power corridor.
- the 3 fixed-face radars in both S and X bands (3 MW total) and the integrated topside arrays (3 MW total) are powered by the same interface converters. The latter has a 4 MW size, thus being capable of supplying two-thirds of the total power from each power corridor. This is because contemporary and usage factors of these two loads are supposed to be not equal to one; despite this, full power operation is possible with both power corridors working and partial operation with half the power system down.
- the VLSs (0.5 MW for each set) are supposed to be fully operable also with one power corridor down, as well as the sonar in the bow (0.5 MW total), thus requiring equally sized interface converters on each side.
- the chillers, sized at 3.8 MW each to correctly manage all heat sources onboard and providing a 2 to 1 redundancy level, are fed alternatively by the two power corridors.
- other loads are also present onboard (e.g., the steering systems depicted in Figure 3, the cabin loads, and so on), which are alternatively supplied by the two power corridors through 2 MW interface converters. The latter are oversized by nearly 50%, to enable the supply of only the vital loads in the nearby zone in case of a fault (requiring a load shedding system to be put in place). This is highlighted by the dotted lines connecting such loads across zones in Figure 3.

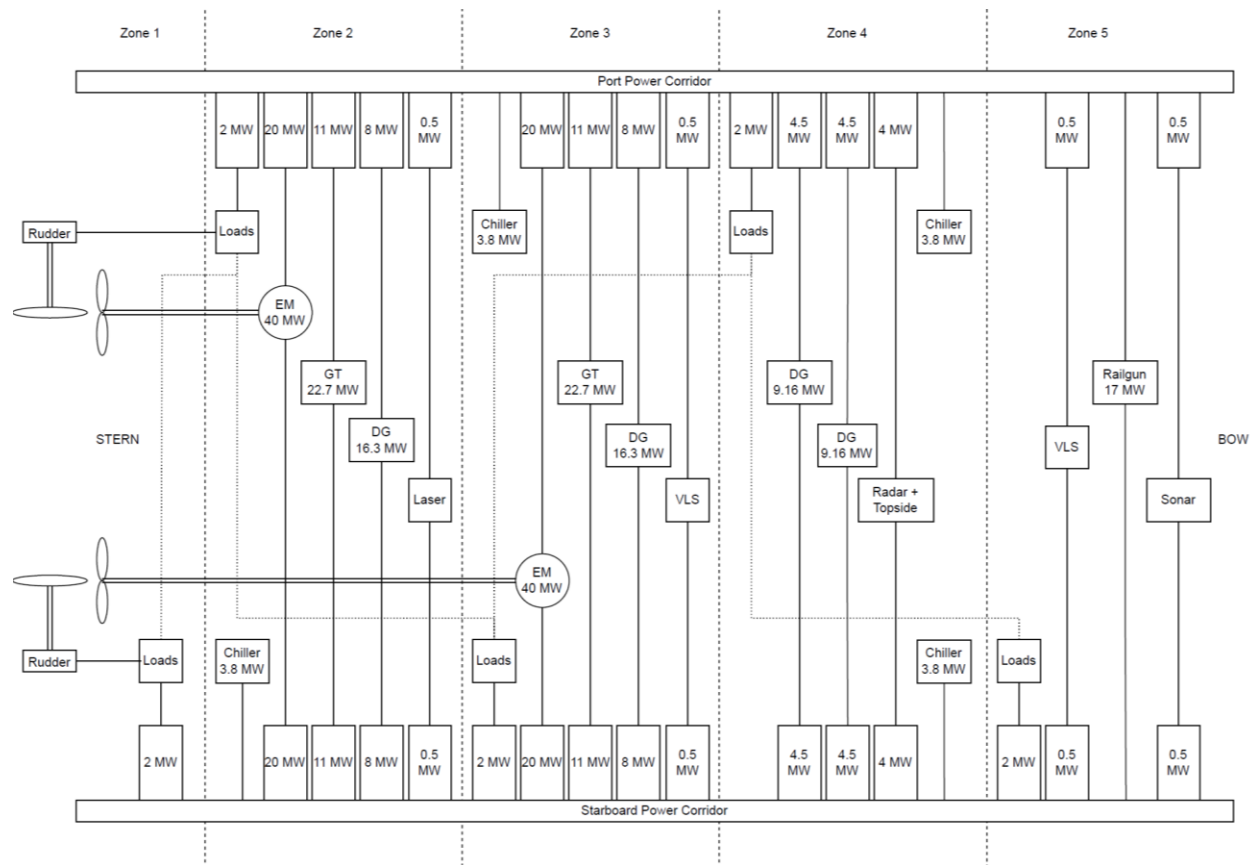

The 80 MW all-electric propulsion system, which requires one 40 MW electric motor on each shaft, is designed to be capable of powering both the propellers (albeit at reduced power) with one power corridor down. To this aim, the electric motors are dual stator winding induction machines, where each winding can provide half of the power. The two windings are thus supplied by 20 MW converters, integrated into the power corridors (thus not located inside the engine rooms).

The electric power generation system (composed by two 22.7 MW gas turbines, two 16.3 MW diesel generators, and two 9.16 MW diesel generators) follows the same approach as the propulsion system, with dual stator winding machines providing half the power to each power corridor. This enables to deliver up to 48 MW of power to the ship loads also with one power corridor faulted. As can be seen in Figure 3, the power corridor is distributed in five zones, whose lengths are shown in Table 2.

Payload weight and volumes have been taken from (Chalfant, 2017), while the non-payload and the HVAC loads weights and volumes are calculated by the above-described mathematical model.

The Power Corridor main distribution, located in its bottom part (refer to Figure 1), operates in medium voltage, at 12 kV. It has been sized to transport up to 60 MW from one extremity to the other in each power corridor, providing a 25% margin with respect to the generators' power for future refitting. Different solutions can be used to deliver such power, here a busbar system has been selected, leading to a minimum required space of 44 cm in height and 15 in width, to which cooling, and power tap systems, must be added. Similarly, a weight of 50 kg/m must be considered for the busbars only, to which additional weight for power tap and enclosures must be added. To reduce the overall weight and volume of this element, a possible solution is to reduce its power sizing in the more external zones (i.e., zones 1 and 5), where only the power needed by the local loads is to be delivered. However, a full distribution sizing has been here used, to both enable the installation of more loads in these external zones and promote standardization of the power corridor components.

For what it concerns the power electronics converters installed in the power corridor, their weight and volume follow the values defined in Chalfant (2017), depicted in Table 5 for reference.

**Figure 3: Zonal Electric Distribution System based on Power Corridor concept**

**Table 2: Available lengths of the zones**

Zone	1	2	3	4	5
Length (m)	14.0	24.8	32.4	29.8	10.0

The overall Power Corridor sizing has a width of 1.6 m, which requires a total reserved space of 3.8 m on each ship side for ensuring correct accessibility for maintenance, and a converter rack height of 1.9 meters maximum, to be installed on top of a 0.6 m height distribution conduit (refer to Figure 1). The total length of the power corridor can be inferred from the ship GAP, while the single converters length has been evaluated as the one required to obtain the Table 3 volume, when the above-mentioned width and height are fixed.

**Table 3: Nominal Power Converter Sizing Chart**

Power Rating (MW)	1	2	3	4	6	8	10	12	14	18	22	24
Weight (t)	2.55	2.73	2.91	3.09	3.72	3.78	3.90	3.96	5.61	5.73	6.44	6.62
Volume (m <sup>3</sup> )	12.9	12.9	12.9	12.9	15.1	15.1	15.1	15.1	20.8	20.8	24.2	24.2

## Preliminary Design

The concept of the prototype design is that of a multi-mission ship whose combat system is fundamentally based on that of the Notional Ship (Chalfant, 2017). It is an all-electric twin-screw and two-rudder destroyer with a “tumblehome” hull form to reduce radar signature. It has a wide flaring bow, which significantly allows high speed in heavy sea conditions. A representative rendering of the ship model is shown in Figure 4 with its main characteristics listed in Table 4.

The main data of the individual fixed-pitch propeller and rudder is listed in Table 5. The propellers are designed based on the hydrodynamic load present in the battle scenario.

The operating profile is assumed on an annual basis and is given in Table 6 in terms of the percentage of time during which the destroyer sails at speeds and related operative conditions given in Table 4.

**Figure 4: Rendering of the reference destroyer (in green: the port power corridor)**

The total electrical power is obtained by adding the vital and non-vital electrical loads to the electrical demand requested by the sensors, weapons and chillers. It is worth noticing that the total power installed on board (95,780 kW) is more than 15,000 kW in excess of the maximum power required at a speed of 31 knots in sea state 4, in anticipation of an increase in power to be installed in the power runner in the future. For powering the full electric propulsion system at low and medium speed, it is sufficient to operate only the Diesel gensets (the size of the running ones depends on the speed, as shown in Table 6), while at peak and combat speed the ship operates with all the Diesel and the Gas Turbine gensets running. Finally, the *MCR* percentages of the gensets are reported for each speed. The values of baseline ship's attributes are given below in section "Ranking for the Best Compromise Design".

**Table 4: General characteristics of the baseline ship**

<i>Length overall</i>	$L_{OA} = 179.000$ m	Range at endurance speed	8000 nm
<i>Length between perpendiculars</i>	$L_{PP} = 170.500$ m	Low speed	12 kn @ SS6 + wind
<i>Length at waterline</i>	$L_{WL} = 170.500$ m	Cruise speed	18 kn @ SS5 + wind
<i>Beam, maximum</i>	$B_{max} = 24.180$ m	Endurance speed	20 kn @ SS5 + wind
<i>Beam at design draft</i>	$B_{WL} = 22.250$ m	Battle speed	28 kn @ SS4 + wind
<i>Draft</i>	$T = 6.520$ m	Top speed	31 kn @ SS4 + wind
<i>Displacement</i>	$\Delta = 12592$ t	Complement	209
<i>Longitudinal center of buoyancy</i>	$LCB = 84.24$ m	Engines	2 x 9160 kW gensets
<i>Longitudinal prismatic coefficient</i>	$C_p = 0.614$		2 x 16030 kW gensets
<i>Waterplane area coefficient</i>	$C_{WP} = 0.732$		2 x 22700 kW tags
<i>Vertical prismatic coefficient</i>	$C_{VP} = 0.675$	Sensors, weapons, cooling	see Chalfant (2017)
<i>Metacentric height</i>	$KM = 11.024$ m	system, power conversion	
<i>Vertical center of gravity</i>	$KG = 8.684$ m	& distribution equipment	

**Table 5: Propeller and rudder characteristics**

<i>Propeller</i>		<i>Rudder</i>	
Diameter	= 4.620 m	Area	= 17.620 m <sup>2</sup>
Pitch ratio	= 1.257	Span	= 4.895 m
Expanded rea ratio	= 0.986	Tip chord	= 3.600 m
Number of blades	= 5		

**Table 6: Powering Performance**

<i>Ship Speed</i>	$V_S = 12$ kn	$V_S = 18$ kn	$V_S = 20$ kn	$V_S = 28$ kn	$V_S = 31$ kn
<i>Operating Time</i>	10.0%	52.5%	30.0%	2.5%	5.0%
<i>Delivered Power</i>	$P_D = 9592$ kW	$P_D = 12968$ kW	$P_D = 17852$ kW	$P_B = 39055$ kW	$P_B = 70855$ kW
<i>Total Electric Power</i>	$P_{EL} = 14726$ kW	$P_{EL} = 19796$ kW	$P_{EL} = 25164$ kW	$P_{EL} = 75415$ kW	$P_{EL} = 79740$ kW

## FUZZIFIED DECISION SUPPORT SYSTEM

In the multiattribute design process, a large number of feasible designs is created by execution of the mathematical design model with a set of design variables generated by an adaptive Monte Carlo method. Constraints of min-max, crisp or fuzzy type may be applied to any attribute value generated within the MDM. A design is feasible if all attributes are within the given limits. Among all feasible designs, only non-dominated ones in the Pareto sense are retained. The product is a hypersurface of non-dominated designs subject to a final selection strategy.

### Membership Grade Function

Ship design is a decision-making process whose nature generally involves uncertainty, vagueness or imprecision in the design attributes and constraints. Some of them are hard, i.e. based on physical laws or statutory norms, whereas some may be soft, i.e. based on the design team's aspiration level with uncertainty included. Moreover, in modeling the concept design process, deterministic algorithms are implemented to predict the attributes' values, which often cannot be determined exactly due to vagueness of many parameters and limited reliability of prediction methods. That is why the decision making necessitates a fuzzified decision support system. In fact, the concept design is intrinsically a fuzzy-logic problem where attributes may be weighed by the degree of membership reflecting the design team's knowledge and experience with the specific ship type. To present the notion that an attribute is a member of a set  $A$  (for example, the RINA weather criterion rules) either fully or not at all, the function  $\mu$  is introduced in Boolean terms as:

$$\mu_A(x) = \begin{cases} 1 & \text{if and only if } x \in A \\ 0 & \text{if and only if } x \notin A \end{cases} \quad [10]$$

stating that the design  $x$  has either a 0 or a 1 membership grade in the given set. When  $\mu_A(x)$  contains only the two points 0 and 1, the set  $A$  is non-fuzzy (crisp); in the above example, the weather criterion determines whether design  $x$  is feasible or unfeasible.

The  $i^{th}$  attribute's scores of a feasible design are viewed as a fuzzy set  $A$ , defined as the ordered set of pairs:

$$\{x_i, \mu_A(x_i)\} \quad i = 1, 2, \dots, n \quad [11]$$

where  $x_i$  denotes a design in the fuzzy set, whereas  $\mu_A(x_i)$  represents the degree of truth, i.e. the membership grade function  $0 \leq \mu_A(x_i) \leq 1$  for any  $x \in A$

The mathematical theory of fuzzy sets (Zadeh, 1965), also referred to as fuzzy logic, is concerned with the aspiration level  $\mu_A(x)$  reached by the outcome of an attribute, hence of a design.

Fuzzy sets may be treated as a collection of crisp sets by using the concept of an  $\alpha$ -cut. An  $\alpha$ -cut determines the crisp set  $A_\alpha$  having all elements of  $A$  with a membership grade greater than  $\alpha$ :

$$A_\alpha = \{x \in A \mid \mu_A(x) > \alpha\} \quad [12]$$

Thus,  $\alpha$ -cut sets correspond to discarding those elements of a fuzzy set that are 'extreme' in the sense of having 'low' membership grade in the set.

Among the three most important operations on any fuzzy sets, e.g. complement, union and intersection, the latter is the one useful in the MADM decision-making process. According to the intersection operation, the membership grade value of design  $x_i$  belonging to set  $A_1$  and to set  $A_2$  cannot be greater than the minimum of the two membership grade values:

$$\mu_{A_1 \cap A_2}(x_i) = \min [\mu_{A_1}(x_i), \mu_{A_2}(x_i)] \quad [13]$$

Generalizing for  $n$  attributes, we can write for the degree of total membership grade  $\mu_{\tilde{A}_j}$  of design  $x_i$ :

$$\mu_{\tilde{A}_j}(x_i) = \min [\mu_{A_1}(x_i), \dots, \mu_{A_k}(x_i), \dots, \mu_{A_n}(x_i)] \quad j = 1, \dots, k, \dots, n \quad [14]$$

### Fuzzy MADM Selection

After generating a number of projects that adequately fill the design space, a fuzzy multiattribute decision-making method was implemented to identify the non-dominated designs and select the optimal vector of design attributes, e.g. the ideal design. It consists of six steps:

1. structuring the decision matrix;

2. determining the membership grade  $\mu(x_i)$  for each attribute;
3. establishing the relative importance of the attributes by pairwise comparison;
4. weighing the degrees of attribute attainment  $\mu(x_i)$  by the respective  $w_j$  so creating the intra-attribute fuzzy sets  $\tilde{A}_j$ ;
5. finding the fuzzy set  $\tilde{D}$  of the non-dominated designs and the ideal design  $x_i^*$ ;
6. selecting the preferred design  $x_i$  that has the minimum distance from  $\tilde{D}$  as the preferred design.

**Decision Matrix.** The decision matrix organizes the data available to the decision maker at the beginning of the selection process. A design problem with a total of  $m$  feasible designs described by  $n$  attributes is structured in a  $m \times n$  matrix  $\tilde{A}$ . Each element  $a_{ij}$  of the matrix is the performance rating of the design  $A_i$  with respect to attribute  $x_j$ .

The decision matrix should include only those attributes which vary significantly among the alternative designs and for which the design team considers this variation significant.

**Intra-Attribute Preference and Attribute Normalization.** Intra-attribute preference reflects the objective importance of the different values of the same attribute according to the maximum target the design team aspires to. Although different approaches look alike (e.g. value function concept), the membership grade approach from the fuzzy set theory is considered the most suitable tool for the purpose (Kosko, 1994). Among different formulations of membership grade functions developed so far, the generalization of Nehrling's function (Nehrling, 1985) is introduced in this study. Four types are defined, i.e. attracting, ascending, descending, and averting, whose formulation is provided in Table 7.

**Table 7: Formulation of membership grade functions**

<i>Attracting</i>	$\mu(x_i) = \frac{1}{1 + \left  \frac{x_1 - x_i}{d} \right ^N}$	<i>Averting</i>	$\mu(x_i) = 1 - \frac{1}{1 + \left  \frac{x_1 - x_i}{d} \right ^N}$
<i>Ascending</i>	$\text{for } x_i < x_1 \quad \mu(x_i) = \frac{1}{1 + \left  \frac{x_1 - x_i}{d} \right ^N}$ $\text{for } x_i \geq x_1 \quad \mu(x_i) = 1$	<i>Descending</i>	$\text{for } x_i \leq x_1 \quad \mu(x_i) = 1$ $\text{for } x_i > x_1 \quad \mu(x_i) = \frac{1}{1 + \left  \frac{x_1 - x_i}{d} \right ^N}$

Two points on the membership grade curve are important and may be defined as

$x = x_1$  the level of an attribute that is 100% satisfactory -  $\mu(x) = 1$  -, i.e. the level that may be expected to be reached by the best design with respect to the specific attribute;

$x = x_1 \pm d$  the level that is only 50% percent satisfactory -  $\mu(x) = 0.5$  -, where  $d$  is the variation imposed subjectively by the decision maker compared to the aspiration level.

Selecting the proper type and assigning appropriate values to  $d$  and  $N$  (2, 4, 6, 8), the design team may shape the membership function for each attribute.

**Inter-Attribute preference.** Design attribute values serve as a basis for selection of the final design among all non-dominated designs. As the attributes are not equally influential, in order to reflect their relative importance it is necessary to weigh them. One solution is to obtain a weighted membership grade by multiplication with a weighting factor reflecting the subjective preferences of the design team. In this respect, the Analytical Hierarchy Process (AHP) method, which was pioneered and developed by Saaty (1980), converts subjective assessments of relative importance to a set of weights. It provides a useful mechanism for checking the consistency of the evaluation measures for attributes generated by the mathematical design model.

**Weighing the Intra-Attribute Fuzzy Sets.** According to Nehrling (1985), weights were originally applied to membership grade as:

$$[\mu_j(x_i)]^{w_j} = \frac{\mu_j(x_i)}{1 + w_i} \quad [15]$$

which did not take into account the number of attributes  $n$ .

To obtain better resolution of small weights when  $n > 5$ , a better solution was derived by Grubišić et al. (1997, 1998) as:

$$[\mu_j(x_i)]^{w_j} = \frac{\mu_j(x_i)}{1 + n(w_i - w_{min})} \quad [16]$$

Hence, membership grades are multiplied by 1 for  $w_i = w_{min}$  and by values progressively smaller than 1 for other weights.

**Choice of the Preferred Design.** Among a large set of feasible designs, no dominant design will exist that is better than all other designs in terms of all attributes. At the same time, it is impossible to minimize/maximize all attributes simultaneously. Since good values of some attributes inevitably go with poor values of others, the goal of the MADM method is to find the ‘best compromise’ solution following the concept introduced by Zeleny (1982). It can be obtained from a set of design alternatives referred to as the Pareto frontier, which consists of designs having a simple and desirable property, i.e. dominance (Pareto, 1906). According to this strong normative statement, a design is non-dominated, denoted as ND, when no attribute can be further improved without causing at least one of the other attributes to decline. Non-dominance can be expressed in terms of a simple vector comparison. If  $x^j = (x_1^j, x_2^j, \dots, x_n^j)$  and  $x^k = (x_1^k, x_2^k, \dots, x_n^k)$  are two designs of  $n$  attributes  $x^j$  dominates  $x^k$  if  $x_i^j \geq x_i^k$  and  $x_i^j > x_i^k$  for at least one attribute  $i$  and thus design  $x^k$  is discarded. Further pairwise comparison between feasible alternatives creates a set of non-dominated designs. At the same time, the collection of the highest achievable membership grades (attribute maxima) with all considered attributes form a composite, an ideal design  $x^*$  or ‘utopia point’ (Yu, 1973), denoted as  $x^* = (x_1^*, x_2^*, \dots, x_n^*)$ .

The hypersurface of the non-dominated designs defines the boundary of the production possibility, e.g. the limits attainable with each primary attribute depending on constraints of technological (and economic) nature. Then for each non-dominated design a fuzzy set  $\tilde{A}$  in  $X$  is the set of ordered pairs:

$$\tilde{A}_j = \{x_i, [\mu_j(x_i)]^{w_j}, \quad x_i \in X\} \quad [17]$$

The intersection of all  $\tilde{A}_j$  forms the fuzzy decision set  $\tilde{D}$  represented by the membership function  $\mu_D(x_i)$  which describes the ‘utopia point’.

The final step is to identify the ‘best compromise’ design from those contained in the fuzzy decision set  $\tilde{D}$  represented by the membership function  $\mu_D(x_i)$ . As the rationale of the designers’ choice is to prefer the solutions that are closer to the ‘ideal design’, the ‘best compromise’ design is that one with the minimum distance to the ideal design. In a fuzzy environment, the degree of closeness to the anchor value is measured via the Čebyšev metric as follows:

$$L_\infty = \min_j \left\{ 1 - \min_i [\mu_j(x_i)]^{w_j} \right\}_{i=1,n} \quad [18]$$

where the distance parameter  $\infty$  means that the maximum possible weight is given to the largest deviation according to Equation [16].

## MADM SELECTION PROCESS

The goal of the decision model is to simulate the decision-making of the design team in selecting the ‘best compromise’ destroyer from the Pareto frontier. The selection process is modelled as a MADM problem. The overall process for generating feasible designs, filtering non-dominated designs and selecting the preferred solution flows through the following steps: (i) identification of design variables, parameters, attributes and definition of individual min-max design space; (ii) generation of feasible design via an adaptive Monte Carlo method; (iii) definition of intra-attribute fuzzy functions and interactive inter-attribute preference; (iv) structuring the non-dominated design hypersurface; (v) selection of the ‘best compromise’ design.

**Generation of Feasible Designs.** The implemented mathematical design model is applied to the concept design of a class of destroyers whose main novelty is the presence of the power corridor. The propulsion system, the power from the electrical generators, the crew size, the vital and non-vital loads, the weapons and ammunition, the sensors, and the conversion and equipment distribution system are the same for all candidate designs. Viable and feasible solutions were generated subject to crisp constraints and soft constraints treated as attributes.

**Variables, Parameters, Attributes and Constraints.** The generated designs are uniquely defined by six independent variables given in Table 8, which define the design space through min-max values.

**Table 8: Initial design space**

Variable	$L_{PP}/B_{WL}$	$B_{WL}/T$	$L_{PP}/T$	$C_P$	$C_{VP}$	$L_{WL}/\nabla^{1/3}$
Minimal Value	7.250	3.000	23.750	0.615	0.600	7.000
Maximal Value	8.000	3.750	27.250	0.675	0.700	7.750

All candidate ships have data that is held fixed in a generation run, such as deck heights, number of zones, gas turbines, gensets, weapons, sensors, radars, cooling equipment, power conversion and equipment data, power corridor size, etc. The geometric topology and equipment are determined in advance as a result of the initial design of a destroyer prototype, which can be considered as the guess value to activate the mathematical design model.

Note that only the hull is defined by the random generation and not the superstructure. The size of the superstructure and deckhouse is a function of the length and beam of the hull. Not all generated ships yield feasible solutions since many other geometrical constraints are introduced which implicitly further restrict the multidimensional design space. The primary min-max constraints, which further restrict the design space, are illustrated in Table 9.

The mathematical design model calculates the primary and secondary attributes of feasible designs given in Table 10 together with their codes to simplify the writing of subsequent tables.

Attributes Y5 and Y10 are given as grades to reduce the number of attributes. Due importance is assigned to seakeeping and manoeuvring attributes because they heavily influence the operability of the ship.

**Table 9: Geometrical constraints**

Parameter	$C_B$	$B_{ML}/L_{PP}$	$KB/B$	$\Delta$ [t]	$B_{MAX}$ [m]	$L_{WL}/\nabla^{1/3}$	$i_E$ [deg]
Minimal Value	0.450	2.015	0.150	12250	23.750	7.000	5
Maximal Value	0.525	2.925	0.205	13000	25.250	7.750	10

**Table 10: Attributes in the design process**

Primary Attribute	Code	Secondary Attributes	Code
Fuel consumption at endurance speed (t/h)	Y1	Tankage volume (m3)	Y11
Power coefficient (-)	Y2	Metacenter height-to-beam ratio (-)	Y12
Weight-buoyancy balance (-)	Y3	Delivered power at endurance speed (kW)	Y13
Maximum speed (kn)	Y4	Delivered power at top speed (kW)	Y14
<i>MOP</i> membership grade function (-)	Y5	Electric load (kW)	Y15
Tactical diameter-to-length ratio (-)	Y6	Non-vital payload electric load (kW)	Y16
<i>P</i> -number (-)	Y7	HVAC electric load (kW)	Y17
Payload fraction (-)	Y8	Pitch (deg)	Y18
Available length for extra power corridor (m)	Y9	Volume of engine rooms (m3)	Y19
Vibration membership grade function (-)	Y10	Volume of power corridor (m3)	Y20

**Outcomes of the Generation Process.** The concept design starts with the generation of feasible designs. Fifty thousand destroyers were randomly generated. Only a little more than two thousand designs were found to be acceptable, overcoming all constraints. The cause of the unfeasibility of most of the ships was due to the fact that they had one or more geometric characteristics external to the design space. Other causes of elimination were, in decreasing order, an excessive detachment from the weight-thrust balance and non-compliance with the criteria of stability, seakeeping and manoeuvrability.

The process of design selection is interactive since designers might change and refine their preferences (sensitivity study). It is, therefore, of great importance to provide the design team with fast insight into multidimensional design and attribute spaces. To help in guiding the decision-making process a graphic support should be added.

For this purpose, three types of diagrams are proposed with the following combinations:

variable – variable	X-design space projection
variable – attribute	cross projection
attribute – attribute	Y-attribute space projection

The first group that relates the main dimensions and geometric coefficients to each other, serves to immediately identify the design space of feasible designs, so allowing to carry out an initial reduction of the feasible design space.

The second group is used to analyze the influence of any variable upon any attribute. It is useful for quantitatively predicting the effect of changing any variable on any attribute and for reducing the spans within which the variables are going to be generated in a next try. In this way, density of the non-dominated designs close to the ideal design may be increased.

The third group may be used as a guide to identify advantageous regions and to gain an impression of what may be the penalty for departing from the ideal solution.

Two examples in the X-design space are given in Figure 5. As can be seen, the feasible range of  $B/T$  ratio is dramatically reduced and reduces as the  $L/B$  ratio increases, making it unthinkable to have destroyers with  $L/B$  ratios tending towards 8. Relationship between  $C_B$  and  $C_{VP}$  allows to determine the feasible range for the waterline design coefficient, e.g.  $0.685 \leq C_{WP} \leq 0.748$ .

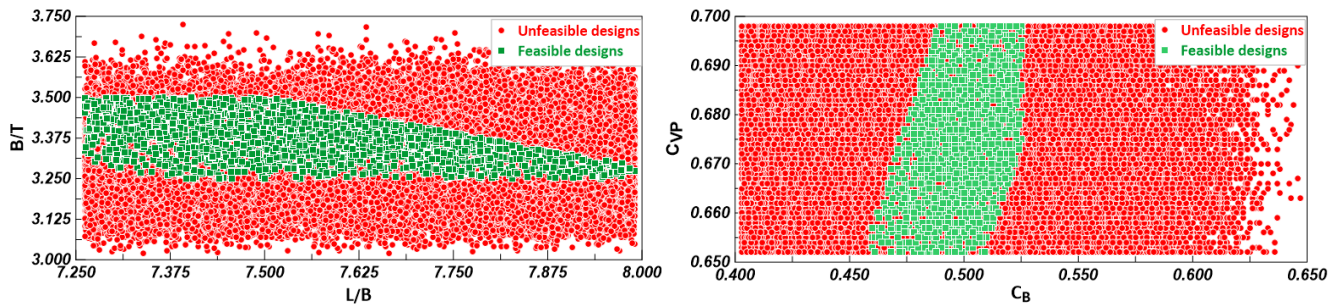

Figure 5: Variable-variable diagrams

### Selecting the Preferred Designs

The purpose of the following analysis is to rate the overall performance of the feasible alternatives via the proper assignment of numerical grades to attributes and to rank the best designs.

**Defining the Fuzzy Functions.** The subjective decision on the aspiration level and relevance of each attribute is summarized in Table 11. A more stringent aspiration level ( $n = 2$ ) is assigned to the hourly fuel consumption and free space in the power corridor for future storage of batteries.

Table 11: Selection of the membership grade functions

Attribute	Y1	Y2	Y3	Y4	Y5	Y6	Y7	Y8	Y9	Y10
Target	4.075	0.455	0	32.500	1.000	2.350	0.600	0.080	12.00	1.000
$d$	0.275	0.020	250	1.000	0.300	0.500	0.030	0.005	8.000	0.400
$n$	2	6	4	6	4	4	6	8	2	2
Fuzzy	Z-type	Z-type	$\Omega$ -type	S-type	Z-type	Z-type	S-type	S-type	S-type	U-type
$\alpha$ -cut	0.60	0.50	0.75	0.50	0.70	0.40	0.35	0.25	0.50	0.60

**Non-dominated and Ideal Designs.** The ideal solution (zenith) is characterized by the values of the attributes shown in Table 12, which represent the highest membership grades reached by different non-dominated designs in the multidimensional attribute space.

Table 12: Attributes of the Ideal Design

Fuel consumption	$MDO = 4.025$ t/h	Vertical acceleration at bridge	$ACC_V = 1.466$
Power coefficient	$C_{Power} = 8.08 \times 10^{-2}$	Relative motion at helideck	m/s <sup>2</sup>
Maximum speed	$V_{Max} = 32.44$ kn	Nondimensional tactical diameter	$RM_{hel} = 0.836$ m
Natural roll period	$T_\theta = 10.82$ s	Available length for future power corridor	$D_{tac}/L = 2.526$
			$L_{PC} = 11.650$ m

It is worth noting that the cross projections in Figure 6 show that both the baseline ship and ideal ship are very close to the Pareto frontier. Since both diagrams represent the power-speed relationship, this attests to the excellent quality of the resistance prediction in calm and confused seas and the design of the propulsion system.

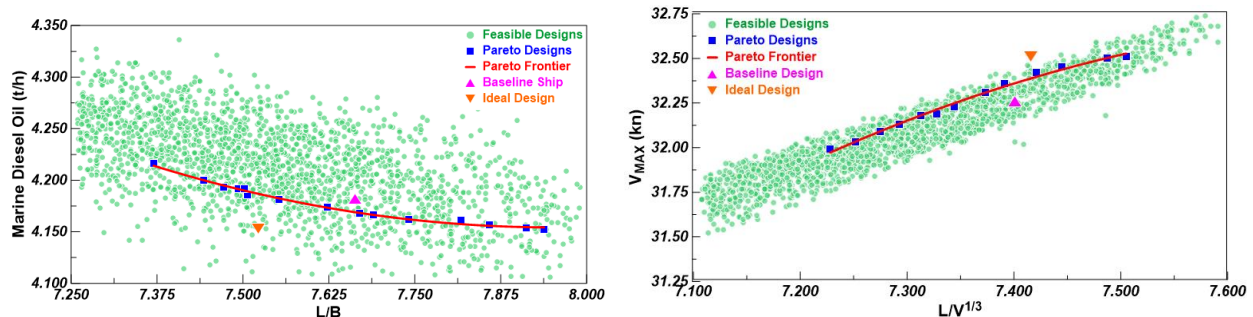

Figure 6: Variable-attribute graphs

Projection in the Y-space of the attribute-attribute relationship between available length for future enlargement of the power corridor and fuel consumption at endurance speed (left graph in Figure 7) shows that there are many possible designs with a longer power corridor than the baseline ship, but at the expense of a higher hourly rate.

**Ranking for the Best Compromise Design.** Measuring the distance of the non-dominated designs from the ideal point allowed us to build the ranking of the ‘best possible’ designs. Table 13 shows the comparison between the baseline ship and the ‘best compromise’ designs, where Design\_1 and Design\_3 are first and third in the ranking, respectively.

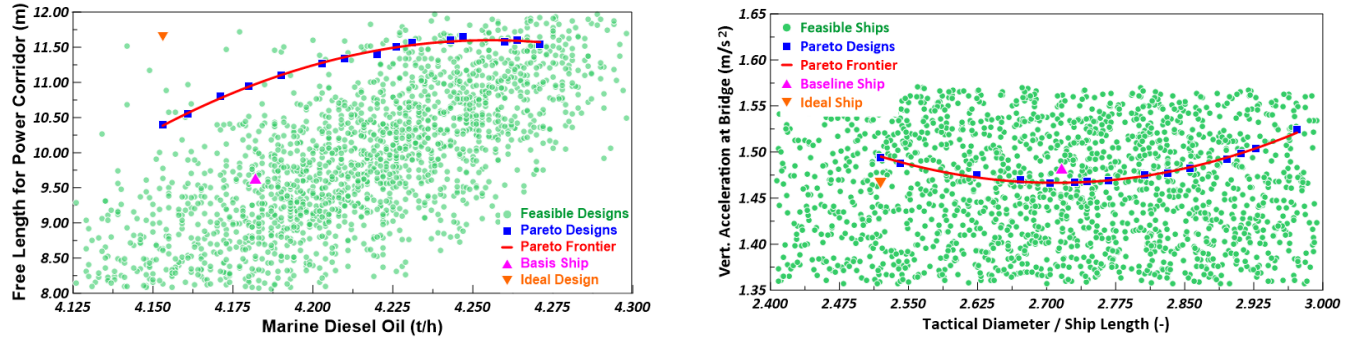

Figure 7: Attribute–attribute graphs

Table 13. Comparison between basic ship and the best possible designs

Item	Baseline Ship	Design_1	Design_2	Design_3
Main characteristics				
$L_{OA}$	179.00 m	180.18 m	181.75 m	180.52 m
$L_{PP}$	170.50 m	171.60 m	173.10 m	172.92 m
$B_{MAX}$	24.18 m	24.50 m	24.35 m	24.16 m
$B_{WL}$	22.25 m	22.52 m	22.40 m	22.18 m
$T$	6.52 m	6.37 m	6.48 m	6.56 m
$\Delta$	12592 t	12500 t	12577 t	12413 t
$C_P$	0.612	0.613	0.606	0.604
$C_{WP}$	0.752	0.768	0.759	0.746
$C_{VP}$	0.656	0.629	0.649	0.642
$KM$	11.024 m	11.029 m	11.008 m	11.459 m
Primary attributes				
Y1	4.082 t/h	4.179 t/h	4.167 t/h	4.168 t/h
Y2	4.57 x 10-2	8.32 x 10-2	8.28 x 10-2	8.11 x 10-2
Y3	32.11 kn	32.03 kn	32.07 kn	32.04 kn
Y4	10.83 s	10.91 s	10.19 s	10.81 s
Y5	0.972	0.986	0.974	0.979
Y6	2.515	2.414	2.538	2.532
Y7	0.512	0.533	0.535	0.525
Y8	8.24 x 10-2	8.35 x 10-2	8.40 x 10-2	8.37 x 10-2
Y9	9.00 m	9.35 m	9.31 m	9.50 m
Y10	0.984	0.987	0.974	0.980
Secondary attributes				
Y11	3908 m3	3924 m3	3951 m3	3961 m3
Y12	0.109	0.110	0.106	0.122
Y13	19913 kW	20031 kW	20201 kW	20318 kW
Y14	74703 kW	74269 kW	76185 kW	75830 kW
Y15	3737 kW	3740 kW	3771 kW	3739 kW
Y16	1695 kW	1698 kW	1714 kW	1697 kW
Y17	1436 kW	1436 kW	1458 kW	1428 kW
Y18	1.145 deg	1.137 deg	1.125 deg	1.079 deg
Y19	3371 m3	3407 m3	3487 m3	3458 m3
Y20	2246 m3	2252 m3	2309 m3	2223 m3

**Final Design Space.** To conclude, one of the most important results of this study is that of having reduced the multidimensional design space, as shown in Table 14, where the initial design space is put in comparison with the final one as limited by the non-dominated designs.

**Table 14. Design space before and after the concept design**

Variable	$L_{PP}/B_{WL}$	$B_{WL}/T$	$L_{PP}/T$	$C_P$	$C_{VP}$	$L_{WL}/\nabla^{1/3}$
Initial Design Space						
Minimal Value	7.250	3.000	23.750	0.615	0.600	7.000
Maximal Value	8.000	3.750	27.250	0.675	0.700	7.750
Final Design Space						
Minimal Value	7.370	3.250	23.950	0.615	0.620	7.225
Maximal Value	7.920	3.500	23.720	0.675	0.675	7.5050

## CONCLUSIONS

The contents of this paper are the result of a multidisciplinary cooperation project between MIT and UNITS, where the primary interest is to transfer know-how and technologies between still separated areas of naval architecture and electric-electronic engineering. We started from the belief that the introduction of advanced electrical and electronic technologies with integration of a power corridor requires a breakthrough in the design methodology (Sulligoi et al., 2016). To this purpose, a multiattribute decision-making process was applied to effectively select the ‘best compromise’ design which incorporates the power corridor. The results of the present work confirm the tendency towards increasing size of main surface combatants. It is about proposing ships that guarantee in the medium and long term the integration of additional systems and equipment that will absorb further electric and electronic power and require adequate space. It is for this reason that due importance has been given to the space available for future lengthening of the power corridor which is treated as a primary attribute in the decision-making process. Nevertheless, it has been here proved that in a main surface combatant, 2 power corridors, instead of original 4, might be sufficient to allocate all the required equipment with some margin.

The current MDM, although capable to provide reliable and interesting insights, can be further improved. Future enhancement of the mathematical model should include: (i) peak shaving to maximize the overall ship propulsive efficiency; (ii) competitive analysis of alternative power trains; (iii) optimization of power corridor layout; (iv) performance evaluation for energy storage systems to mitigate electric load fluctuations; (v) estimate of exhaust emissions by improvement of power distribution; and (vi) preliminary economic feasibility.

A limitation of this work is that all the primary and secondary attributes determined in the mathematical model are technical only. An economic module that calculates the annual average cost (AAC) index is completely missing. For a full picture of life-cycle costs, the economic module should include operating costs during the destroyer lifetime in addition to building costs including shipyard installation cost (excluding procurement cost) for command and armament. The AAC will be a dominant design criterion in a final analysis and selection of the ‘best possible design’. This future activity requires knowledge of cost constraints.

# Comparison and Evaluation of Learning Capabilities of Deep Learning Methods for Predicting Ship Motions

Mingyang Zhang <sup>1,\*</sup>, Cong Liu <sup>1</sup>, Pentti Kujala <sup>1,2</sup>, and Spyros Hirdaris <sup>3</sup>

## ABSTRACT

*The development of intelligent ship control systems in real-world conditions relies heavily on the accurate identification and prediction of ship seakeeping and maneuvering trajectories. In this study, we comprehensively evaluate a selection of deep learning methods to assess their learning capabilities in terms of idealizing ship motion behavior in realistic operational environments. To recover real conditions, we utilize historical Automatic Identification System (AIS) data and a time domain 6 Degree of Freedom (6-DoF) grounding dynamics model to generate ship motion sequences for a Ro-Ro passenger ship operating in the Gulf of Finland. Via a rigorous evaluation process, we validate the performance of these methods using extensive data streams. The analysis includes the identification and estimation of uncertainties between two ports. The paper demonstrates the proficiency of the selected deep learning methods in capturing ship maneuvering features, their potential use in the design of ship control and intelligent decision support systems.*

## KEY WORDS

Seakeeping, Maneuvering, Deep learning methods, Design for safety, Ship systems.

## INTRODUCTION

Seakeeping prediction methods can enhance our understanding of the dynamic behaviour of ships in stochastic seaways. The models are valuable for improving ship design operational efficiency and safety of ship operations. The development and use of intelligent decision support systems should account for motions and manoeuvres in real operational conditions. Predicting ship motions under real conditions provides a unique opportunity to help crew members understand ship dynamics in advance of a collision or grounding event (Zhang et al., 2023). The integration of empirical data with neural networks in deep learning models shows great promise. However, among the multitude of neural network models, the method that best captures ship manoeuvring features requires comparison and evaluation. Therefore, this paper aims to evaluate the learning capabilities of selected deep learning methods.

With the ongoing advancement in sensor and identification technologies, ship maneuvering system identification methods have emerged as a distinct set of techniques for predicting ship motions. Ship maneuvering parameter identification models are categorized into parametric and non-parametric. Parametric estimation models quantify ship dynamics using established ship theory (e.g., Maneuvering Modelling Group - MMG or Abkowitz models), to train large data sets. Recently the nu- Support Vector Machine (SVM) and a 3-DOF Abkowitz model have been utilized (Wang et al., 2019), while the extended Kalman Filter (EKF) has been coupled with the MMG model (Zeng et al., 2021) to predict hydrodynamic derivatives (Liu et al., 2021). Taimuri et al., (2022) introduced a predictive analytics approach for grounding avoidance using a rapid 6-DoF ship manoeuvring model. However, incorporating hydrometeorological conditions (wave, wind, current, etc.) into these methods poses challenges.

Non-parametric estimation methods quantify ship dynamics without relying on predefined models. Prominent models include Artificial Neural Networks (ANN) (Silva et al., 2022), machine learning methods, such as Gaussian Process Regression (GPR) (Ouyang et al., 2021; Ramirez et al., 2022), Recurrent Neural Networks (RNN) (D'Agostino et al., 2023), Long Short-Term Memory models (LSTM) (Sun et al., 2022; Zhang et al., 2021), Gated Recurrent Units (GRU) (Zhou et al., 2023), and Transformers (Zhang et al., 2023). These models can be trained using data from simulated free-running tests or sea trials. Recently, Luo et al. developed an ANN model to predict the 3-DOF motion of unmanned surface vehicles (Luo et al., 2022). Non-parametric models have shown potential in identifying ship motion features and rapidly predict ship motions.

To analyze the differences in predicting ship motions using deep learning methods this paper evaluates and compares the learning efficacy and capabilities of the above-mentioned methods.

## SHIP MOTIONS AND DATA

The analysis of ship motions often treats the ship as a rigid body moving in six degrees of freedom (6-DOF), using an earth- and ship body-fixed systems. In this paper, to capture the 6-DOF ship motions in real operational conditions, AIS (Automatic Identification System) ship trajectories are reconstructed for a ship operating between two ports. Time-domain hydro-meteorological data are sourced from now-cast data providers, and GEBCO (General Bathymetric Chart of the Oceans). Bathymetry data are employed to map the waterway (see Zhang et al., 2023 and Figure 1).

**Figure 1: 6-DoF ship motions along ship trajectories between two ports.**

The data collected serve as inputs to the FSI model of Taimuri et al., (2022) which idealizes the impact of operational conditions and control devices on ship motions. A Proportional Derivative (PD) controller is utilized to adjust the rudder according to the ship predefined heading, thus autonomously maintaining the desired AIS track for each voyage in real-time, see Zhang et al. (2023). The 6-DOF motions of the ship are depicted in Figure 2. The data utilized to compare and evaluate the learning capabilities of the selected deep learning methods are outlined in Section 3.

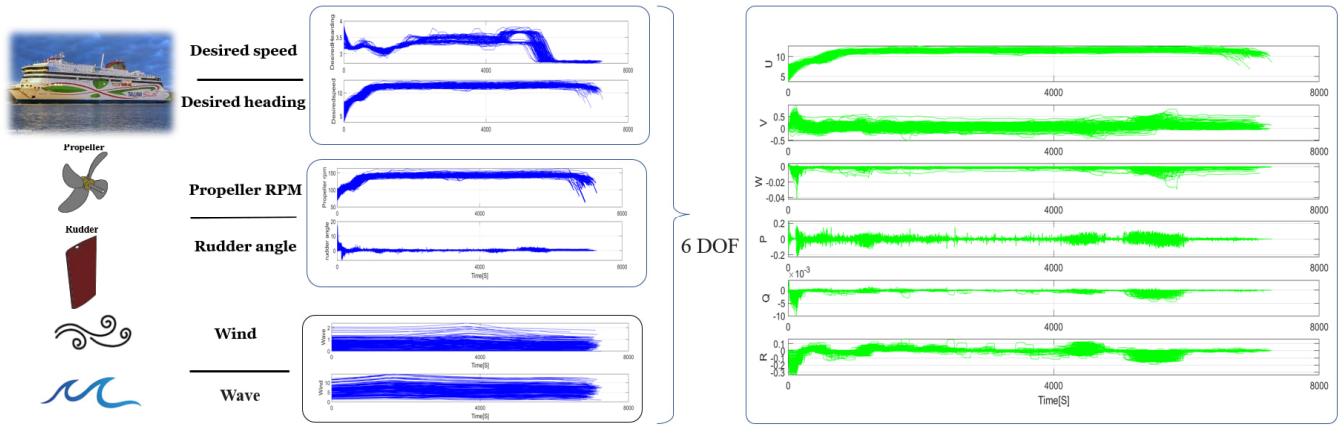

Figure 2: The ship maneuvering commands and the corresponding 6 DOF ship motions

## METHODS

This section offers an overview of 6 deep learning methods used for ship motion predictions, illustrating the operating principles of them and briefly describes the underlying mathematical logic of each method. In addition, these models are used to train ship motion prediction models using varying length of training dataset for the evaluation of model learning capabilities, as shown in Figure 3.

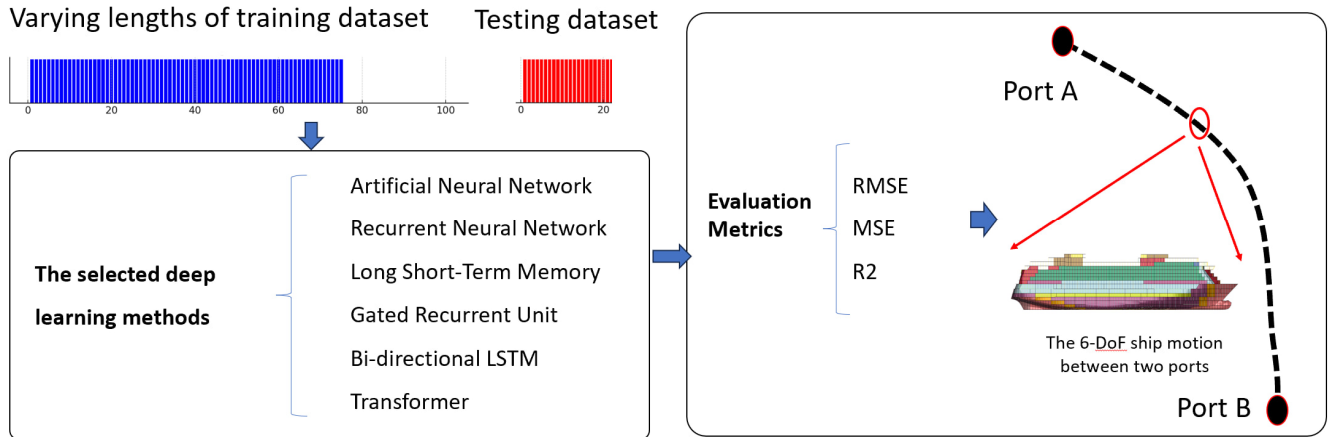

Figure 3: The flowchart of comparison and evaluation of learning capabilities of selected deep learning methods

### Selected Deep Learning Models

In this section, the theories behind the 6 deep learning methods (ANN, RNN, LSTM, Bi-LSTM, GRU, and Transformer) used in existing studies are presented to help understand the mathematical logics and the advancements in deep learning technologies for predicting ship motions.

#### (1) Artificial Neural Networks (ANN)

ANN are a foundational neural network type and a critical component of deep learning technology that may be utilized to predict ship motions (Luo et al., 2022). It comprises of three main layer blocks, namely, an input layer, one or more hidden layers, and an output layer. Each neuron in a layer is connected to every neuron in the preceding and following layers, see Figure 4, where the connections (represented by arrows) contain learnable parameters. The principle of back propagation is employed to adjust the network parameters, by effectively mapping inputs to outputs to approximate various nonlinear functions as follows:

$$h = XW^h + b^h \quad (1)$$

$$y = hW^y + b^y \quad (2)$$

where  $W^h$ ,  $W^y$  are weights and  $b^h$ ,  $b^y$  are biases.

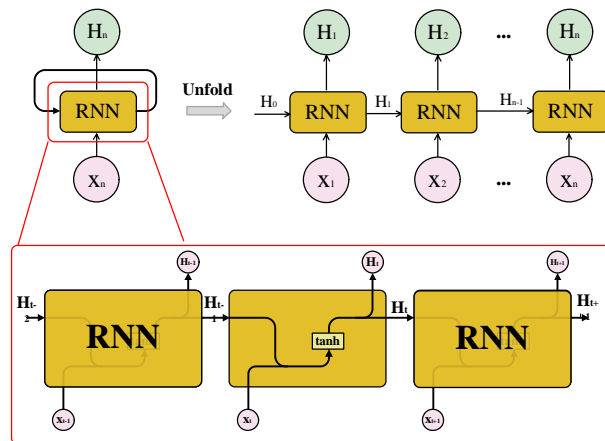

**Figure 4: Diagram of ANN architecture**

## (2) Recurrent Neural Networks (RNN)

RNN represent a type of neural network known for their robust processing of time-series data. Recently, they have been used to predict ship motions (D'Agostino et al., 2023). Unlike ANN, RNN models excel at considering temporal correlations by integrating historical and current information. RNN also serve as a comprehensive framework of neural networks, encompassing various variants, see Figure 5. In a standard RNN, the process begins with an initial hidden state, denoted as  $H_0$ . At each time step  $t$ , the input  $X_t$  is fed into the hidden layer of RNN, where it is combined with the hidden state from the previous time step, see Eq. (3). This combination introduces nonlinearity to the model through an activation function. The activation function, see Figure 5, is typically the hyperbolic tangent -  $\tanh$ . Ultimately, this process results in the generation of the current output and the updated hidden state.

$$H_t = \tanh(X_t W_x + H_{t-1} W_h + b_h) \quad (3)$$

where  $W_x$ ,  $W_h$  are the weight matrices and  $b_h$  is the bias.

**Figure 5: The framework and architecture of RNN**

## (3) Long Short-Term Memory (LSTM)

In conventional RNN, the issues of gradient explosion and gradient vanishing often arise, hindering a network's ability to predict long sequences effectively (Bianchi et al., 2017). To address this limitation, the LSTM model introduced by Graves, et

al. (2012) was used to train ship motion prediction models (Sun et al., 2022). The LSTM enhances the standard RNN architecture by incorporating three distinct gates namely input, output, and forget gates. These gates allow to selectively retain or discard information, thereby enabling it to effectively utilize long-distance temporal information and significantly improve the model's learning capability.

As illustrated in Figure 6, at a time step  $t$ , the current input information is fed into the LSTM, along with the hidden state from the previous time step. This information is then nonlinearly processed by the Sigmoid ( $\sigma$ ) activation function to compute the values of the three gates. The computations for these gates are defined as follows:

$$F_t = \sigma(W_F \cdot [H_{t-1}, X_t] + b_F) \quad (4)$$

$$I_t = \sigma(W_I \cdot [H_{t-1}, X_t] + b_I) \quad (5)$$

$$O_t = \sigma(W_O \cdot [H_{t-1}, X_t] + b_O) \quad (6)$$

where  $W_F$ ,  $W_I$ ,  $W_O$  are the weight matrices of the forget, input and output gates respectively, and  $b_F$ ,  $b_I$ ,  $b_O$  are the biases of the three gates respectively.

The candidate memory element  $\tilde{C}_t$  is calculated as shown in Eq. (7), utilizing the hyperbolic tangent activation function  $\tanh$ . This process determines the information to forget or retain by multiplying the forget gate output  $F_t$  with hidden state  $H_{t-1}$  at the previous moment. The new cell state  $C_t$  is then obtained by adding the memory cell to the information selected by the forget gate. Finally, the latest hidden state  $H_t$  is derived by combining the output gate  $O_t$  and the new cell state  $C_t$  as indicated in Eqs. (8) - (9).

$$\tilde{C}_t = \tanh(W_O \cdot [H_{t-1}, X_t] + b_O) \quad (7)$$

$$C_t = F_t * H_{t-1} + I_t * \tilde{C}_t \quad (8)$$

$$H_t = O_t * \tanh(C_t) \quad (9)$$

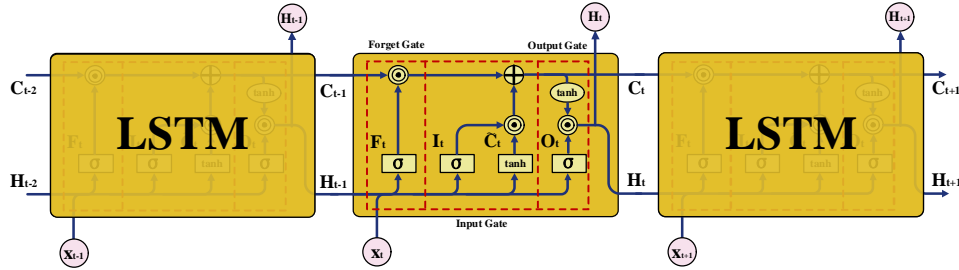

Figure 6: Diagram of LSTM architecture

#### (4) Gated Recurrent Units (GRU)

GRU are RNN models improved via LSTM and designed to address issues of gradient explosion and vanishing gradients (Chung et al., 2014). Their application for ship motion predictions are presented in Zhou et al. (2023). As compared to LSTM, the GRU simplifies the model architecture by featuring only two gates namely the update gate  $Z_t$  and the reset gate  $R_t$ , see Figure 7. This streamlined structure allows the GRU to achieve performance comparable to that of LSTM while enhancing training efficiency and computational speed. The computational process of the GRU is outlined as follows:

$$Z_t = \sigma(W_Z \cdot [H_{t-1}, X_t] + b_Z) \quad (10)$$

$$R_t = \sigma(W_R \cdot [H_{t-1}, X_t] + b_R) \quad (11)$$

$$\tilde{H}_t = \tanh(W_H \cdot [R_t * H_{t-1}, X_t] + b_H) \quad (12)$$

$$H_t = (1 - Z_t) * H_{t-1} + Z_t * \tilde{H}_t \quad (13)$$

where  $W_Z$ ,  $W_R$ ,  $W_H$ , are weight matrices,  $b_Z$ ,  $b_R$ ,  $b_H$  are biases,  $\sigma$  is the Sigmoid function, and  $\tanh$  is the hyperbolic tangent function.

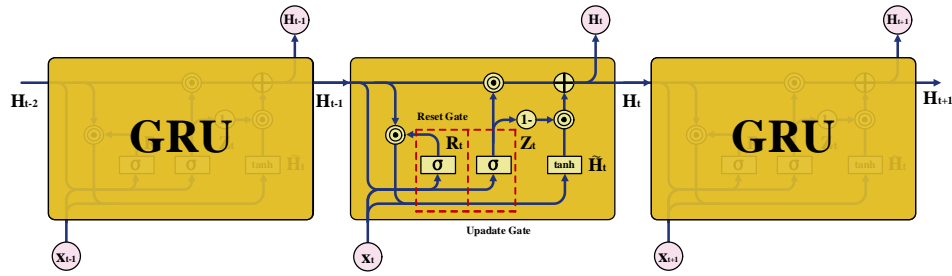

Figure 7: Diagram of GRU architecture

#### (5) Bi-directional LSTM

In the traditional LSTM model, information can only be recorded from the past, propagating from front to back. However, Bi-directional LSTM (Bi-LSTM) networks are also capable of combining information from both the past and the future (Zhang et al., 2024). This is achieved by constructing associations between the current time step information and the information from both preceding and succeeding time steps, see Figure 8. By leveraging this approach, Bi-LSTM models can learn more complex temporal features, leading to improved prediction accuracy and robustness, see Eqs. (14)-(16).

$$H_t^{fwd} = LSTM_{fwd}(X_t, H_{t-1}^{fwd}) \quad (14)$$

$$H_t^{bwd} = LSTM_{bwd}(X_t, H_{t+1}^{bwd}) \quad (15)$$

$$H_t = [H_t^{fwd}, H_t^{bwd}] \quad (16)$$

where  $X_t$  is the input at moment  $t$ ,  $H_t^{fwd}$  is the state of the forward LSTM,  $H_t^{bwd}$  is the state of the reverse LSTM, and  $H_t$  is the output of the Bi-LSTM after combining the positive and negative states.

Figure 8: Diagram of Bi-directional LSTM structure

#### (6) Transformers

The introduction of attention mechanisms has significantly enhanced deep learning methods with widespread application in time series prediction (Zhang et al., 2023). Transformer models employ a multi head self-attention mechanism and an encoder-decoder architecture to extract deep features from training data. Supervised learning trains on historical data, with model parameters updated via back-propagation to progressively approximate true values. The Transformer encoder comprises a series of  $N$  identical layers, each containing two sub-layers: a multi-head self-attention mechanism and a fully connected feed-forward network. Both sub-layers undergo normalization operations and incorporate residual connectivity to facilitate information flow. The decoder, similarly, comprises of  $N$  identical layers. However, it includes an additional third sub-layer in each sub-layer. This additional sub-layer tasks with masking the self-attention mechanism to ensure predictions for a given position can only depend on previously known outputs, see Figure 9. To incorporate position information within the model, positional encoding is applied at the base of both encoder and decoder layers as follows:

$$PE_{(pos, 2i)} = \sin(pos/10000^{2i/d_{model}}) \quad (17)$$

$$PE_{(pos, 2i+1)} = \cos(pos/10000^{2i/d_{model}}) \quad (18)$$

where  $pos$  is the position and  $i$  is the dimension of the  $d_{model}$ .

The attention mechanism utilized in the Transformer model is the scaled dot-product attention. This mechanism involves stitching together multiple attention heads to form distinct subspaces, enabling the model to learn features from various perspectives. Additionally, each layer includes a fully connected feed-forward neural network. This network is independent and applied to each position identically across the sublayers. The computation within this network proceeds through the ReLU (Rectified Linear Unit) activation function, as follows:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V \quad (19)$$

$$MultiHead(Q, K, V) = Concat(head_1, \dots, head_h)W^O \quad (20)$$

$$\text{where } head_i = Attention(QW_i^Q, KW_i^K, VW_i^V) \quad (21)$$

$$FFN(x) = max(0, xW_1 + b_1)W_2 + b_2 \quad (22)$$

$$ReLU(x) = (x)^+ = max(0, x) = \begin{cases} x & \text{if } x > 0 \\ 0 & \text{if } x \leq 0 \end{cases} \quad (23)$$

Where Q, K, V are query, key, and value respectively,  $\sqrt{d_k}$  is the vector dimension, h is the number of parallel attention heads,  $W_i^Q$ ,  $W_i^K$ ,  $W_i^V$  are the weight matrices,  $W_1$ ,  $W_2$  are the weights, and  $b_1$ ,  $b_2$  are the biases.

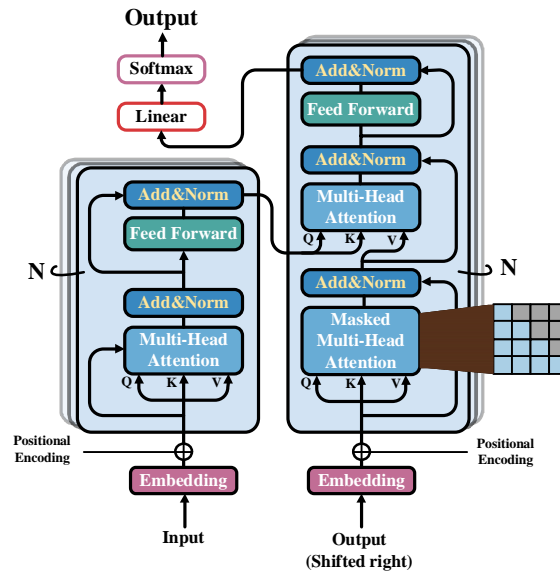

Figure 9: Diagram of Transformer architecture

### Model Evaluation Metrics

To evaluate the performance of these selected deep learning models and quantify the errors between the real and the predicted ship motions, Root Mean Square Error (RMSE), Mean Square Error (MSE), and  $R^2$  value (coefficient of determination) were evaluated, as:

$$RMSE = \sqrt{\frac{1}{N} \sum_{n=1}^N (y_n - \hat{y}_n)^2} \quad (24)$$

$$MSE = \frac{1}{N} \sum_{n=1}^N (y_n - \hat{y}_n)^2 \quad (25)$$

$$R^2 = 1 - \frac{\sum_{n=1}^N (y_n - \hat{y}_n)^2}{\sum_{n=1}^N (y_n - \bar{y}_n)^2} \quad (26)$$

In the above expressions,  $y_n$  is the actual value,  $\hat{y}_n$  denotes the predicted value,  $\bar{y}_n$  is the mean value.

## RESULTS AND DISCUSSION

The results presented utilise 400 (80%) of the 500 ship trajectories from Section 2. A 6 DOF ship motions model of each ship trajectory is used to train the selected 6 deep learning models presented in Section 3.1. The remaining 100 (20%) ship trajectories serve for validation purposes. (See Section 4.1). To keep the hyperparameters of these deep learning models unchanged, training sessions encompassing different data volumes are used to examine how the amount of data influences model efficacy, see Section 4.2. Through this comprehensive analysis, attempts to pinpoint the predictive accuracy of models and identify the data volume necessary to achieve training saturation. In this sense the results presented may be useful to develop ship motion prediction models that possess the ability to learn and adapt.

### Results of Ship Motions Prediction Using Various Deep Learning Models

Based on the data presented in Section 2, different machine learning models have been utilized to train predictors for ship motions. The inputs to these models are propeller RPM and rudder angle. The outputs are the 6 DOF of ship motions along ship trajectories. Their configurations are outlined in Table 1. Hyperparameters are optimized using a grid search method, with the best parameters determined by the lowest MSE obtained during validation (Zhang et al., 2024).

**Table 1: The characteristics of the selected models and the optimal hyperparameters**

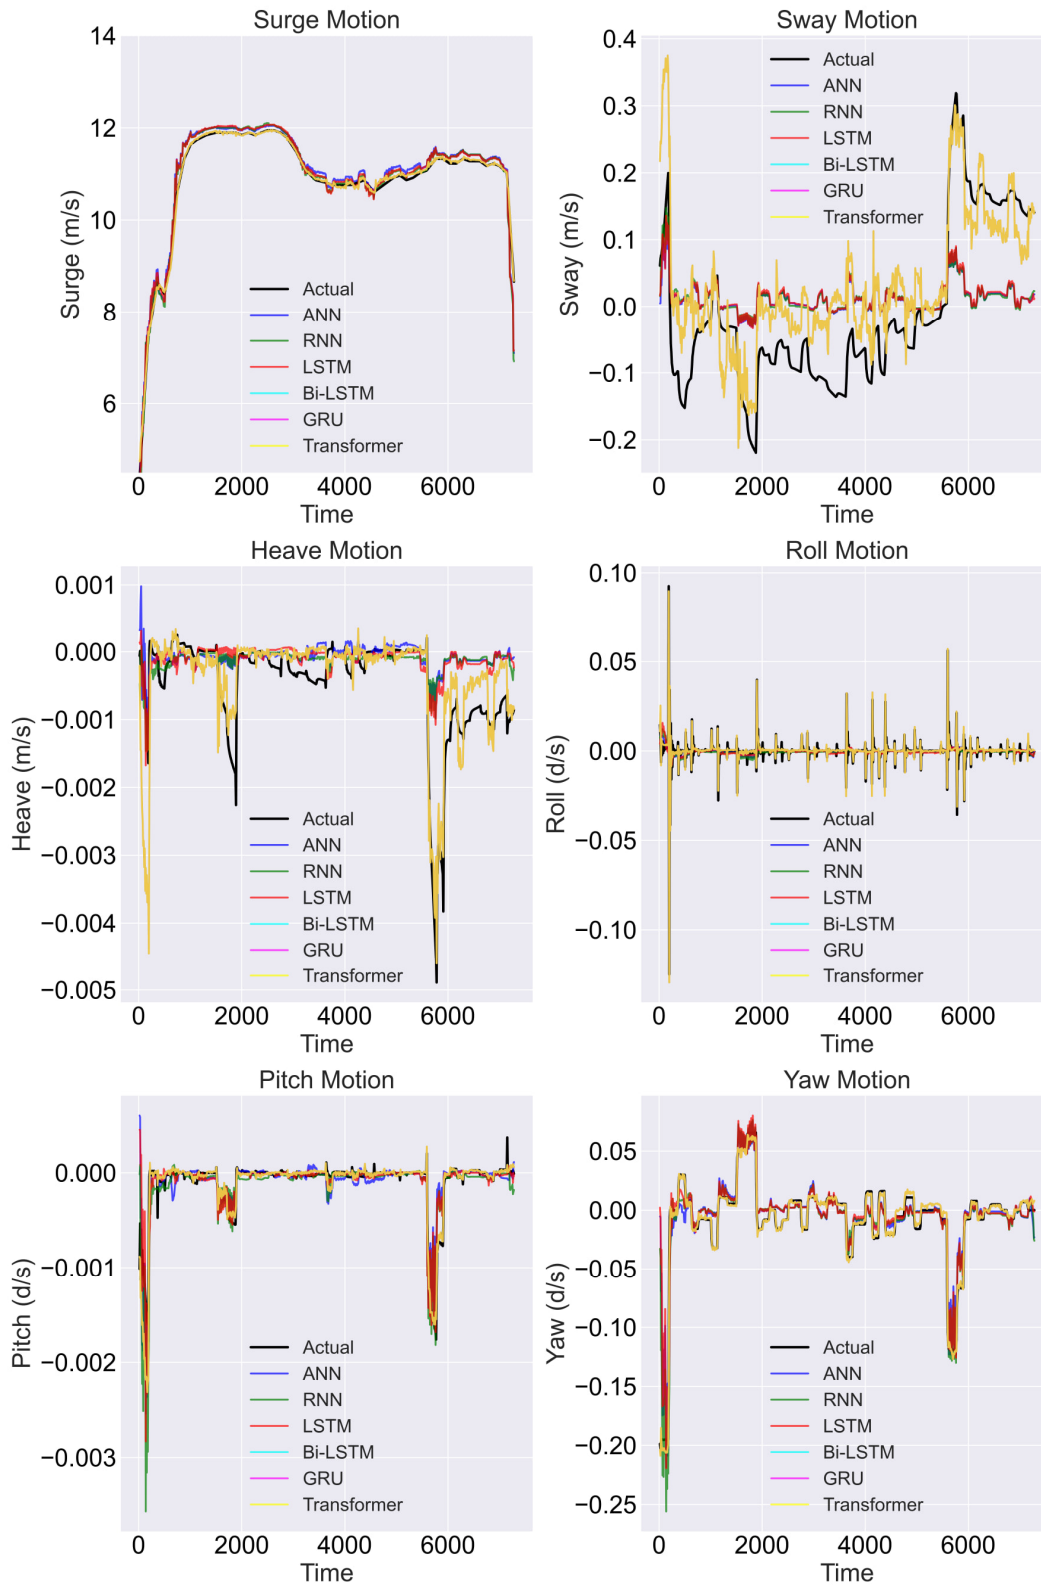

Model	ANN	RNN	LSTM	Bi-LSTM	GRU	Transformer
Data	2 input variables and 6 output variables					
Architecture	3 layers; 64 hidden units per layer; Early stopping: Patience=10; Optimizer: Adam; Dropout rate: 0.2; Regularization param: 0.1					Encoder: 6
Learning rate	0.001	0.001	0.001	0.001	0.001	Decoder: 6
Epochs	18	32	17	21	28	Batch Size: 8
Batch size	10	15	5	10	10	Epochs: 48
						Inner layers: 1,024

The training and validation losses were calculated based on the basis of training 80% and 20% of 500 ship trajectories, respectively. Table 2 showcases the validation losses for various models, illustrating that the Transformer model exhibits a stronger capability for handling the degrees of freedom in ship motions as compared to models like ANN, RNN, LSTM, GRU, and Bi-LSTM. Theoretically, a Transformer model's advantage stems from its extensive parameter scale, which enhances its predictive performance and learning capabilities. It is also possible that the observed superiority of the Transformer model is partly due to the relatively simplistic complexity settings of the ANN, RNN, LSTM, GRU, and Bi-LSTM models.

**Table 2: The performance evaluation on the teasing dataset of the selected ship models**

	ANN	RNN	LSTM	Bi-LSTM	GRU	Transformer
RMSE	0.096	0.098	0.067	0.055	0.042	0.022

To further assess these models, propeller RPM and rudder angle, were chosen to evaluate the generalization capabilities of the trained models. The results indicate that the trained deep learning models are proficient in capturing the characteristics of ship maneuvering under real conditions. However, their accuracy varies. This difference is observed not only in the overall accuracy of the models but also in the prediction accuracy for various motions (Surge, Sway, Heave, Roll, Pitch, Yaw), see Figure 10. Overall, the results indicate that the Transformer model is more effective in capturing nonlinear ship motions that mirror actual operational conditions. This also suggests that its learning capabilities are superior for predicting ship motions in real conditions, as compared to selected deep learning methods.

**Figure 10: The results of the prediction of ship motion dynamics using different models**

### Evaluation of Learning Capacities

In Section 4.1, this paper trains and predicts the 6 DOF ship motions using the selected deep learning models. Subsequently, the paper explores how much data is required to saturate results, i.e., to the point where increasing the amount of data no longer

reduces the accuracy. Initially, 400 ship trajectories have been divided into 20 datasets, with the first dataset containing the first 20 trajectories, the second set containing the first 40 trajectories, and so on, until the 20<sup>th</sup> dataset, which includes all 400 trajectories. An additional 100 trajectories have been reserved as a fixed testing dataset, see Figure 3. The selected deep learning models have been trained, keeping the hyperparameters from Section 4.1 unchanged. This allowed for the incremental increase in the amount of training data against the same testing set and the calculation of test loss, thereby identifying the data volume at which model training reaches saturation.

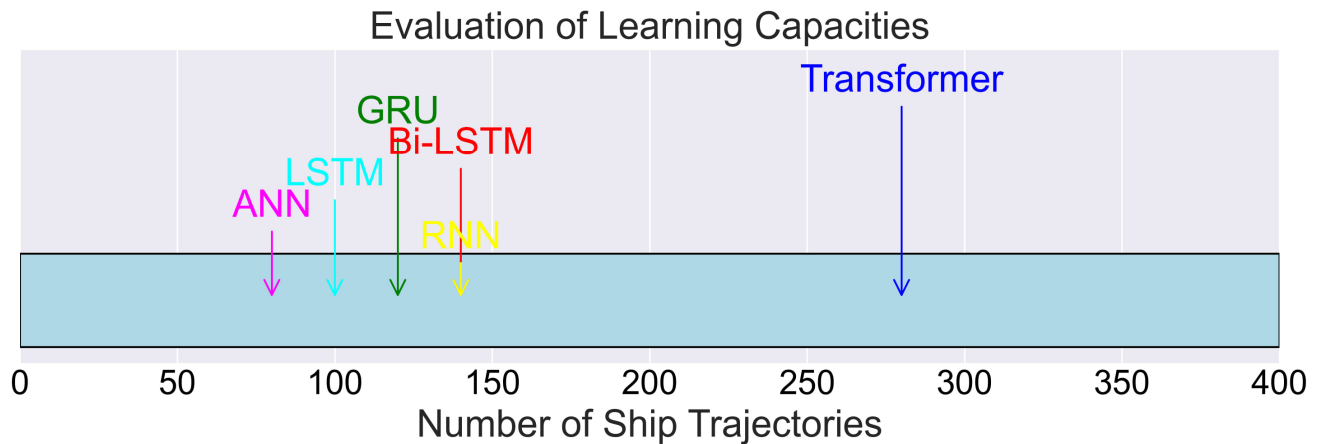

The test error curves for the various models have been plotted based on the given data with different lengths, see Figure 11. Each line represents the change in error as the lengths of training dataset increases, which could represent iterations in training ship motion predictors using the selected models. It displays the general trend that as the number of ship trajectories increases, the testing loss for each model decreases. This indicates an improvement in the prediction accuracy of these models with the increase of the training database. Figure 11 illustrates that upon reaching saturation, the loss error of these models ranges from  $0.4e-3$  to  $12.5e-3$ . Among them, the transformer model exhibits the highest accuracy, while the RNN model performs the poorest, with its error being threefold higher than that of the transformer. The losses of LSTM, Bi-LSTM, and GRU are between them.

**Figure 11: The influences of different lengths of training data on testing loss evaluation**

Figure 12 illustrates the data volume thresholds at which various deep learning models reach saturation, demonstrating that each model requires a different dataset size to achieve optimal performance. For instance, the Transformer model reaches peak efficiency at a data volume of 280, while the RNN model achieves its best performance with a data volume of 140, and the ANN requires only 80. Overall, as the training dataset expands, the increase in predictive accuracy halts, indicating that the models have reached their maximum learning capabilities. The ANN and LSTM models appear to plateau earlier than others. This suggests that they require less data to reach their performance limits. It is noted that reaching performance limits does not imply that these models have attained the highest prediction accuracy for ship motions. It merely indicates that the deep learning model may not process additional data to further enhance the model's prediction ability to capture ship motion characteristics.

Other models continue to show improvements with additional data before reaching a plateau. Notably, when data is scarce, the Transformer exhibits the highest accuracy, implying that it has superior learning ability compared to the others and is more adept at capturing the nonlinear movements of ships influenced by hydrological and meteorological conditions. An RNN model requires a substantial amount of data to train effectively, and even then, their accuracy may not be sufficient.

**Figure 12: The learning capacities of the selected deep learning model**

In predicting nonlinear ship motions, the Transformer model excels due to its remarkable accuracy, especially when dealing with complex dependencies over long sequence in the time domain. However, this model requires substantial computational power and a large volume of training data. Bi-LSTM and GRU models provide a compromise, handling sequences with moderate complexity more efficiently and using fewer resources while maintaining dependable accuracy. On the other hand, traditional ANNs and RNNs are quicker but faultier. The intricacies involved in predicting nonlinear ship motions, render them less effective for sophisticated tasks.

Figure 10 highlights the diverse proficiencies of various models in capturing the six degrees of freedom (6 DOF) of ship motions in the time domain. The Transformer model significantly outperforms others in predicting sway motion. However, for roll and surge predictions, other models also exhibit high accuracy and require less data. There is potential for future research to explore combining two or more models to predict each motion separately. Such hybrid approaches could enhance the precision of predictions by leveraging the strengths of diverse modelling techniques.

## CONCLUSIONS

The paper presents a framework for the comparison and evaluation of learning capabilities of the selected deep learning methods that could be used for the prediction of ship motions. To validate the framework, six existing deep learning methods for ship motion predictions are selected, namely ANN, RNN, LSTM, Bi-LSTM, GRU, and Transformer. The models are used to train 6 DOF ship motions predictors displaying the influence of nonlinear effects by using the same data streams along ship trajectories between two ports. It is concluded that their level of accuracy varies (see Table 2 and Figure 11). The paper also evaluates the learning capacities of these selected models in analyzing the impact of data volumes on their effectiveness by utilizing datasets of varying lengths. Generally speaking, the transformer model stands out in terms of accuracy.

In the future, results of this comparison and evaluation of the selected deep learning models may assist in selecting appropriate models for the development of online ship motion prediction tools with adaptive learning capabilities. Such tools are a crucial component of intelligent navigational decision-making systems.

# **INFLUENCE OF REGULATIONS**

# A time-dependent ice accretion model for trap-setting fishing vessels with filigree structures

Thomas DeNucci<sup>1,\*</sup>, Daniel Brahan<sup>2</sup>, Peter McGonagle<sup>1</sup>, Colman Schofield<sup>1</sup> and Delaney Taplin-Patterson<sup>1</sup>

## ABSTRACT

*This paper describes a time-dependent methodology for calculating the rate of ice accretion on vessels with filigree structures. It combines Newton's Second Law for spray droplet trajectories with time varying flow velocities determined using computational fluid dynamics (CFD). The mass flux of ice is determined by solving a set of partial differential equations describing the conservation of mass, heat, and salt in the boundary layer of brine near the ice surface. Icing predictions numerically generated by this approach are evaluated against current stability regulations for fishing vessels.*

## KEY WORDS

Ice Accretion; Safety; Stability; Fishing Vessels; Porous Surface

## INTRODUCTION

The fishing vessel *Scandies Rose* capsized off the coast of Alaska, USA, in heavy spray-icing conditions on December 31, 2019, with five of the seven onboard perishing. A Marine Board of Investigation conducted by the U.S. Coast Guard and the National Transportation Safety Board (NTSB) identified inaccurate accounting of ice on deck gear, specifically fishing pots, as a causal factor, National Transportation Safety Board (2021).

This tragedy follows in the wake of another capsized event. In 2017, the fishing vessel *Destination* sank off St. George Island, Alaska, under heavy spray icing conditions with the loss of all six crew members onboard. Figure 1 shows icing on *Sandra Five*, a vessel operating in the same vicinity as *Destination* during the fatal storm.

Since *Scandies Rose* and *Destination* were operating on domestic voyages, they were subject to the stability standards identified in US 46 CFR Part 28 Subpart E instead of those prescribed by international regulation and survey requirements of Safety of Life at Sea (SOLAS) set forth by the International Maritime Organization (IMO). However, the maximum assumed icing quantities on fishing vessels are identical between these two codes –  $30 \frac{kg}{m^2}$  of ice on horizontal surfaces and  $15 \frac{kg}{m^2}$  on vertical surfaces.

**Figure 1:** Ice accumulation on *Sandra Five*, National Transportation Safety Board (2017).

There are limitations to these rule-sets. First, both regulatory schemes assume uniform ice loading and do not consider the effects of list due to off-center weight additions. Uniform ice loading in storm conditions is a rare occurrence because fishing vessels rarely have wind and seas directly off their bows. Second, these rule-sets assume that icing is applied over the top and sides of the fishing pots, commonly referred to as the “shoebox method.” However, crab pots are porous, being constructed of steel tubing with netting, which enables ice to accumulate in the interior of the crab pot stack.

The goal of this paper is to develop an icing model that specifically considers both the time-varying effects of icing on fishing pots and the nature of ice formation on filigree structures themselves. Knowing how, where and the rate of ice accretion will provide opportunities to develop fishing vessel designs less prone to icing. This work forms the foundational knowledge required before changes to regulations may be proposed. The results have the potential to change the modeled icing quantity and location for naval architects performing stability analysis on fishing vessels subsequently improving safety conditions for mariners onboard while protecting the marine environment.

## BACKGROUND

The effects of marine icing on vessels at sea can be catastrophic. Ryerson (2009) cites hazards including a reduction in stability, damage to vessel structure, damage to equipment including winches, cranes, and antennas and slipping hazards on decks, ladders, and handrails. In the worst case, rapidly accumulating ice can cause a rise in the vessel centre of gravity which can result in a reduction of the righting arm and possible vessel capsize.

*Scandies Rose* and other trap-set fishing vessels are distinctive because their deck load ices differently than solid plates and cylinders because they are porous. Ice can accumulate not only on exterior surfaces, but also inside the fish pot itself, filling up space normally assumed to be empty voids on deck, National Transportation Safety Board (2021).

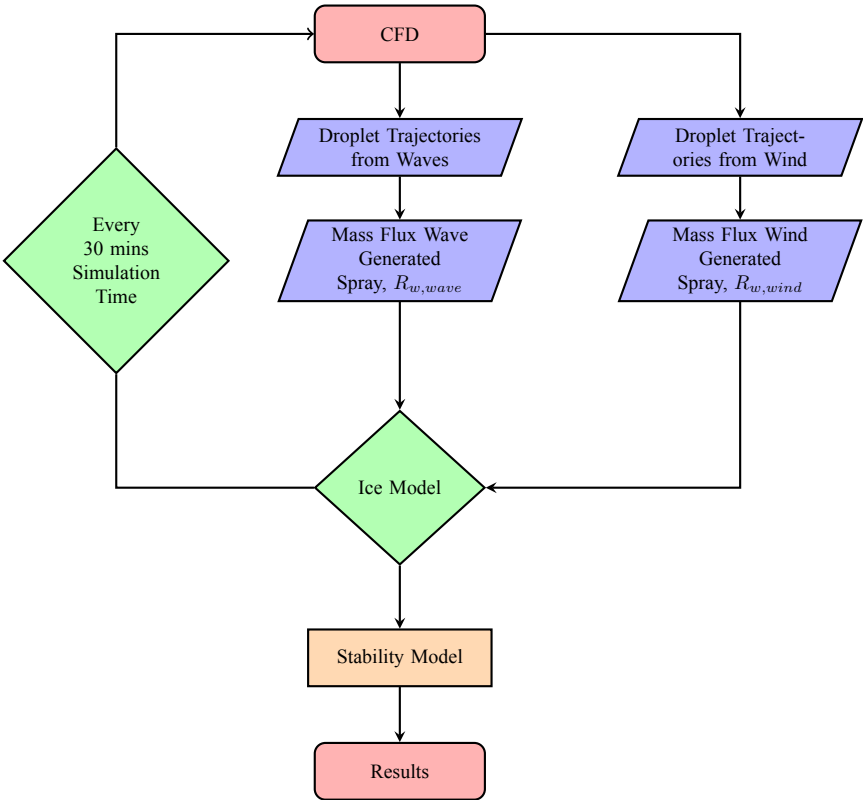

**Table 1:** *Scandies Rose* on-scene weather conditions reported by rescue team and survivors, National Transportation Safety Board (2021).

Weather Element	Value
Wind Velocity	18 – 25 m/s (35 – 50 kts)
Wind Direction (Relative to the Vessel)	045°
Significant Wave Height	6 – 10 m
Wave Period	9 – 10 sec
Water Temperature	3°C
Air Temperature	–12°C

All too often, all hands are lost on vessels that capsize in the Bering Sea. However, weather conditions on the night of *Scandies Rose* capsize, shown in Table 1, have been corroborated by the may-day call, survivor testimony and on-scene reports from the rescue helicopter and offer unique insight into the on-scene conditions. This paper applies these weather data and the knowledge gained from survivor testimony to the ice accretion approach outlined next.

## APPROACH

Figure 2 highlights the key elements of the presented approach. The model assumes that a thin layer of ice already exists on all surfaces. The velocity flow across the vessel and crab pots are solved using CFD. The flow field is important because it influences both droplet trajectory and heat convection coefficients. However, as ice accumulates on the crab pot netting, the crab pot geometry and flow field change DeNucci et al. (2023). To account for this, the flow field is recalculated after every 30 minutes of simulation.

**Figure 2:** Flow chart of ice accretion analysis on porous surfaces.

Using the environmental conditions described in Table 1, the mass flux of spray striking the vessel is calculated. A thermodynamic heat balance between the mass and salinity of brine is solved to determine the rate of ice accretion. After 30 minutes, the crab pot porosities, flow field, mass flux and heat convection coefficient are recalculated and the rate of ice accretion is again solved using the updated data.

After the simulation finishes, the impact of ice on overall vessel stability is analysed using General Hydrostatics Software (GHS). Stability is evaluated using the wind magnitude and direction reported on the night of the capsize. Details of this approach follow.

## TIME VARYING VELOCITY FLOW FIELDS

One challenge with filigree structures, crab pots on fishing vessels, are their nature of icing. As ice accumulates on the netting structure, the pot porosity changes, which results in new geometry, and subsequently, different velocity flow across the pot structure. These changes have an important effect on ice accretion and have not been accounted for in previous icing models.

### Darcy-Forchheimer Law

Computational fluid dynamics is used to determine velocity flow across the crab pots. To achieve this, the pots are modelled as porous surfaces using the Darcy-Forchheimer law so that the permeability and drag coefficient of the pot structure can be determined. The Darcy-Forchheimer law serves as an augmented version of Darcy's law, which characterizes the flow of fluids through porous media. Unlike Darcy's law, the Darcy-Forchheimer equation accommodates non-linear effects observed at elevated flow velocities within porous media, offering a more comprehensive understanding of fluid dynamics at higher flow speeds.

The law, shown in equation 1, is comprised of a linear and quadratic term. At low Reynolds numbers, the pressure loss is directly proportional (linear) to the flow velocity. At higher Reynolds numbers, the pressure losses across the medium increase rapidly and become a quadratic function of velocity.

$$\Delta P = -\left(\frac{\beta}{\alpha}\mu\vec{V} + \frac{\beta^2}{\sqrt{\alpha}}\rho C_d|\vec{V}|\vec{V}\right)\delta \quad (1)$$

where

$C_d$  = quadratic drag coefficient ( $\frac{1}{m}$ )

$\Delta P$  = change in pressure (Pa)

$\vec{V}$  = velocity magnitude ( $\frac{m}{s}$ )

$\alpha$  = permeability ( $m^2$ )

$\beta$  = porosity

$\delta$  = the thickness of medium (m)

$\mu$  = dynamic viscosity (Pa s)

$\rho$  = density ( $\frac{kg}{m^3}$ )

To solve for permeability and drag coefficient, the pressure drop across a singular crab pot of specific porosity is measured for various wind velocities (0 to 40 knots). The net orientation and webbing thickness of the crab pot match those loaded on *Scandies Rose*. After varying the wind speed across the pot, the pot porosity is changed and the pressure drop is measured again at the new porosity. Changes in porosity, illustrated in Figure 3, are achieved by changing the web thickness to achieve the desired porosity value (80% - 10%). Results are shown in Table 2.

Using the Darcy-Forchheimer Law, a second-order polynomial is fit to the data describing the pressure drop and wind velocity at each crab pot porosity. The coefficients of this polynomial curve describe the crab pot permeability ( $m^2$ ), a linear term, and quadratic drag-coefficient ( $m^{-1}$ ), a quadratic term. Results are shown in Table 3.

**Figure 3:** Crab pot netting at various porosities.

**Table 2:** Change in pressure across crab Pot netting at different wind velocities [Pa]

Wind Velocity		Crab Pot Porosity ( $\gamma$ , %)							
( <i>knots</i> )	( <i>m/s</i> )	80	70	60	50	40	30	20	10
0	0	0	0	0	0	0	0	0	0
2.5	1.29	0.22	0.27	0.35	0.48	0.50	0.63	0.69	0.82
5	2.57	0.86	1.05	1.33	1.64	1.98	2.49	2.88	3.26
10	5.14	3.37	4.15	5.30	6.54	7.99	10.01	11.59	13.05
15	7.72	7.52	9.335	11.89	14.69	17.97	22.56	26.14	29.38
20	10.29	13.39	16.25	21.09	25.91	31.93	40.14	46.45	52.26
25	12.86	20.96	25.78	32.90	40.75	49.95	62.3	74.5	81.54
30	15.43	30.13	37.08	47.33	58.66	71.8	90.57	104.5	117.5
40	20.58	53.6	65.89	84.17	100.15	127.55	158.20	184.7	208.8

Using values in Table 3, the crab pot stack can then be modelled as a porous surface and the velocity field is again determined using CFD. Local icing quantities ( $kg/m^2$ ) are directly related to porosity by assuming the ice accumulates on the crab pot webbing in a half-cylindrical fashion. This is discussed later in the paper.

## SEA SPRAY FLUX, $R_w$

Sea spray flux is the precursor to ice formulation and is required to accurately predict the rate of ice accretion on the vessel. Spray originates from both wind-wave and vessel-wave interactions, although the majority of the sea spray striking the vessel comes from vessel-wave interactions. Wind-generated sea spray is caused by lifting droplets from wave crests on the ocean surface. Wind-spray is a small, but constant water flux present in the air when the wind speed is greater than nine metres per second. Deterministic methods to calculate wind-generated spray flux are found in Jones and Andreas (2012). Wave-generated sea spray is caused by the collision of waves with the vessel. Wave-generated sea spray is generally the source of large but brief periodic water flux that originates near the bow of the vessel Hansen (2012). Zakrzewski (1986) and Lozowski et al. (2000) provide methods to calculate this flux. Sea spray flux calculations specific to *Scandies Rose* can be referenced in Brahan et al. (2023).

Using Newton’s Second Law for droplet motion, individual water droplets were injected into the velocity flow field and tracked throughout their flight to determine if they intersect the vessel. Since it is impractical to simulate every droplet of water generated by sea spray, droplets are re-characterized as “parcels” of the mass flux Brahan et al. (2023). Jones and Andreas (2012) determined the size and quantity of droplets at a given height above a free surface for given wind speeds. Since the total water mass present in a cubic meter of air can be calculated, a relationship between percent contribution of

**Table 3:** Permeability and drag coefficient values for crab pots as a function of porosity.

Porosity	Permeability ( $\alpha$ )	Drag Coefficient ( $C_d$ )
80	1.02E-02	1.59E-02
70	4.82E-03	1.77E-02
60	1.32E-03	1.61E-02
50	1.07E-04	9.96E-03
40	6.82E-04	3.64E-02
30	4.96E-05	2.14E-02
20	1.95E-05	3.78E-02
10	2.43E-04	6.16E-01

mass for a given droplet size was established Brahan et al. (2023). An analogous correlation was developed by Ryerson (1995), who measured the droplet number concentration and droplet size distribution of a wave-spray cloud using a stroboscopic camera on the U.S. Coast Guard Cutter *Midgett* in the Bering Sea.

Since wave-generated spray only occurs when encountering a wave and for the duration of the wave encounter, the wave-generated flux behaves like a step function. When the vessel encounters a wave, wave flux comes into the system; it is zero at all other times Brahan et al. (2023).

## ICING MODEL

A system of partial differential equations governs the ice and brine flux. The ice flux depends on several factors including the incoming latent heat of mass from the ocean, heat flux, brine flux, and brine salinity. The set of differential equations which follow are analyzed as a series of nodes on the side of the crab pot stack. These are numerically solved for each time step at each node using the method of lines DeNucci et al. (2023).

### Wet Icing

Normally, marine icing occurs in a wet state. This occurs when atmospheric conditions are conducive to freezing, but only part of the incoming spray flux freezes. The remaining spray flows off the surface as brine. Modelling the crab pot net as series of nodes, each node receives water from the free surface and brine flux. Conservation of mass, heat and salt give the approximate differential equations of the brine film, Horjen (1990); DeNucci et al. (2023):

$$\frac{\delta X}{\delta t} + \nabla_t(v_b X) = R_w - I \quad (2)$$

$$c_b X \left( \frac{\delta}{\delta t} + v_b \nabla_t \right) T_b = Q + (1 - \sigma) l_f I \quad (3)$$

$$\frac{X}{S_b} \left( \frac{\delta}{\delta t} + v_b \nabla_t \right) S_b = I(1 - \sigma) - R_w \left( 1 - \frac{S_w}{S_b} \right) \quad (4)$$

where  $X$  is the local brine amount per unit area ( $\frac{kg}{m^2}$ ),  $T_b$  is the brine temperature and  $S_b$  the brine salinity (in parts per thousand).  $R_w$  is the impinging sea spray flux ( $\frac{kg}{m^2 s}$ ) and  $I$  ( $\frac{kg}{m^2 s}$ ) is the rate of accretion of both the ice and the brine trapped in the ice. The variable  $v_b$  is the brine velocity and  $\nabla_t$  is the differential operator in the tangential direction, i.e., along the direction in which the brine will move.  $c_b$  is the specific heat capacity of the brine,  $\sigma$  is the fraction of entrapped brine in

the accretion,  $l_f$  is the latent heat of freezing and  $S_w$  is the salinity of seawater. Mass flux due to evaporation is neglected.

### **Dry Icing**

If the sea spray flux is relatively low, and the weather is sufficiently cold, it is possible for all the incoming spray to freeze on impact, Hansen (2012). This condition, referred to as dry icing, occurs when the heat transport away from the brine is greater than or equal to the latent heat produced if all the impinging spray freezes. The initial assumption was that only wet icing occurred on the vessel. However, initial simulations revealed that certain portions of the crab pot stack do not receive heavy quantities of mass flux into the system. Furthermore, the cyclical nature of heavy then light mass flux due to vessel-wave interaction causes different locations on the crab pot stack to freeze differently.

These factors combine to create a cycle of wet and dry icing, where dry icing often occurs between the wave-generated sea spray events. Initial simulations showed that wet and dry icing occurred concurrently on different nodes and at the same node for different instances of time, DeNucci et al. (2023). This phenomenon impacts the rate of ice accretion because residual brine flux may still be present at a given node location as the process of icing repeats itself. One important result of this phenomenon, shown in equation 5, is the modification of established icing equations to include the impact of brine on the different icing modes DeNucci et al. (2023).

$$R_w + X \leq \frac{Q}{l_f(1 - \sigma)} \quad (5)$$

where  $R_w$  is the spray flux during a spray event and  $\sigma$  is the interfacial coefficient, assumed to be 0.34.  $X$  is the local brine amount per unit area ( $\frac{kg}{m^2}$ ) and  $l_f$  is the latent heat of freezing.

### **Heat Balance**

The icing model requires a thermodynamic heat balance governed by a set of differential equations Horjen (1990). When water droplets strike a vessel, they freeze due to various heat fluxes. The heat fluxes are convective heat flux ( $Q_c$ ), evaporative heat flux ( $Q_e$ ), radiant heat flux ( $Q_r$ ), and the heat capacity of impinging water droplets ( $Q_d$ ). The heat flux due to viscous aerodynamic heating ( $Q_v$ ), conduction ( $Q_a$ ), and kinetic energy of in-coming droplets ( $Q_a$ ) are usually neglected because they are small. The icing model uses a parameterized form in which heat flux equations are presented as functions of  $T_s$ , where  $T_s$  is the equilibrium freezing temperature of the surface brine.

The convective heat flux is the sensible heat flux between the freezing surface and the surrounding air and is given by equation 6.

$$Q_c = h_c(T_s - T_a) \quad (6)$$

where  $h_c$  is the heat transfer coefficient, where  $T_s$  the temperature of the water at the air-water interface, and  $T_a$  the air temperature.

The heat transfer coefficient is given by equation 7:

$$h_c = \frac{Nuk_a}{L} \quad (7)$$

where  $k_a$  is the thermal conductivity of air and  $L$  is the characteristic length of the component, which for cylindrical com-

ponents is the diameter.  $Nu$  is the Nusselt number defined for cylindrical components.

$Q_e$ , the evaporative heat loss to the surrounding air flow is given as equation 8.

$$Q_e = h_c \left( \frac{Pr}{Sc} \right)^{0.63} \frac{\epsilon l_f}{P_{c_a}} (e_s(T_s) - RH e_a(T_a)) \quad (8)$$

where  $h_c$  is the heat transfer coefficient,  $Pr$  is the Prandtl number,  $Sc$  is the Schmidt number,  $\epsilon$  is the ratio of molecular weights of water vapor and dry air,  $P$  is the atmospheric pressure,  $l_v$  is the latent heat of vaporization for water at the surface temperature,  $c_a$  is the specific heat capacity of dry air at constant pressure,  $RH$  is the relative humidity of the air, and  $e_s(T)$  is the saturated water pressure.

$Q_r$ , the radiative heat flux is given by equation 9.

$$Q_r = \sigma (\epsilon_s T_s^4 - \epsilon_a T_a^4) \quad (9)$$

where  $\sigma$  is the Stefan Boltzmann constant, and  $\epsilon_s$  and  $\epsilon_a$  are the emissivity of the air flow and icing surface, both considered to be 1.

$Q_d$ , the heat capacity of impinging water droplets, is presented as equation 10, Zarling (1980).

$$Q_d = R_w c_w (T_s - T_d) \quad (10)$$

where  $c_w$  is the specific heat capacity of water,  $T_d$  the droplet temperature of the wave spray prior to impingement, and  $R_w$  the total mass flux of water. Although the droplet temperature,  $T_d$ , can be calculated on the individual droplet scale using a method proposed by Kato (2012), a simplified assumption proposed by Stallabrass (1980) is used. The total heat out of the system,  $Q$ , is the summation of the individual heat fluxes.

Using relationships between brine salinity and brine temperature by Assur (1958) and Horjen and Vefensmo (1987), equations 3 and 4 are combined to determine the ice accretion rate:

$$I = \frac{(1 - \frac{S_w}{S_b}) R_w \frac{F(S_b)}{l_f} Q}{(1 - \sigma)(1 + F(S_b))} \quad (11)$$

## CALCULATING RELATIONSHIP BETWEEN ICE ACCRETION AND POROSITY

Across the fishing industry, there is a high degree of variation in the size of pots vessels carry due to the many species, regions, and state or federal regulations they may operate under. Accordingly, the approach should not be bound by any set dimensions. Therefore, a general geometric relation between ice accretion and porosity was created to accommodate the majority of pot types and configurations with little to no change between each simulation.

Assuming the crab pot netting is flat, continuous, and at a  $45^\circ$  bias across the entire face presented towards the oncoming spray, it is possible to subdivide the large net into individual squares show in Figure 4. This approach allows full simulation of icing event given only two dimensions,  $R$ , the thickness of webbing material in the net, and  $L$ , the distance between intersections in the net.

**Figure 4:** Location and geometry of a sub-square in the net structure.

Initially, we assumed that ice would form in a cylindrical manner around each line in the netting. However, this reflects the behavior of *snow* accretion on power lines, which, given their ubiquity around the world, are well documented and researched.

**Figure 5:** Profiles of ice accretions for various values of angle from horizontal,  $\alpha$ , around stream wise axis under freezing rain conditions, Kollár and Farzaneh (2010).

Admirat (2008) notes that the *cylindrical accretion mechanism* seen on power lines is dependent on their ability to rotate due to the low torsional resistance seen by the long wires. While this rotational ability seen in the netting of crab pots, it is the accumulation of ice rather than snow drastically affects the resulting shape, making the initial cylindrical model inadequate.

Kollár and Farzaneh (2010) demonstrate that icing events on shorter, fixed, cylindrical objects, while certainly not uniform, appear much closer to a semi circle as seen in Figure 5. To better reflect this new *semi-cylindrical icing accretion mechanic*, equation 12 shows that the amount of mass due to icing is such that only half of the line would be covered in ice, thereby doubling the amount of radius ( $R$ ) “consumed” per kg of ice accumulated ( $m_{Ice}$ ).

$$m_{Ice} = \frac{\rho\pi}{2} \left[ L(R^2 - r^2) - \frac{4}{3}R^3 + \frac{4}{3}r^3 \right] \quad (12)$$

where

$m_{Ice}$  = mass of ice accumulated per sub square (kg)

$L$  = side length of net sub square (m)

$\rho$  = density of ice ( $\frac{kg}{m^3}$ )

$R$  = overall radius of line and accumulated ice (m)

$r$  = initial radius of line (m)

$\gamma$  = porosity of netting (%)

Equation 13 shows the relationship between icing volume and porosity. Given  $R$ ,  $L$  and  $r$ , crab pot porosity is determined from the weight of ice onboard the vessel. This information is then fed back into the CFD solver, droplet trajectory and icing models to change droplet trajectory, mass flux of water into the side of the crab pot, and convection coefficients in the icing model.

$$\gamma = \frac{4r(L - R)}{L^2} \quad (13)$$

## MODEL IMPROVEMENTS

One significant improvement in this approach is the incorporation of a feedback loop. Previous simulations only considered constant crab pot porosity. To implement the time varying nature of porosities in crab pots as they ice, the CFD model was updated to allow varying porosity values.

The previous model had five tiers of crab pot stacks with uniform porosity within each layer of the crab pot stack. Early simulations showed that porosity varied only in the forward third of the stack, DeNucci et al. (2023). Additionally, icing was non-uniform, meaning certain areas saw ice form at a rapid pace and indicated that the original model was not representative of the location or rate of ice accumulation. An updated model, shown in Figure 6, subdivides the crab pots into 14 clusters to more accurately capture the localized areas where porosity varies the most. Since ice rapidly accumulates on the forward starboard side of the vessel, eight smaller clusters are modelled in that location.

**Figure 6:** *Scandies Rose* CFD model. The different colored regions represent areas where porosity can be individually defined.

The CFD solver and the icing model were run at 30 minute intervals. The 30 minute interval balanced computational time with obtaining an accurate model of the phenomenon. After each interval, the porosities of the crab pots would be updated

based on the amount and extent of icing that occurred. The total simulation time was four hours, mirroring the total time icing occurred on *Scandies Rose*. Initial porosity was set to 90% throughout the crab pot stack and then reassessed for the 14 subdivided regions after every 30 minutes of simulation time.

## RESULTS

Figure 7 shows the simulation results from the model presented in this paper. Ice accretes in a non-linear fashion, both in total mass accumulated and *vcg* of the ice on the crab pot stack. Previous simulations with 90.5% porosity (constant), shown in Figure 8, did not show any appreciable change in icing distribution.

The results showed that the vertical center of gravity (*vcg*) of the ice in the crab pot stack rises, as does the rate of ice accretion on the crab pot stack. This is an important point. If constant porosity is assumed throughout the simulation, the *vcg* remains constant and therefore underestimates the stability impact of added weight.

**Figure 7:** Mass versus *vcg* of ice versus time for the simulation length.

Figure 9 shows ice progression as it begins to accumulate in the upper forward region of the crab pot stack. Note, the icing scales are different between the two images. Simulation results highlight the need for a time-dependent model in order to more accurately simulate the phenomenon of icing on porous surfaces.

## Stability Analysis

After obtaining ice data (mass and *vcg*) from the icing simulation, vessel stability was analyzed using GHS software. Figure 10 shows the hydrostatic righting curves from the icing simulation compared to the regulatory icing requirements in US 46 CFR 28.550 and International Code on Intact Stability (IS Code) 6.3 using the “shoebox” method DeNucci and Brahan (2022). The regulations required the addition of 19.89 MT of ice on the centerline of the vessel. The righting arm curve for this condition is shown as the dashed line in Figure 10.

The simulated results most nearly match the regulatory icing after a half hour of simulation time with *only* 4.26 MT (vs. 19.89 MT) of ice added to the vessel. It is important to note that the resultant ice from the simulation only accounts for ice

**Figure 8:** Ice mass per unit area ( $\text{kg}/\text{m}^2$ ) for a one hour simulation with constant porosity (no feedback loop implemented). Figure displays ice accumulation for outboard starboard side of pot stack on main working deck. Origin - point (0,0) - is located at amidship and based at waterline.

**Figure 9:** Ice mass per unit area ( $\text{kg}/\text{m}^2$ ) at discrete times in the simulation. Crab pot porosity values are updated every 30 minutes.

on the *outer edge* of the crab pots, whereas the regulatory icing applies ice across the entire surface area of the vessel. Simulated icing also occurs farther forward on the vessel than assumed by regulation, as the centroid of ice is forward of amidships. This creates an increased righting arm at higher angles due to the large buoyant volume in the forward location of the vessel. This assumes the forward volume in the hull is watertight throughout all angles analyzed and did not take into account downflooding points.

The icing model also induces a list from off-center ice loading. Regulations require ice to be loaded uniformly centerline, whereas this icing model puts the ice loading on the outer edge of the crab pot stack. The righting arms show an induced list of almost  $3^\circ$  after one hour and  $5^\circ$  after an hour and a half. Additionally, the hour and a half case shows a lolling condition possible - an indicator the vessel is in dire circumstances. This lolling condition is a result of less ice onboard than what is applied by regulation (approximately 15 MT versus 20 MT) DeNucci and Brahan (2022). Given the extreme environment which induces these icing conditions, the righting area may not be enough to absorb the dynamic effect of wind and waves on the vessel.

Initially, *Scandies Rose* experienced wind off the starboard bow. Applying this wind as a restoring moment created an almost-imperceptible change to the righting arm and angle of list.

This analysis highlights the importance of modeling ice accretion in an off-center fashion. A comparison of righting arms

**Figure 10:** Static Righting Arm of *Scandies Rose* for the icing simulation. Regulatory icing, 46 CFR 28.550, is shown in the bold dashed line. Of note, downflooding points were not taken into account. Ice loads from the longer simulations cap-sized the vessel.

using regulatory icing requirements and the results after 89 minutes show the stark difference in a vessel’s ability to withstand external forces.

## CONCLUSIONS

With this model, a more accurate depiction of crab pot icing is captured. Implementing a feedback loop in the vessel icing model, while concurrently updating the pot porosities as they ice, showed both an increased rate of icing and a rise in the center of gravity of the ice over time. The accumulating ice:

1. changes the flow field, causing subsequent droplets to land in higher regions than previous simulations showed, and
2. decreases crab pot porosity, thereby increasing the sea spray flux into the system.

If permitted to continue, the center of gravity of ice will continue to rise, thereby increasing the vessel’s overall center of gravity.

Off-center weight, which negatively impacts the vessel’s stability, can ultimately cause vessel capsize. The effect of off-center ice is clear: less ice than required by regulation modeled in an off-center fashion puts the vessel in a worse situation than witnessed in with regulations. This paper presents an accurate, time-dependent study of how quickly ice can accumulate on the outer surface of the crab pot stack. The goal of future regulation should be to provide reasonable amount of time for the crew to intervene to prevent catastrophic capsizing.

## FUTURE WORK

This study presents an ice accretion model that improves the quantitative understanding of icing phenomena on filigree structures. It only considered the outer edge of the crab pot stack and does not take into account all the intermediate surfaces where ice can accumulate. Future work should aim to quantify the ice accumulation on the interior surfaces and equipment (coiled line and buoys) of each crab pot.

While modeling the events leading up to *Scandies Rose*'s capsize was one aim of this research, another is to prevent these occurrences in the future. This might be accomplished by updated stability regulations, but it is also of interest to reduce the amount of icing on the structure in the first place.

To match the net orientation on *Scandies Rose*, crab pot netting was arranged at a  $45^\circ$  bias to the structure of the crab pot. As a result, the brine flows in both the x- and z- directions along the webbing. Modeling the nets in the vertical direction might reduce ice accumulation because the amount of time the brine is exposed to the high convection coefficients may decrease. Other areas of interest are the effects of spray rails and the addition of flare to the hull design. All three design changes have the potential to impact the quantity of ice accumulation on a vessel in extreme weather conditions such as those *Scandies Rose* and *Destination* were subject.

# Integrated infection and crowd behavior model for COVID-19 infection risk assessment onboard large passenger vessels

N.A. de Haan<sup>1</sup>, A.A. Kana<sup>1,2,\*</sup> and B. Atasoy<sup>1,3</sup>

## ABSTRACT

*The development of the global COVID-19 pandemic from 2020 onward has had significant impact on the world and specifically the maritime industry. Striking examples were COVID-19 outbreaks onboard the Diamond Princess cruise vessel and the U.S.S. Theodore Roosevelt aircraft carrier at the start of the pandemic. Contagious disease management onboard large passenger ships remains a complex issue, amplified by the international character of the industry, confined environment and shared facilities. This paper therefore presents an integrated infection and crowd behavior model used to calculate agent-specific infection risk, incorporating guest and crew circulation through a passenger ship layout. The integrated model is used to investigate the effect of ship layout design, capacity reduction and mask wearing on COVID-19 airborne infection risk onboard large passenger vessels.*

## KEY WORDS

Contagious disease; passenger vessel; layout design; COVID-19; infection risk

## INTRODUCTION

The development of the global COVID-19 pandemic from 2020 onward has had a significant impact on the world and specifically the maritime industry. The shipping industry had to deal with restricted travel, changing trade volumes, increased waiting times and stricter security measures in ports (Yazir et al., 2020). As seafarers kept working through the COVID-19 pandemic, quarantines, travel restrictions and country entering measures became standard practice (Keçeci, 2022). Striking examples of the pandemic's impact were COVID-19 outbreaks onboard the Diamond Princess cruise vessel and the U.S.S. Theodore Roosevelt aircraft carrier at the start of the pandemic. During these outbreaks, over 20% of the total population tested positive for SARS-CoV-2 with major implications (Kasper et al., 2020; Turvold and McMullin, 2020). Contagious disease management onboard large passenger ships remains a complex issue, amplified by the international character of the industry, confined environment and shared facilities. This paper therefore aims to:

*Investigate the effect of ship layout design, capacity reduction and mask wearing on COVID-19 airborne infection risk onboard large passenger vessels*

Since the COVID-19 pandemic, significant research has been done into the characteristics of this contagious coronavirus, covering incubation periods, (asymptotic) infection rates and transmission mechanisms (Zhao et al., 2022; Rocklöv et al.,

\* A.A.Kana@tudelft.nl

2021; Lipsitch et al., 2020). Other literature focuses on ways to prevent or control disease spread, like the research by Gupta et al. (2021) discussing the choice between ship quarantine or disembarkation of suspected cases and the article by Li et al. (2021) proposing “A timeline and system framework for cruise ship disease risk management”. Additionally, there is a wide availability in research relating COVID-19 disease spread to behavioral measures like mask wearing, social distancing and personal hygiene. Besides operational and behavioral measures, layout adjustment might be an option for disease prevention and control. This can be connected to the concept of prevention through design (PtD) Brewster et al. (2020). The layout design should thus aim to prevent a disease outbreak and facilitate disease control in case prevention fails. Research connecting ship layout design with contagious disease was done by Ruggiero et al. (2008) as they present a retrofit design for an Italian fast medical support vessel. Furthermore, the Healthy Sailing HORIZON EUROPE research project specifically supports “substantially reducing the spread of communicable disease on board passenger ships” (Healthy Sailing, 2024).

The novelty of this paper lies with the integrated infection and crowd behavior model used to calculate agent-specific airborne infection risk, incorporating guest and crew circulation through a passenger ship layout. These location- and agent-based infection risks can be considered complementary to COVID-19 studies onboard large passenger vessels presenting retrospectively calculated attack rates and reproduction numbers (Rocklöv et al., 2021; Mizumoto and Chowell, 2020; Liu et al., 2020; Rosca et al., 2022).

The scope of this paper is described by the details in the research objective. The ship type is defined and the scope of the measures and interventions tested is limited to capacity reduction, mask wearing and ship layout adaptations. The effect of these measures will be investigated by means of model simulations. The study of ventilation and ventilation system design onboard large passenger vessels in relation to contagious disease spread falls outside the scope of this research.

This paper starts by describing the required background information related to contagious disease transmission, disease prevention and control. This background leads into the development of the integrated model. The first part of the method covers the model requirements where after a specific movement model and infection model were selected for integration. The second part of the method handles the model architecture implemented in order to integrate the movement and infection model. Three interventions are investigated using the integrated model and the results are compared against two sample cases. The interventions feature layout adjustments, capacity reductions and mask wearing. The paper closes with a discussion and concluding summary.

## BACKGROUND

Diseases have been a part of daily human life throughout history and the recent COVID-19 pandemic showed the impact of a contagious disease on a global level. Next to coronaviruses; Tuberculosis, Noroviruses and influenza have been linked to life at sea (Mangili and Gendreau, 2005; Kak, 2007). These diseases can spread via four modes of disease transmission as described by Mangili and Gendreau (2005):

- *Contact transmission*  
Contact transmission includes person-to-person contact, contact with a contaminated intermediate host and large droplet transmission; if someone for example inhales large droplets generated when an infector sneezes or coughs. The contaminated intermediate host might be something like a surface or door handle. The densely populated environment, confined and shared spaces onboard large passenger vessels may amplify contact transmission.
- *Airborne transmission*  
Airborne transmission covers very small droplet residua (nuclei) that travel over long distances. These aerolized infectious agents move around because of circulation inside a space, mechanical ventilation or they end up in filtration systems (Tan et al., 2022).
- *Common vehicle transmission*  
Common vehicle transmission route is associated with food and water sources.

- *Vector-borne transmission*  
Vector-borne transmission relies on insects or rodents to spread a disease.

Measures to prevent or control disease transmission onboard large passenger vessels cover three categories: ship layout adjustments, operational measures and behavioral measures. An improved ship layout could feature additional medical facilities, optional isolation and quarantine zones and a lower passenger-space ratio (Rosca et al., 2022; Li et al., 2021). Also, high-risk spaces might benefit from an area or location change. Possibilities for operational measures are: embarkation requirements, extensive onboard disease management and monitoring, and restricted movement onboard or on-shore (Mouchtouri et al., 2010; Kordsmeyer et al., 2021; Moon and Ryu, 2021). Another measure with large potential can be found in the research by Guagliardo et al. (2022). They investigate the effect on COVID-19 infection cases when the general capacity onboard a cruise ship is reduced. The last group of measures is related to the behavior of crew and guests who can improve their personal hygiene, get vaccinated, keep a social distance and wear personal protective equipment like a mask (Noakes et al., 2006; Nicolaides et al., 2020; Kak, 2007; Sun and Zhai, 2020).

## METHOD

The development of the integrated movement and infection model followed a two-step approach. The first step is the integrated model analysis. In this step, the model requirements are presented after which a model combination is selected from the various investigated movement and infection models. The second step describes the developed model architecture in order to achieve integration between the movement and infection model.

### Integrated Model Requirements

The integrated model requirements are given in Table 1. These requirements can be connected to the scope and specific boundaries of this research. R1 and R9 are related to the considered design stage as converging results are required within a time frame that is acceptable for *initial stage retrofit design*. R2 specifies the population size which is related to the ship type: *large passenger vessels*. The preferred result of this investigation is the *limitation of contagious disease spread* which can be linked to R3 and R12. R10 and R11 specify requirements to monitor the time spent in specific spaces and the space occupation. These requirements can be used to inform *layout adjustments* and the exposure time and space occupation might be relevant when implementing *operational and behavioral measures*. Finally, R4 up to R8 are formulated to achieve two key model specifications: *incorporating crew and guest circulation* and *incorporating movement through a ship layout*.

Keeping the requirements in mind, different types of agent movement and infection models were investigated. Both the investigated movement and infection models describe varying levels of detail, from macroscopic pipe flow models to microscopic agent-based movement models. Widely used compartment models, infection risk models and complex agent-based models were investigated as options to cover the medical aspect of the integrated model. The movement and infection models were brought together in twelve combinations and their integration compatibility was evaluated. After careful consideration, the combination of a mesoscopic route-choice model developed by Narayan et al. (2021) as used in van Gisbergen (2022) and the modified Wells-Riley infection model presented by Sun and Zhai (2020) was selected. Comparing all model combinations against the requirements, this option showed the most potential. The combination is less complex and time-intensive than an agent-based model but it does provide a strong disease performance indication. The performance indication is layout dependent and agent specific.

**Table 1: Integrated model requirements**

Requirement	Details
1 Convergence	The simulation results converge within an acceptable time frame
2 Population size	3000-4000 Individual agents can be modelled (guests and crew)
3 Disease performance indication	Model results indicate scenario performance for contagious disease spread
	Model results indicate <i>where</i> in the layout agents are most at risk for infection
	Model results enable performance comparison between different scenarios
4 Layout incorporation	Model is layout dependent
	Model support layout dimensions from 5 up to 50 meters per space.
5 Space capacity and flow	Model takes limited capacity of spaces into account
	Model takes limited flow between spaces into account
6 Individual movement	Movement can be modelled for each individual agent
	Individual agent movement can be tracked and movement data is stored
7 Random movement	There is controlled randomness in the activities that agents undertake
	There is controlled randomness in <i>when</i> agents start different activities
	There is controlled randomness in the routes agents take to their destinations
8 Multi-leg movement	Agents can move between multiple destinations in one simulation
	The time an agent stays at a single destination can be adjusted
9 Medical complexity	Medical model is as simple as possible while producing relevant results
10 Time spent	Time spent at each location is known for every agent
	Time spent at each location is incorporated when calculating infection risk
11 Space occupation	Space occupation is known for each time step
	Space occupation changes with the agents entering and exiting spaces
	Space occupation is incorporated when calculating infection risk
12 Disease specific	Model should (to a degree) take differences between diseases into account

## Integrated Model Architecture

The chosen route choice model simulates the normal-day movement of guests and crew onboard a cruise ship based on an activity schedule. The activity schedule provides the destinations and duration of activities while the agents choose their individual routes between destinations based on a mixed logit route choice model. The agents can hold four different states in the route choice model: activity, wayfinding, stay and walk. The ship layout is converted into nodes representing one or multiple spaces and these nodes are connected via bi-directional links.

The implemented infection model presented by Sun and Zhai (2020) calculates Wells-Riley infection probability for airborne disease transmission in confined spaces, taking the social distance into account. The social distance index is shown in Equation 1 where  $d$  equals the social distance in meters. The modified Wells-Riley infection risk is given in Equation 2 with the following parameters:  $P_I$ : probability of infection,  $C$ : new cases,  $S$ : susceptible individuals,  $I$ : number of infectors,  $p$ : pulmonary ventilation rate of susceptible individuals [ $m^3/s$ ],  $q$ : quanta production rate per infected individual [ $q/s$ ],  $t$ : time [ $s$ ],  $Q$ : room ventilation rate [ $m^3/s$ ] and  $E_z$ : ventilation index.

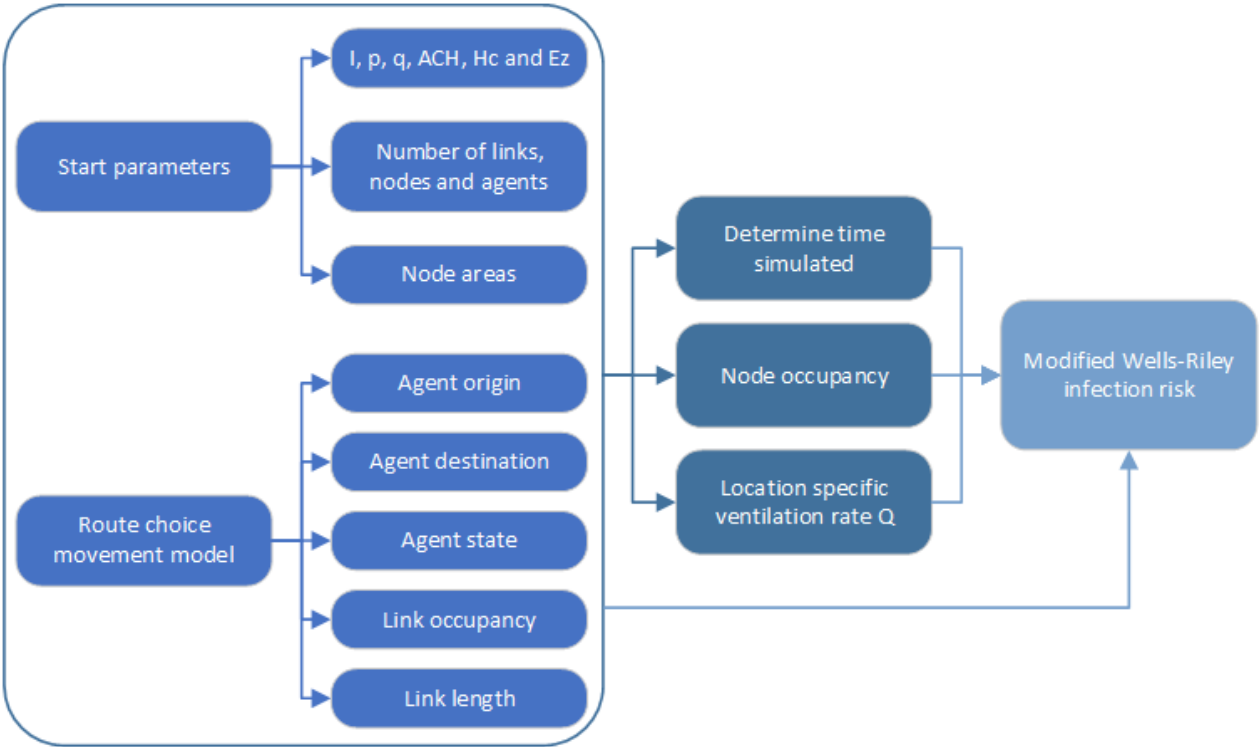

$$P_d = \frac{-18.19 \ln(d) + 43.276}{100} \quad (1)$$

$$P_I = \frac{C}{S} = 1 - \exp\left(-P_d \frac{I q p t}{Q E_z}\right) \quad (2)$$

An overview of the integrated model architecture can be found in Figure 1. The route choice model (RCM) is coded in C++ and run in Microsoft Visual Studio 2022 with an academic license. The output for every RCM simulation consists of five .CVS files. The integrated infection and crowd behavior and model itself is coded in Python and run in Spyder. Every investigated case was repeated five times and the infection results in this paper correspond to an average over these five repetitions.

The parameters from Equation 2 are recognized in Figure 1 as start parameters, except the ventilation rate  $Q$ . This parameter is no longer a constant start parameter as the ventilation rate  $Q$  has become location specific based on the Air Change per Hour  $ACH$ , the location floor area and the space height  $H_c$ . The node occupancy and local ventilation rate is calculated using the start parameters and RCM output. The last step consists of the modified Wells-Riley infection risk calculation. The infection risk is given in a matrix format with the infection risk for every agent per timestep. The size of this matrix covers approximately 60000 time steps (rows) and 2848 agents (columns) for the total population. The exposure time is tracked for the time an agent stays in the same location and the exposure time is reset when an agent changes node location.

In the infection risk calculation, two assumptions have been made. The first assumption is related to the situation where the social distance is more than  $10.8m$ . At social distances greater than this, the social distance index becomes negative which results in a negative infection risk. This situation lies outside the scope of the modified Wells-Riley equation and one could question if there is infection risk at all when the infector and the susceptible agent are so far apart. Therefore, the infection risk is set to zero for negative social distance index results. The second assumption concerns the time when agents are not yet moving to their first destination or when agents have finished their activity schedule. The infection risks for these situations are also assumed to be zero. The assumption does not affect the risk calculations for the rest of the day as the exposure time is reset. The reasoning behind this assumption can be found in the fact that the implemented ship layout does not realistically model the guest and crew cabin spaces. For example, the guest cabins are modelled in large groups, as if agents are staying together in one large space. This situation leads to unexpected high risks before starting and after finishing the activity schedule. Also, the focus of this research is not the infection risk calculation for long-term risk inside a cabin, but infection risk during normal-day movement. Normal-day movement is still captured in the model results when the described assumptions are implemented.

**Figure 1: Integrated model architecture**

## SAMPLE CASES AND VALIDATION

This section presents two sample cases for the integrated infection and crowd behavior model. These sample cases are continuously presented as a reference when investigating ship layout adjustments, capacity reductions and mask wearing. The sample cases can be described covering three main topics: the ship layout, the activity schedule and the chosen start parameters. The ship layout is based on the second data-set from the SAFEGUARD project which features the layout from a cruise ship operated by Royal Caribbean International (Galea et al., 2012; Brown et al., 2021). The layout corresponds to the Radiance of the Seas cruise ship as seen in Figure 2. The ship characteristics are provided in Table 2. It is relevant to note that the Radiance of the Seas has undergone retrofitting after the SAFEGUARD project and the deck plans are no longer a complete match (Royal Caribbean Press Center, 2024). The current dataset is sufficient for this research as it does provide a realistic representation of ‘a large passenger vessel’.

Figure 2: Radiance of the Seas (CruiseMapper, 2024)

Table 2: General characteristics Radiance of the Seas (Royal Caribbean Press Center, 2024)

Ship	Radiance of the Seas
Owner	Royal Caribbean Group
Maiden Voyage	7 April 2001
Tonnage	90,090 GT
Length (LOA)	293.2 m
Beam	32.2 m
Draft	8.63 m
Decks	13 (12 guest accessible)
Speed	25 kts

The activity schedule prescribes the node destinations per individual agent over the course of a day. The structure of the schedules can be found in Table 3 and Table 4. The guests complete seven legs per day: cabin → breakfast → activity → lunch → activity → dinner → activity → cabin. All agents follow the same trend (seven legs) but the activity and meal locations are chosen arbitrarily. The crew schedule specifies eight legs: cabin → shift → break → shift → break → shift → break → shift → cabin. The cruise ship can host over 850 crew of which 700 crew are modelled. These crew members have frequent contact with the guests.

**Table 3: Sample case guest activity schedule characteristics**

Number of agents	2148
Groups	Every 4 agents follow the same schedule
Activity/Meal duration	140 minutes $\pm$ 10 minutes
Moving to breakfast	Uniform distribution 08:00 till 09:00
Final move to cabin	Between 21:00 and 24:00

**Table 4: Sample case crew activity schedule characteristics**

Number of agents	700
Shift duration	180 minutes (4x)
Break duration	30 minutes (3x)
Early shift	07:30 $\pm$ 3 minutes till 21:00 $\pm$ 3 minutes
Late shift	10:30 $\pm$ 3 minutes till 00:00 $\pm$ 3 minutes

Next to the layout and schedule, the start parameters were investigated and defined. The start parameters can be found in Table 5. The  $I$  parameter is set to 1 infected person per space, introducing a fundamental assumption for the integrated model: the agent risk is determined ‘as if there were a single infected agent in every space the agent enters’. In reality, there might be multiple infectors or no infectors at all in a particular space. However, tracking the actual amount of infectors would require the model to assign disease states like ‘infected’, ‘susceptible’ or ‘recovered’. The model would then become a microscopic agent-based model while the choice has been made to work with a less complex risk-based model instead.

The pulmonary ventilation rate  $p$  is set to  $8\text{ L/min}$  associated with resting, sitting and light indoor activities. The quanta production rate and air change per hour have a significant impact on the infection risk results. The quanta production rate  $q$  is set to  $100\text{ qph}$  as a compromise dealing with the variation for this medical parameter in literature (Gaddis and Manoranjan, 2021; Dai and Zhao, 2023; Buonanno et al., 2020). Increasing the  $ACH$  value to 25 or even 30 air changes per hour leads to lower infection risks in the integrated model. However, there is also research that suggests that higher ventilation rates might increase virus spread because droplets spread further (Ritos et al., 2023). This phenomenon is not captured in the integrated model as droplet spread itself is not modelled. This consideration, together with ventilation values mentioned in literature, led to the choice of 15 air changes per hour for the  $ACH$  parameter (Sodiq et al., 2021; Azimi et al., 2021; Zheng et al., 2016). The space height  $H_c$  is set to  $2.35\text{ m}$  and the ventilation index lies outside the scope of this research and is therefore determined to be 1.

**Table 5: Start parameters for integrated model**

$I$	1
$p$	$8\text{ L/min}$
$q$	$100\text{ qph}$
$ACH$	15
$H_c$	$2.35\text{ m}$
$E_z$	1
Number of links	968
Number of nodes	389
Number of agents	2848

The two sample cases were validated against similar cases presented in literature. Most COVID-19 studies onboard large passenger vessels present attack rates and reproduction numbers based on real-life cases (Rocklöv et al., 2021; Mizumoto and Chowell, 2020; Liu et al., 2020). These attack rates and reproduction numbers are retrospectively calculated. The National Institute for Infectious Diseases in Japan determined that over a 20-day COVID-19 outbreak, 22% of the population

onboard the Diamond Princess cruise vessel was “detected to have been infected with SARS-CoV-2” (Rosca et al., 2022). Using the average daily infection risk for sample case 1 (0.807%) and sample case 2 (1.05%), the attack rates were calculated to be 15% and 18% for a 20-day outbreak. This calculation directly removes infected cases from the susceptible population, assuming that infected cases isolate directly. Additionally, the average infection risk does not change over the 20-day period. In reality, infected individuals might not isolate because they are pre-symptomatic or asymptomatic and it is possible that symptomatic agents do not isolate at all. The result will be an increase of infected individuals in the agent population, increasing the average infection risk over time. The actual number of cases and therefore attack rate will thus be higher which explains the slight difference between the calculated attack rates for the sample cases and the value reported for the Diamond Princess outbreak.

The sample cases were also compared to the infection risk inside a single office space described by Dai and Zhao (2022) and a multi-room office space from the research by Srivastava et al. (2021). The single office space scenario in Dai and Zhao (2022) features the Wells-Riley infection risk equation adjusted to include a regression equation based on a CFD analysis. For a 40  $m^2$  office hosting six people, the infection risk over an eight hour period is described to be 13.2%. Using the developed integrated model, an infection risk of 19.6% was calculated. Differences might be attributed to the presence of portable air cleaners and the incorporation of complex air/particle circulation (CFD) in the research by Dai and Zhao (2022).

For the multi-office space, Srivastava et al. (2021) used a CFD tool to simulate the air-flow within a 59-person office geometry which resulted in an average infection risk of 3.10%. The average infection risk was calculated to be 1.97% implementing the integrated model while assuming the office space to be a single open space. Taking the geometry and calculation approach differences into account, equal results were not expected but the integrated model does present a result in the same range as the CFD-based average infection risk.

Specifically focusing on location based infection risks, the top 20 high-risk locations from sample case 1 were compared to 20 waiting rooms in an out-patient hospital building in Shenzhen, China (Li and Tang, 2021). The day average infection risk for the SC1 locations ranges between 0.75% and 3.58% with an average of 1.49%. The day average infection risks for the 20 hospital rooms ranges between 0.19% and 2.63% with an average of 0.79% (Li and Tang, 2021). Lastly, infection risk at one of the restaurants onboard was validated against a reception scenario with similar space characteristics, occupation and exposure time (Lelieveld et al., 2020). The average infection risk for the restaurant over a three hour exposure period was calculated to be 3.2% compared to 1.6% reported by Lelieveld et al. (2020).

## SHIP LAYOUT DESIGN

The integrated model was used to investigate the effect of ship layout adjustments on COVID-19 infection risk. For sample case 1, the average infection risks per node and links are presented in Figure 3 and Figure 4. The average infection risk is calculated as the average risk over all agents at that location for a specific timestep. These values are then averaged over time. The figures show that the node locations reach average infection risks 10000 times higher than the infection risks at links. There is one outlier at node 107 with an average infection risk of 16.8% which is not completely visible in Figure 3 because of the limited y-axis. This outlier concerns a local schedule inconsistency which does not affect the full-scale infection risk results. The inconsistency was resolved for the combined tested measures. The modified Wells-Riley infection equation only covers airborne transmission and the occupancy and extended exposure times at nodes cause higher infection risks compared to the links.

**Figure 3: Average node infection risk (limited y-axis)**

**Figure 4: Average link infection risk**

Based on the average infection risks and number of agents who reach their maximum infection risk at a certain node, two high-risk node locations were selected for further investigation. These nodes feature a restaurant on deck 11 (N293) and a restaurant on deck 12 (N330). The partial deck plans corresponding to these locations can be found in Figure 5 and Figure 6. The floor area of N293 was increased with  $12m^2$ , decreasing the area associated with neighboring corridor N295. The N330 restaurant is located next to a sundeck (N331) which was converted to become part of the N330 restaurant. The agents originally visiting the sundeck were relocated to adjacent sundeck nodes on the same deck.

**Figure 5: Deck 12 SAFEGUARD layout at N330 (Galea et al., 2012)**

**Figure 6: Deck 11 SAFEGUARD layout at N293 (Galea et al., 2012)**

The location-specific infection risk for N293 and N330 can be found in Figure 7 and Figure 8. In Figure 7, there is a significant local risk improvement for the N293 restaurant. The average infection risk at N293 decreases to 1.57%, compared to 2.67% for sample case 1 (SC1) and 2.61% for sample case 2 (SC2). The N293 layout adjustment does not lead to higher infection risks for the surrounding nodes. Figure 8 presents a different picture as the N330 layout adjustment does not improve the local risk to a similar degree as the N293 adjustment. The average risk for N330 only decreases from 3.59% (SC1) or 3.51% (SC2) to 3.30% for the adjusted layout. The infection risk of adjacent node 331, which was converted from sundeck to restaurant, shows a risk increase to 1.57% compared to 1.17% for SC1 and 1.07% for SC2. The rerouted guests who are now using other sundecks do not significantly increase the infection risks for these sundeck nodes. If a local risk improvement for node 330 is to be achieved, a larger layout adjustment might be required. The N330 adjustment also shows that in trying to decrease the infection risk for a specific location, surrounding nodes might present with increased risk. This compromise should be considered whenever discussing layout adjustments in an effort to improve local infection risk.

**Figure 7: Infection risk at N293**

**Figure 8: Infection risk at N330**

Moving from local risk results to overall ship infection results, local improvements are not distinguishable from the risk variation related to the randomness in the route choice model output. This was expected as the layout adjustments were small compared to the size of the complete ship. Also, the agents affected by the layout change only cover part of the population. Thus, the improvements are simply too small to be visible in full-ship infection results even if local risk improvements are achieved.

## CAPACITY REDUCTION

The integrated model was also used to test an operation measure, namely the capacity reduction for both the crew and guests. This measure was implemented for the following reductions  $CR = [2562, 2280, 1994, 1708, 1422, 1140, 711]$  agents corresponding to reduction percentages  $CR = [10, 20, 30, 40, 50, 60, 75]\%$ . The guest-to-crew ratio was kept constant and the reduced number of guests and crew was randomly removed from the activity schedule.

Figure 9 gives the total infection risk for the investigated capacity reductions. Sample case 1 and 2 are presented in the figure for 0.807% (SC1) and 1.05% (SC2). The average infection risk reveals a decreasing trend for increasing capacity reductions. The main mechanism behind this risk improvement can be related to increasing social distances through lower space occupancies. The average risk increase between 20% and 30% is unexpected but can be connected to the randomness in the integrated model input. This randomness is found in the population draws for the capacity reductions and in the route choice model outcomes used as integrated model input. This variation can also be recognized in the two sample cases for which the first sample case provides more favourable infection risk results. During the simulations, SC1 was used as a conservative reference in the sense that this sample already has low infection risks without any layout intervention or

implemented operational measures. Sample case 2 presents a more average situation related to infection risk. All capacity reductions lead to smaller infection risks than the second sample case with risk reductions from 4.8% (CR=10%) up to 40% (CR=75%). Compared to SC1, capacity reductions above 50% result 2.6% (CR=50%), 6.5% (CR=60%) and 22% (CR=75%) risk reductions.

In Figure 10, the percentage of the population with an infection risk above 50% over time is visualized. The capacity reduction below 50% are not presented in the figure as they only showed small improvements for the number of high-risk agents around 13:00. However, the capacity reductions above 50% show an infection risk improvement compared to sample case 2, especially for the risk peaks around 13:00 and 15:30. These times correspond to the end of the morning activity and the end of lunch.

Combining the results from Figure 9 and Figure 10, some general conclusions can be drawn. Improvements are achieved in the average infection risks, especially for higher capacity reductions. Additionally, for higher capacity reductions, the percentage of agents at high risk decreases compared to sample case 2. The improvements for smaller capacity reductions remain limited. A possible reason for this could be linked to the initial crowdedness onboard cruise vessels. When the number of guests and crew is slightly reduced, the ship remains crowded and social distance might not significantly improve. In this situation, large capacity reductions are required in order to achieve larger infection risk improvements. These increased capacity reductions might introduce issues around economic and operational feasibility. A possibility could be to implement a small capacity reduction as part of an intervention plan; also covering other operational or behavioral measures which together achieve infection risk improvements.

**Figure 9: Average infection risk over CR**

**Figure 10: Infection risk above 50% for CR**

## MASK WEARING

A third investigated scenario is the behavioral intervention covering mask wearing by guests and crew. Mask wearing can be conveniently implemented in the modified Wells-Riley from Equation 2 through the definition of an adjusted pulmonary ventilation - and quanta production rate. The adjusted pulmonary ventilation rate is given in Equation 3 with respiratory filtration efficiency  $\eta_R$ . Equation 4 defines the adjusted quanta production rate  $q$  for an exhalation filtration efficiency  $\eta_E$ . The respiratory and exhalation filtration efficiencies are assumed to be 50% for surgical masks (Zheng et al., 2016; Dai and Zhao, 2020).

$$p_{adjusted} = p(1 - \eta_R) \quad (3)$$

$$q_{adjusted} = q(1 - \eta_E) \quad (4)$$

Three measure variations were formulated, specifying in which conditions guests and crew wear a mask. In the first case (MASK1), guests are wearing masks whenever they are moving between locations and crew members wear their masks continuously over the course of the day. The second case (MASK2) features a situation where guests are continuously wearing a mask except when they are at breakfast, lunch or dinner. The crew is, again, wearing their masks for the entire day. The final case (MASK3) relates mask wearing to the actual local social distance. In this situation, the crew and guests are obliged to wear a mask when the social distance becomes smaller than a specified safe distance. This safe distance is set to be 1.5m (CDC, 2020; European Centre for Disease Prevention and Control, 2023).

For all scenarios involving face masks, the average total risk results are lower than both sample cases as seen in Table 6. For MASK1, the average infection risk reduction is 2.4% compared to SC1 and 25% compared to SC2. This improvement can be solely attributed to a decreased risk for the crew who are wearing masks. The average guest risk shows no significant improvement compared to both SC1 and SC2. Notable average risk improvements are found for MASK2 and MASK3 with a risk reduction over 40% compared to SC1 and more than 50% compared to SC2. The guest infection risk for continuous and social distance-based mask wearing lie close together. A possible reason could be that the guests in MASK3 are almost continuously wearing a mask because the social distance is smaller than the set safe distance for the majority of the time.

**Table 6: Average infection risks for mask wearing**

Result [%]	SC1	SC2	MASK1	MASK2	MASK3
Average infection risk	0.807	1.05	0.787	0.451	0.487
Average guest infection risk	0.730	0.935	0.925	0.478	0.481
Average crew infection risk	1.04	1.39	0.362	0.369	0.506

Figure 11 presents the average infection risk over time for the three mask wearing scenarios. In scenarios MASK2 and MASK3, a pronounced risk decrease is recognized for the activities in between the meals around 13:00, 17:00 and after 21:30 for the evening activity. The 10:15 risk peak presents different behavior which can be explained by the fact that passengers do not wear a mask during breakfast. Continuing on this reasoning, the end of lunch peak around 15:30 and end of dinner peak around 20:00 are also expected to show less risk improvement. The figure indeed shows that for these timings there is little risk improvement for the tested cases compared to sample case 2.

**Figure 11: Average infection risk for mask wearing**

In Figure 12, the guests at high risk are presented. MASK1 follows a similar trend as sample case 2, with a peak increase around 15:30. This increase might be the result of route choice model output variations. In general, wearing a mask solely during movement does not significantly improve the infection risks experienced by the guests. This matches with the findings for the ship layout design, where the nodes presented with higher infection risks than the links. The figure also shows that for MASK2 and MASK3, there are no guests with a risk above 50% except around 13:00. This is a major improvement compared to sample case 2. Looking at Figure 13, the crew at high risk is reduced for all scenarios involving masks, especially compared to SC2. The maximum number of crew members at high risk is 6 (MASK1-3) compared to 9 (SC1) and 38 (SC2) crew members.

**Figure 12: Guest infection risk above 50%**

**Figure 13: Crew infection risk above 50%**

Continuous (MASK2) and social distance based mask wearing (MASK3) show most potential. Choosing between these two behavioral measures, with similar infection risk results, might instead be a question of preferred policy. Continuous mask wearing provides more clarity because guests and crew know when to wear a mask. Additionally, this measure avoids the situation where agents are frequently switching between mask on and mask off. Social distance based mask wearing could increase awareness around social distancing and crowded spaces. Guests might actually choose a different activity or route based on crowdedness and whether or not they have to wear a mask. Leaving these considerations aside, both measures do present significant average risk improvements and a reduction in the number of guests and crew at high risk.

### COMBINED MEASURES

The previous sections described the implementation of capacity reduction, mask wearing and possible layout adjustments. The interventions can also be combined to further reduce COVID-19 infection risk. The combinations can be found in Table 7. The N293 layout adjustment was applied as it proved to decrease local infection risk without compromising surrounding nodes. The 50% capacity reduction is tested as this was the first scenario which presented with lower average risk results than sample case 1. Also, a 30% capacity reduction is investigated. This capacity reduction functions as a compromise between infection risk, profitability and operability. These two capacity reductions and N293 layout adjustment are combined with continuous mask wearing (MASK2) and social distance based mask wearing (MASK3).

**Table 7: Specifications combined measures**

	Layout adjustment	Capacity reduction	Mask wearing
C1	N293	CR = 30%	MASK2
C2	N293	CR = 50%	MASK2
C3	N293	CR = 30%	MASK3
C4	N293	CR = 50%	MASK3

The average infection risks are given in Table 8. The highest risk improvements are achieved for C1 and C2 when capacity reductions are combined with continuous mask wearing. The average risk from SC1 is reduced by 57% for C1 and by 64% for C2; compared to a 44% risk reduction when continuous mask wearing is applied as a stand-alone measure. The difference between a 30% and 50% capacity reduction is visible between C1 and C2 (-0.05%) and between C3 and C4 (-0.03%). Although, these differences seem rather small compared to the economic and operational impact that a 50% capacity reduction might have compared to a 30% capacity reduction. Figure 14 shows that for the combined cases, the average infection risk over time significantly decreases. The infection risk peak for breakfast does remain for the combined cases even as the other peak moments significantly decrease. A possible explanation for this is the fact that in a relatively short time, all guests move to breakfast and both crew shifts start in the same period. The movement of the guests still needs to spread out as they experience variations in activity duration over the day. For C1 and C3 there are no agents with an infection risk above 50%. C2 and C4 respectively have a maximum number of 2 guests and 2 crew with a risk above 50% at a single moment during the day. This is a significant improvement for the crew compared to Figure 13 for mask wearing without capacity reduction.

**Table 8: Average infection risks for combined measures**

Result [%]	SC1	SC2	C1	C2	C3	C4
Average infection risk	0.807	1.05	0.343	0.295	0.427	0.396

**Figure 14: Average infection risk for C1-C4**

## DISCUSSION

The developed model presents a proof of concept for integrating a route choice movement model and a modified Wells-Riley infection model with the goal of investigating COVID-19 airborne infection risk onboard large passenger vessels. During the development and scenario evaluation, certain assumptions were required in order to move forward. These assumptions concerned the ship layout, agent activity schedule, compliance with implemented measures and chosen parameters. The infection results of the two sample cases revealed the variation related to the route choice model output. This in itself is also a strength of the integrated model because the movement of people is difficult to predict and should therefore feature a degree of randomness. However, to further improve the consistency of results it would be beneficial to increase the number of repetitions for further research. This also includes the repetition of population draws for the capacity reduction cases.

With respect to the integrated model, there are several areas available for further improvement and research. Firstly, the social distance calculation in the model is purely based on the location floor area and occupation. It was assumed that the agents distribute themselves over the available space and do not group together. In reality, the agents will probably group together and use the available space less efficiently, leading to smaller social distances and higher infection risks.

Secondly, the ship layout presents an opportunity for further improvement. The current layout does not model crew accommodation and the guest cabins are modeled in large groups. It could be interesting to implement a risk indication for the time agents spent in their cabins. This might require a different infection model than the one currently implemented. Also, the SAFEGUARD dataset was specifically created for the evaluation of large passenger evacuation models. During evacuations, elevators are not in use and they are thus not included in the current ship layout. These elevators are small spaces where agents stand close together, potentially resulting in high infection risks.

Thirdly, the integrated model only accounts for the airborne transmission of COVID-19. There are other modes of transmission, like contact transmission, which are relevant for infection risk onboard large passenger vessels because of the crowded spaces and shared (sanitary) facilities. These other transmission modes can increase the infection risks and specific control or preventive measures might show inferior or superior results when additional transmission modes are taken into account. Next to the transmission modes, there are medical parameters with a constant value that require further attention. For example, the pulmonary ventilation rate is constant for the integrated model. When someone is exercising in the gym, this ventilation rate will increase significantly and a crew member at work might have a higher pulmonary ventilation rate compared to the guests.

Suggestions for future research can move in either a microscopic or macroscopic direction. For the macroscopic direction, it is relevant to notice the boundaries of the current infection risk calculation, as the integrated model assumes the passenger vessel to be a confined environment without any outside influences. Additionally, the model is focused on infection risk and does not specify disease progression in terms of cases. If the ship were considered in its environmental setting, ports and travel routes become relevant because infected individuals might embark or disembark the vessel. In summary, the integrated model could be further developed describing cases over an extended period of time while incorporating the environmental setting of the passenger vessel.

Future research could also move in the microscopic direction, related to the ship layout, the investigated disease and the tested measures and adaptations. This research might describe an extended sensitivity study for the base cases where the activity schedule and the ship layout are radically changed. Additionally, the current research covered a COVID-19 application of the integrated model for a cruise vessel layout. The integrated model could also be applied to a large naval vessel or a ferry to investigate the risk of another contagious disease in different circumstances. A final suggestion beyond retrofit design is the option to determine infection risk performance for a set of initial stage design plans. This could provide infection risk insight before a ship design is finalized and the ship is built.

## CONCLUSIONS

This paper aimed to: *Investigate the effect of ship layout design, capacity reduction and mask wearing on COVID-19 airborne infection risk onboard large passenger vessels*. This investigation is based upon the development of an integrated model that calculates agent-based infection risk, incorporating guest and crew circulation through a passenger ship layout. Various movement and infection models were studied in an effort to find the model combination that best fits the proposed model requirements. After careful consideration, a mesoscopic route choice model and a modified Wells-Riley infection model were selected for model integration. The integrated model was validated for two sample cases without any applied measures or layout adjustments.

Ship layout design, capacity reductions and mask wearing measures were evaluated using the integrated model. The node locations presented with higher infection risks than the links, caused by high occupancy and extended exposure time at nodes. The proposed layout adjustments resulted in local risk improvements. Investigating these layout changes is important as risk reduction for one location might lead to a risk increase somewhere else in the layout. For increasing capacity reductions, the average infection risk decreases. This is specifically visible for higher capacity reductions above 50%. A possible reason could be the initial busy and crowded environment onboard a large cruise ship, which requires large capacity reductions in order to achieve larger infection risk improvements. These large capacity reductions do raise questions regarding operational and economic feasibility. It might be interesting to combine a ‘smaller’ capacity reduction with other control or prevention measures like mask wearing. For the mask wearing scenarios, the highest average risk improvements from the three tested interventions were achieved. Continuous and social distance based mask wearing reduced the average risk over 40% compared to the sample cases.

When continuous mask wearing is combined with a 30% or 50% capacity reduction, average infection risk reductions over 55% are achieved compared to the sample cases. The average risk improvement between a 30% and 50% capacity reduction, combined with mask wearing, is relatively small compared to the economic and operational impact of a 50% capacity reduction. For all tested combined measures, there is a significant reduction in the number of agents that present infection risks above 50% over the course of a day.

Considering the evaluated infection risk for the different layout adjustments, measures and combined scenarios; the aim of this paper was reached using the developed integrated infection and crowd behavior model. Additionally, the model presents opportunities for further research and evaluation of different interventions, alternative ship layouts and application during the initial design stage.

# Introduction to the Concept of the German Navy Stability Standard DMS 1030-1

P. Russell<sup>1,\*</sup>

## ABSTRACT

*Following World War II and the founding of the German Armed Forces, lessons learned from ship accidents as well as scientific advancements called for a new stability regulation specific to the Federal German Navy, the BV 103. While certain minor modifications have been made through the years since then, the basic concept behind this standard still remains effective up to the succeeding regulation DMS 1030-1 of this day. With the most recent additions it has been proven to keep up with and even outclass the safety levels of current civilian stability regulations. The key to this success is early adaptation of available scientific techniques outside the usual constraints of large regulatory bodies.*

## KEY WORDS

Stability; Standard; German Navy; Regulation; Code

## INTRODUCTION

Just by their designed purpose, naval vessels are subject to use cases and loads different from regular civilian merchant craft. At the same time, they still have to work on a day-to-day basis during peacetime operations. As sufficient stability and floatability form the necessary baseline of any functioning ship, having an appropriate regulation for these parameters has a major impact on the viability of a ship design and needs to accommodate both scenarios.

Therefore, the German Armed Forces (Bundeswehr) decided early after its (re)founding past World War II, that a specific stability standard was needed for the new Federal German Navy (Bundesmarine), especially since existing regulations at that time considered stability issues very simplified, if at all. This code was originally called BV (Bauvorschrift, meaning construction regulation) 103. It was later renumbered to BV 1033-1, according to the numerical identifier for “intact stability” as per the structured breakdown in the official German list of naval components and assemblies, “-1” denoting the applicability for surface vessels.

In 2001, it was again renumbered to BV 1030-1, referring to the numerical identifier for “stability” as a whole, as it also integrated inclining test requirements now. Following a recent new approach in requirement engineering of the 2020s within the German procurement organization BAAINBw (Federal Office of Bundeswehr Equipment, Information Technology and In-Service Support), the code was renamed DMS (Deutscher Marinestandard, meaning German Navy Standard) 1030-1.

This paper explains the rationale behind the creation of the original standard in the 1960s, its philosophy of stability criteria and the principal steps in its further development into the most recent edition DMS 1030-1 of 2023. A short comparison of safety levels with respect to current civilian standards is also outlined within the paper. It thereby provides the necessary basic understanding, given by the actual regulatory body responsible for said regulation, to further evaluate its impact on current as well as future navy ship designs. These design impacts themselves and the improvements to the standard derived from them are then presented by Krüger (2024).

## **HISTORICAL CONTEXT**

### **Early Regulation Efforts**

Historically, the very first regulations for seagoing ships established in the 19<sup>th</sup> century considered reserve buoyancy, i.e. sufficient freeboard, to be of most importance for ship safety. In principle, these early considerations still remain in effect up to today in form of the International Convention on Load Lines (ICLL), with every ship above a certain size being subject to corresponding calculations and markings.

Stability issues were of course also considered, at least academically, over the course of several past centuries. However, most of the time this work focused on the initial stability in form of the metacentric height GM. While it was found around the same time as the first local freeboard regulations entered into force, that ships with the same GM might have different stability issues at higher heeling angles (Reed, 1868), no mandatory rules for stability were established for quite some time after that.

Regulation efforts at those times were of course also impeded by choosing international competition rather than cooperation. Following the TITANIC disaster for example, a very early version of SOLAS was discussed for the first time internationally, but was thwarted by the outbreak of World War I. Both the impact of TITANIC as well as the World Wars also meant, that the safety of damaged ships got a lot more focus than intact stability. And even then, the safety of damaged ships was mostly considered a problem to be solved rather with freeboard and subdivision than with stability requirements – that might have developed differently if TITANIC had capsized before it sunk due to progressive flooding.

Therefore, safe ship design from a stability point of view relied mostly on experience and best practice by naval architects and generally not on mandatory requirements. Even after Rahola (1939) came up with his famous basic intact stability criteria, it was not until late into the 1960s that the Inter-Governmental Maritime Consultative Organization (IMCO, today's International Maritime Organization IMO) finally adopted these officially, albeit first as a recommendation (!) for fishing vessels only, becoming mandatory for all ships as late as with the 2008 International Code on Intact Stability (IS Code). Mandatory damage stability criteria also were not available until 1960 at the earliest, and even then, they were very basic and not applicable for all ship types.

### **Rationale for a New German Navy Stability Standard**

The Federal German Navy was founded on January 2, 1956 after the reestablishment of the German Armed Forces in late 1955. In its very early days, it consisted mostly of ship designs from World War II as well as ships bought from allies. However, the new role of Germany within NATO as well as technological advancements soon required a new quality and quantity of naval ships and corresponding designs.

On the other hand, rebuilding efforts after World War II led to an increase in commercial shipbuilding activity around the world, now trying to keep to the non-mandatory Rahola criteria as the newest best practice as far as reasonably possible. Having lost the war, Germany was limited to a certain size of ships under its flag, which then were designed and operated with very little regard even to these still very basic criteria to maximize payload. As a result of this, a lot of stability accidents including capsizings of undamaged German-flagged merchant ships happened in the 1940s and 1950s, which were noticed especially in the German scientific community of the time (Wendel, 1958).

The German government as the responsible flag authority of course had to investigate these accidents and therefore cooperated closely with these scientific institutions, in this case the Technical University of Hanover and the University of Hamburg. Implementing the German lessons learned from these investigations on an international level for the merchant navy had to wait due to the number of nations involved, as described above. Germany however took initiative trying to avoid the failure modes leading to said accidents at least for its new military, as regulations for warships were in the own interest of each nation and therefore excluded from IMO regulations up to this day. Furthermore, the special stability needs due to the varying military usage of navy ships are not accounted for by civilian standards, e.g. maneuvering a tight turning circle at full speed for example.

Therefore, it was decided to create a new stability standard for the Federal German Navy together with the mentioned German scientific institutions. Ironically, the first ship these rules were applied to was the sail training vessel GORCH FOCK of 1958, a modified design of the 1930s and in service up to this day. A preliminary version of the standard then became official in 1961, incorporating full-scale stability measurements and experiences from designing and operating the GORCH FOCK, and applied to other vessels as well.

As a baseline, the German researchers looked at the Rahola criteria (Arndt, 1965), as they were best practice at the time. While they appreciated that these took the whole righting lever curve beyond the initial stability GM into account, they reasoned that general safe criteria for the righting lever curve cannot be formulated without considering the individual inclining levers for each ship and load case as well. In principle, they also looked back into the work of Reed (1868), who had already found out about decisive effects of the same inclining lever acting on ships with different righting levers, and argued to combine his approach (with modified and additional inclining levers) with modified criteria of Rahola.

In addition, and as their investigations into the post-war accidents had shown, it was also deemed necessary to formulate requirements for stability in a seaway. Due to the failure modes encountered in these accidents, stability in longitudinal waves had been found especially important to consider.

These two main factors, comparison of individual righting versus inclining levers and consideration of stability in a seaway, form the successful backbone of the German Navy stability standard up to this day and are at least in combination still somewhat unique to other regulations.

# REGULATORY FRAMEWORK OF THE DMS 1030-1

Every basic concept explained in this section applies to the original edition of BV 103 of the 1960s as well as its later variants BV 1033-1/1030-1 in several following editions and the newest DMS 1030-1. For ease of readability however, within the text the regulation referred to will always be DMS 1030-1, with differences to earlier editions being outlined as they apply.

## Universal Design Assumptions

The starting point for applying DMS 1030-1 is given by the so-called operating area group, see Table 1, which has to be chosen depending on the use cases of the ships by the navy and by the procurement organization. Historically, larger ships like frigates, destroyers and tankers were assigned to the highest operating area group A, medium-sized ships like corvettes and squadron tenders were designed for operating area B, while operating area C was intended for small combatants like minehunters and offshore patrol vessels. These three operating areas were already present in the first version of the standard and have remained unchanged to this day. The operating areas D to F were added later and are used for small craft, which will not be subject of this paper.

**Table 1: Operating area groups in DMS 1030-1 (BAAINBw, 2023)**

Operating area group	Operating area	Design wind speed in knots	Additional limitations
A	Worldwide, unlimited	90	n/a
B	Worldwide, outside tropical storms	70	n/a
C	Coastal	50	n/a
D, E, F	Shore-based, harbors, inland	20 - 40	restricted wave height and distance to the shore, decreasing from D to F

Nowadays, the military focus of the German Navy has generally shifted from operating mainly in the Baltic and North Sea to being able to perform missions worldwide, while relying more on single ships per mission rather than small squadrons. Thereby range and endurance considerations have made former small ship types bigger and so operating area group A is demanded more and more as a de-facto default for most of the ongoing newbuilds of the German Navy.

Then there are several standard load cases defined in DMS 1030-1, the most important ones are given in Table 2. These have been heavily modified in their total extent, numbering structure and detailed definition since the original BV 103, but the principles shown in Table 2 have always been implemented in the standard. These standard load cases consider the special purpose of navy ships with many details, e.g. with respect to endurance requirements and ammunition depletion during the mission they are designed for. There are some additional standard load cases defined for special mission requirements, but they are seldom design-driving and therefore omitted in this paper.

Each of the seagoing load cases 1, 1A, 2 and 2A however also has a variant with heavy ice accretion of up to 15 cm thickness, depending on the operating area group. As Figure 1 shows, this is not an academic problem, because being able to operate all-year around also in colder regions is mission-critical for a navy faced with potential adversaries in said cold regions. These ice

load cases do not have to fulfil damage stability requirements, but are regularly design-driving for intact stability, as several hundred tons of ice mass at a very high center of gravity have to be considered in the calculations.

**Table 2: Standard load cases in DMS 1030-1 (BAAINBw, 2023)**

Load case ID	Designation	Explanation
0	Light displacement	Non-seagoing, empty vessel with crew and specified equipment and system fillings
0V	Short move displacement	Same as load case 0, but with additional ballast due to trim restrictions for docking and warping
1	Limit displacement	End of mission, ammunition only partly depleted, other consumables fully depleted
1A	End-of-life limit displacement	Same as load case 1, but with commissioning reserves
2	Full-load displacement	Begin of mission
2A	End-of-life full-load displacement	Design load case, same as load case 2, but with commissioning reserves

Another factor not to be overlooked is the commissioning reserve, which started at 2 to 6 percent of the light ship weight at delivery (depending on the ship type) in older versions of the standard. It has now been increased to 10 percent of this value and at a higher center of gravity, as the lifetime of German Navy ships tends to be extended more and more and lots of weight-intensive retrofits accumulate over this period, so that several older ship classes now operate at their stability limits and can only be modified further with expensive countermeasures, if at all. As a side note, the German Navy also uses a realistic person weight derived from several actual measuring campaigns resulting in 91 kg per soldier, which of course is also used in other areas such as the design of life saving equipment.

**Figure 1: Ice accretion (Source: NATO)**

Especially for naval auxiliaries carrying large amount of supplies, additional variants and/or intermediate stages of the mentioned load cases need to be added. As per DMS 1030-1 all tank fillings are assumed at a maximum of 95% filling of the net tank volume and the tanks are actually built to physically achieve only this limit. This is done to achieve at least a basic protection against hull ruptures from underwater explosion shock pressures by allowing the incompressible fluids to move. As a side effect, this also leads to a clearly defined maximum free surface moment of the tanks.

In this context, it is important to note that in DMS 1030-1 the effect of free surfaces is always considered as an inclining lever  $l_f$  with the actual tank moments, not some simplification using the surface moment of inertia, see Equation 1 with  $p$  denoting the individual tank masses and  $b(\varphi)$  denoting the tank cross-curves of stability.

$$l_f = \frac{\sum_i p_i \cdot b_i(\varphi)}{\Delta} \quad [1]$$

This inclining lever is always present in all load and damage cases and used in every stability criterion. In addition, all hydrostatic calculations are to be done with free instead of fixed trim.

As a consequence, this also means that the actual righting lever curve has to be treated and presented separately without free surface correction in the German Navy stability documentation. This documentation follows a unified approach for every ship class designed according to DMS 1030-1 and presents a lot of data at a quick glance on a single page per load or damage case, which is useful for training purposes as well as quick decision making under pressure in combat. For this purpose and some ship classes, a stability computing software with decision making support is developed by the Bundeswehr itself and supplied to the contractors responsible for the automation software, whose hardware (operating station and sensors) it then uses.

The complications mentioned in the paragraphs before had to be argued for quite a lot back in the 1960s – and even today for some projects –, as they meant a calculation effort at the yards hitherto unknown, and later also made a solid business case for the increasing use of computers and corresponding software programs in naval architecture developed in cooperation with the German scientific community.

## General Criteria Approach

As a first step for every load or damage case to be investigated according to DMS 1030-1, a lever balance with the applicable righting and inclining levers has to be established. Then, all of the stability criteria follow the same basic concept, as two conditions have to be satisfied. Firstly, the inclining angle has to stay below a certain value, depending on the condition (still water, seaway, damaged, special) and operating area group. Secondly, a reference angle is determined, at which a minimum residual righting lever “GZ<sub>S</sub>-Rest” has to be reached, see Figure 2. The reference angle  $\Phi_{ref}$  for the intact condition is then determined by

$$\phi_{ref} = \max(2 \cdot \phi_{equi} + 5^\circ; 35^\circ) \quad [2]$$

from the inclining angle at the equilibrium  $\Phi_{equi}$ , while the reference angle for damaged conditions is derived from

$$\phi_{equi} + 15^\circ \leq \phi_{ref} \leq \min(40^\circ; \phi_{df}) \quad [3]$$

with  $\Phi_{df}$  denoting the angle of downflooding. The limit for the residual righting lever depends on the inclining angle in the equilibrium, but is never lower than 0.1 m in the intact and 0.05 m in the damaged condition.

Figure 2: Typical DMS 1030-1 lever balance with inclining levers, reference angle and residual righting lever (BAAINBw, 2023)

This two-part approach allows to account for several requirements. First off, the inclining angle part of the criteria is able to consider limits set by the crew and operations on board and is in itself not primarily driven by safety concerns. The necessary safety is then given by the residual righting lever part of the criteria, which is intelligently coupled with the inclining angle at the equilibrium resulting from the applied inclining levers. Due to the third factor, the use of minimum values for the reference angle, at which the residual righting lever is to be achieved, a minimum safety level is always guaranteed, even for very little inclining levers. Lastly and maybe most importantly, the reference angle concept implicitly also leads to restoring energy reserves in addition to the pure static requirements, as should be immediately clear from Figure 2, if the areas between the righting and inclining lever curves left and right of the equilibrium angle (in this case  $\Phi_{TC}$ ) up to the reference angle (in this case  $35^\circ$ ) are compared.

As a boundary condition of course, sufficient freeboard with regard to watertight and weathertight integrity has to be achieved for the stability assessment. Historically, the revisions of BV 103/1033-1/1030-1 up to 2015 required the bulkhead deck to be not submerged in any condition. Since per the standard and in difference to civilian regulations the bulkhead deck had to be completely watertight anyway and as a result of investigations explained further down below, it was decided for the 2015 revision of BV 1030-1 to review this approach and now allow consideration of individual watertight and weathertight openings in the same way as in civilian standards.

## Intact Stability in Still Water

The intact stability requirements of DMS 1030-1 for still water conditions focus on the main use cases of navy ships in general as well as the individual ship type. This means, that as a baseline every ship subjected to the regulation has to be able to perform a turning circle at maximum speed and maximum rudder angle in every seagoing standard load case, while at the same time being subjected to a steady cross wind of 40 knots and the actual fluid shifting moments, with sufficient stability. This means that a maximum heeling angle of  $15^\circ$  and a minimum residual righting lever at the reference angle of in this case  $35^\circ$  have to be complied with. These criteria have to be met even with up to 15 cm of ice accretion, depending on the operating area group. Until BV 1030-1 was revised in 2015, this criterion with ice accretion often was design-driving in the intact condition.

**Figure 3: High speed turning circle (Source: Bundeswehr / Carsten Vennemann)**

As Figure 3 shows, the actual turning circle at full rudder can be quite tight, while the speed loss might be quite significant. Because the actual turning circle parameters can be quite difficult to compute properly (and were nigh impossible to do back in the 1960s), DMS 1030-1 uses an equation with an empirical factor  $C_D$  derived from a range of real ship types (Arndt, 1965):

$$l_{TC} = \frac{C_D \cdot v_{max}^2 \cdot (\overline{KG} - 0.5 \cdot T)}{g \cdot L_{DWL}} \cdot \cos \phi \quad [4]$$

As a matter of fact, and despite all shifts in naval design since the 1960s, this factor (default value 0.3) holds up quite well until this day if no other data is available. The wind inclining lever is then derived from Equation 5, the factor 0.25 ensuring proper developing of values at higher angles (Arndt, 1965).

$$l_v = \frac{A_v \cdot (A_{VZ} - 0.5 \cdot T)}{\Delta \cdot g} \cdot p_v \cdot (0.25 + 0.75 \cdot \cos^3 \phi) \quad [5]$$

Explicit values for the wind pressure are prescribed in the standard for every 10 knots increase of wind speed. To determine the windage area  $A_v$ , individual drag coefficients for different shapes are required in the standard, e.g. for lattice structures often found on radars in older navy ship designs.

Factors other than turning circle, wind and free surfaces in still water conditions are then considered depending on the ship type. Replenishing ships for example need to be able to withstand an inclining lever of its replenishment-at-sea (RAS) gear,

basically a pulling force (equivalent to the breaking strength of the gear already including safety margins) acting very high up in the supply mast. This is because for technical reasons the RAS gear is fastened much higher on the supplying ship than on the supplied ship, see Figure 4. The criterion for the RAS residual righting lever at the reference angle of  $35^\circ$  remains the same as for other criteria, the permissible inclining angle however is project-specific to the type of supply ship, but generally lower than  $15^\circ$ .

**Figure 4: RAS maneuver (Source: Bundeswehr)**

Tugs are designed using a similar approach to the RAS inclining lever, albeit with slightly modified parameters. In addition, smaller ships (operating area group E especially) are generally subject to unsymmetrical loading criteria in DMS 1030-1 as they are vulnerable to persons shifting positions, but are as mentioned omitted in this paper. Lastly, if the ship type calls for it, project-specific inclining levers can very easily be integrated using the described criteria philosophy.

## Intact Stability in a Seaway

In addition to the intact stability requirements in still water, DMS 1030-1 requires every ship in intact condition to be resistant to lateral wind pressure as per Table 1, while at the same time being underway in longitudinal waves. This combination of longitudinal and lateral influences might seem contradictory and too conservative at first, but in conditions with such high wind speeds, wind direction might change much quicker than wave direction (Arndt, 1965).

The design wave length  $\lambda$  in DMS 1030-1 is set to the length between perpendiculars  $L_{PP}$  of the ship, while the wave height  $H$  is derived from this length as per Equation 6 and both are then combined to a sinusoidal wave. It should be noted that the aft perpendicular (AP) of German Navy ships usually is defined by the intersection of the design waterline with the transom instead of the civilian definition with AP at the rudder post.

$$H = \frac{\lambda}{10 + 0.05 \cdot \lambda} \quad [6]$$

Using Equation 6, for a typical navy ship of 120 m in length a wave height of 7.5 m is the result, resulting in a wave steepness of 1/16. On the one hand, this is quite a large design wave for this ship size, especially compared to some other standards. On the other hand, this steepness is close to the breaking limit of natural waves, so the approach is also very conservative.

With this wave length, righting and inclining levers for three conditions have to be calculated and evaluated for different criteria: ship on wave crest, ship in wave trough and the average of these two, called “ship in a seaway”. Historically, the investigation of different wave phases between these extrema as well as trochoidal waves had also been used in the standard, but were omitted at some time in favor of the current conservative approach of just these three conditions.

In the condition “ship in a seaway”, the inclining levers due to free surfaces and wind pressure as per Equation 1 and 5 are combined and then subjected to the general criteria approach explained above. The permissible inclining angle is depending on the operating area group and can be up to  $25^\circ$  for operating area group A, leading to a reference angle of up to  $55^\circ$ , which then can be of consequence design-wise for the placement of non-weathertight openings such as large gas turbine air intakes.

In a second requirement, the worst of these three righting lever curves, usually ship on wave crest, has to be subjected to the inclining lever curve from free surfaces. It then still has to achieve positive residual righting lever values all the way from the equilibrium with this inclining lever up to 45° inclining angle, reaching 0.05 m at least once during this range. Both requirements have to be reached including ice accretion also, although the wind speeds for the first requirement may be reduced in this case to as low as 40 knots, depending on the operating area group.

With these two steps, the German Navy stability standard had already considered two out of the five failure modes as per the IMO Second-Generation Intact Stability Criteria, namely “dead ship” and “pure loss of stability”, back in the 1960s, i.e. several decades beforehand. This was only possible due to the circumstances mentioned in the historical summary above, which presented Germany with the opportunity to come up with something better than what was (insufficient) best practice at that time. One decisive factor to achieve this was of course also the relatively small and at the same time scientifically open-minded regulatory body responsible for the German Navy stability, being able to make quick decisions, which has continued to be like that until this day. In that sense, in the early 2010s it was decided to enhance the German Navy stability standard, finally resulting in BV 1030-1 of 2015 with an additional criterion for the intact stability in waves (Krüger, 2012).

This was deemed necessary because the design of German Navy ships had changed quite a bit over the 50 years since its founding. These design changes can be attributed to a number of factors. One major step was the increased use of helicopters now requiring large flight decks, a trend which also afflicted supply vessels. Another one was the introduction of more complex gun systems requiring more space on deck as well as below deck at the bow. Both trends are illustrated by Figure 5 with two ship pairs, each of a comparable base type but several decades apart.

Then there was a general trend to increase the endurance of ships, leading to larger tank volumes. With growing endurance – and also increasing demands for more comfort on board, i.e. bigger and less crowded rooms, by crews of younger generations – the ship hulls got bulkier and have much more enclosed decks now. At the same time service speed requirements were lowered from 35+ knots down to 20 to 30 knots due to changes in mission profiles, allowing for this increase in block and midship section coefficient in the first place.

**Figure 5: Development of German Navy ship types (Sources: Bundeswehr / Christian Klöcking, Marcel Kröncke and Carsten Vennemann)**

As a consequence of more flared frames and increased bulkiness, German Navy ships got generally more susceptible to righting lever alterations in waves and therefore parametric excitation of roll motions, which called for an additional criterion to limit these. The scientific background applied for this is described in more detail by Kluwe (2009), Krüger (2012) and Krüger (2024). Using the conditions ship on wave crest  $GZ_C$  and ship in wave trough  $GZ_T$  in DMS 1030-1, the criterion is then formulated using Equation 7 with the areas defined in Figure 6.

$$A_2 \stackrel{!}{\geq} 2 \cdot A_1 \quad [7]$$

**Figure 6: DMS 1030-1 area criterion (BAINBw, 2023)**

With this new area criterion, DMS 1030-1 now also directly addresses a third failure mode of the IMO Second-Generation Intact Stability Criteria, namely “parametric rolling”. Ever since its introduction in 2015, it has now become the design-driving intact stability criterion of DMS 1030-1 in several projects, especially if ice accretion is involved. This then leads designers to rethink their approaches and reintroduce some features from older proven hull forms, such as V-hulls, larger bilge radii and lines with less flare of frames and buttocks (especially in the bow area), because the righting lever alterations in waves are primarily governed by the change of waterplane area in vertical direction.

## Damage Stability

The damage stability in DMS 1030-1 follows a deterministic approach with a given damage length as per Equation 8. Keeping an absolute upper limit for the damage length is considered to be a sufficient compromise as a result of investigations into the safety levels described further down below, even for larger ship types.

$$L_l = \min(0.18 \cdot L_{DWL} - 3.6 \text{ m}; 18 \text{ m}) \quad [8]$$

This damage length is then to be applied with half the ships breadth penetration depth (up to centerline and excluding centerline bulkheads, if applicable) and unlimited penetration height at any given point (!) in longitudinal direction. That means there is not a specific number of compartments to be damaged like in some civilian standards, which could be directly derived from the damage length, but instead the actual damage resulting from the described cuboid is to be assumed, so compartment-internal additional subdivisions are also of importance. If a lesser extent of this baseline damage at one position leads to a more severe condition, this condition is to be evaluated with regard to the damage stability criteria and shown in the stability documentation. The same principle holds true for several cases of intermediate flooding stages differentiated in DMS 1030-1.

With respect to watertight integrity, there has to be one defined bulkhead deck as a horizontal watertight barrier to prevent up- and downflooding, which means any staircase or elevator casing penetrating the bulkhead deck also has to be watertight at minimum at that deck, but not necessarily below the bulkhead deck. Doors and hatches below the bulkhead deck are not permitted since the 2022 revision of DMS 1030-1 and are assumed open if above the bulkhead deck (no V-lines). This has two main reasons derived from experience: firstly, in general operation of the ship and especially in combat any existing opening will generate traffic of persons and often remain open, when it should not be. This has been proven time and again to be a contributing factor to many total losses including ships of foreign navies. Secondly, it presents an immense challenge to design a door or hatch, which can uphold its integrity even after a shock incident from weapon damage. For these reasons, if a door or

hatch is to be fitted below the bulkhead deck as an exemption, it will be considered open in the damage stability evaluations. From experience, ammunition and cold storage rooms provide a sufficient pressure resistance to be assumed watertight in DMS 1030-1.

The DMS 1030-1 damage stability criteria follow the same general concept as the intact stability criteria, i.e. a lever balance has to be established first, in this case with the inclining levers from free surfaces and 40 knots of wind pressure. It should be noted in this context, that ice accretion as well as waves are not considered in the damaged condition in DMS 1030-1. Damage stability however is required for every seagoing load case of the intact condition, with an exchange of fluids in damaged tanks to sea water, if applicable.

The maximum permissible inclining angle at the equilibrium from this lever balance has to be less or equal than  $25^\circ$ . Cross-flooding devices to achieve this angle are generally not permitted in the standard. The latter also implicitly drives designers to choose a more symmetrical layout, which has additional value beyond stability in combat situations, where situational awareness and short routes are beneficial. The reference angle then has to be reached as per Equation 2, with at least 0.05 m of residual righting lever in the range between the equilibrium and  $40^\circ$  inclining angle and at the same time a minimum righting lever range of at least  $15^\circ$  before reaching  $40^\circ$  heeling angle or the downflooding angle. Again, the applied reference angle concept also means that there is an inherent level of safety against residual energy from rolling motion even in the damaged condition.

With regard to freeboard requirements, until 2015 any submergence of the bulkhead deck described above was the permissible limit within the standard. Starting with the 2015 revision of BV 1030-1, it was then decided to switch freeboard requirements from considering a whole deck, which had to be completely watertight anyway, to considering individual openings. This had been deemed acceptable from a safety point of view (see also below), allowed designers more freedom of arrangement for new ships, while at the same time making no discernible difference in evaluating already existing designs. Since then, the minimum freeboard in the damaged condition required in DMS 1030-1 is 0.5 m for weathertight openings. With the latest revision of DMS 1030-1, it was decided to enhance this approach with a requirement of half the height of the design wave as per Equation 6 for non-weathertight openings to consider the effect of a seaway also in the damaged condition.

## SAFETY LEVELS

### Comparison with 2008 IS Code

The safety level of intact ships in a seaway can be quantified using the so-called Insufficient Stability Event Index (ISEI), developed by the Institute of Ship Design and Ship Safety at Hamburg University of Technology (Kluwe, 2009). A summarized introduction into the concept is given by Krüger (2022). In very short terms, an ISEI value indicates the probability of a specific failure criterion of a ship – generally a special criterion for capsizing is used, but the concept allows for other criteria also – to be reached during a calculation of a significant timeframe in a seaway with a significant statistical parameter distribution.

Figure 7: Safety levels of different civilian ships in a seaway (Krüger, 2022)

Figure 7 shows the ISEI values derived from several full-scale accidents and later model tests for ships designed according to the six Rahola criteria and the later added weather criterion, i.e. the minimum set of criteria as per the 2008 IS Code applied to any civilian ship nowadays. In a first step, the ISEI values for the actual stability – represented by the value of GM – in each accident condition are computed, resulting in the upper threshold of definitely unsafe values at 0.1 and above. In a second step, the same calculations are done after raising the stability in several steps until all of the mentioned IS Code criteria are only just fulfilled. Using the assumption that the ship loss rate resulting from applying these criteria is deemed socially acceptable, the lower threshold of definitely safe values of 0.001 and below is then determined.

**Figure 8: Safety levels of ships designed to different standards in a seaway (Krüger, Hatecke, Rinke & Tammen, 2014)**

The same concept is applied by Krüger et al (2014) to determine the safety level of BV 1030-1 for a select number of ship types of combat vessels (NCV) and auxiliary vessels (NAV) designed to said standard and compared to two merchant vessels (MV), see Figure 8. These ship types are then given stability values to only just fulfil the minimum stability criteria for the IS Code (diamonds in Figure 8) and BV 1030-1 (triangles in Figure 8) respectively.

As a result, ISEI values for ships designed and operated according to BV 1030-1 are found to be two to three order of magnitudes smaller than those designed and operated according to the 2008 IS Code. This implicitly means that the probability of capsizing in heavy weather is lower by said magnitude, which is underlined by the fact that there has never been a single loss of any German Navy ship over 60 years since the introduction of the first BV 103 and with a sizeable fleet especially during the Cold War. Even if these naval ships were to be operated with the lower stability values according to IS Code, they still would be a lot safer than any merchant vessel thanks to their design according to BV 1030-1.

However, two particular naval ship types are identified, which get a lot closer to the investigated merchant vessels with regard to safety levels than the rest of the group, even if given BV 1030-1 stability values. Looking into the source of this, the reasons described above (see around Figure 5) are found and counteracted by the introduction of the new area criterion. This means that the picture painted by Figure 8 will look even with the most recent edition of DMS 1030-1 applied for future ships. In return of course this also means, that the 2008 IS Code without the application of Second-Generation Intact Stability Criteria presents a severe safety deficit for civilian vessels, which is only somewhat healed by stability values required for damage stability – which, mind you, generally only apply for ships over 80 m in length.

## Comparison with SOLAS 2009

As described above, DMS/BV 1030-1 follows a deterministic approach to damage stability, opposed to SOLAS, which since 2009 uses a probabilistic damage stability approach for all types of ships. The damage safety index in SOLAS is determined by using the probability of a specific damage condition derived from accident statistics, then evaluating the survivability of this damage condition by fulfilment of SOLAS stability criteria to a value between 0 and 1, multiplying probability and survivability of this damage condition and then repeating the process for additional damages by adding up damage safety index until a minimum index at several draughts is reached. As the potential damage suffered by navy ships is not just inflicted by collision

or grounding, which are statistical events, but by weapon impact, which is impossible to predict and can be aimed at any part of the ship, the mentioned deterministic approach is the only viable solution for evaluating the damage stability of navy ships.

However, to compare the two standards, a theoretical design of a civilian RoPax vessel only just fulfilling the minimum damage stability requirements of SOLAS 2009 B1 is used by Krüger (2012). The damage safety index resulting from this then forms the baseline for the comparison, see the uppermost line in Figure 9. Using a comparable set of damages and damage probability, but now evaluating the survivability of each damage case with the damage stability criteria from DMS/BV 1030-1 described above, results in less than half the damage index than as per SOLAS 2009 B1 for the same ship, see the lowermost line in Figure 9. In other words, even the minimum damage stability criteria of DMS/BV 1030-1 result in more than double the safety compared to SOLAS 2009 B1.

Figure 9: Damage safety index of the same ship design assessed by different standards (Krüger, 2012)

In the same investigation, the survivability of a recent German Navy ship beyond its design damage cases is investigated. As a result, it is found that the default scope of deterministic damage cases to be investigated as per DMS/BV 1030-1 covers about 82% of all theoretically possible probabilistic damage cases. The same ship however was able to survive about 95% of all theoretical damage cases beyond its design, even with DMS/BV 1030-1 stability criteria applied, which implies a lot of implicit additional safety generated by the deterministic approach used in DMS/BV 1030-1.

## CONCLUSIONS

This paper has presented the basic principles of the German Navy Standard DMS 1030-1 as well as the rationale behind individual criteria decisions and their development over the years. Furthermore, the main reasons for its technical success were discussed upon in detail and related to the historical background during the creation of the standard. The safety levels achieved by the standard have been quantitatively shown and compared to civilian regulations. As a result, it should be clear that proper stability regulations will drive a ship design to work well in everyday civilian usage first before it then will be a good warship in combat usage as well. This is achieved by naval administrations being able and willing to react quickly to scientific developments in working closely with competent academic communities. Finally, it is found that the standard remains valid and up to date until this day and with relatively minor improvements – compared to civilian standards over the same timeframe – will continue to provide successful designs for the foreseeable future.

# The Impact of the new DMS-1030 Stability Standard on the Future Design of Navy Ships

Stefan Krüger<sup>1,\*</sup>

## ABSTRACT

In 2022, the German BAAINBw launched a revised issue of their 1030-1 stability regulations for Navy surface vessels. The improvements of the revised code concerned (inter alia) a new stability criterion for minimizing the effect of parametric rolling combined with pure loss of stability on the wave crest and revised damage stability calculation assumptions, which mainly focus on the submergence of openings and a special treatment of watertight doors. The improvements of the code were found to be necessary to keep track of recent developments in IMO for commercial ships and to update the safety level represented by the code. At the same time, the revised code gives more freedom to the ship designer, a fact which may allow novel and more cost effective concepts of Navy Ships in the near future, provided, the evaluation of the stability according to the code takes place immediately during the very early design phase of the ship. The present paper gives insight into the important updates of the code and it demonstrates at the same time how the design of Navy Ships may benefit from the revised code, if it is applied throughout the very first design phase of the ship. The paper will further present an improved design regime for the early design stage.

## KEY WORDS

Navy Ship Design, Navy Ship Stability

## INTRODUCTION

Due to their mission profile, Navy Ships encounter more and different threats compared to commercial vessels. As a consequence, Navy Ships require higher safety levels with respect to the survivability in intact and damaged conditions. Consequently, commercial safety standards such as the International Code on Intact Stability or the SOLAS, which define minimum requirements only, cannot be applied to Navy Vessels, as one of their core abilities is to survive extreme situations. This holds for the intact stability in adverse weather conditions as well as for the survivability after a damage. For this reason, Navy Ships have to comply with other, more demanding stability standards compared to commercial ships. Navy Ships may be in principle subdivided into surface ships and submarines. The present paper addresses solely Surface Vessels, which may be further subdivided into Navy Combatants and Auxiliary Ships. In 2022, the German Federal Office of Bundeswehr Equipment, Information Technology and in Service Support (Bundesamt für Ausrüstung, Informationstechnik und Nutzung der Bundeswehr), abbreviated BAAINBw) published a revised version of their stability standard for surface ships of the German Navy. The revision of this well proven and established stability standard, which was developed by Wendel in the mid-sixties of the last century (Wendel 1964) seemed to be necessary for the following reasons:

- New hull forms of Navy Ships lead to a higher risk of experiencing large roll angles due to parametric rolling. This was not explicitly addressed by the standard.
- Recent developments in damage stability assessment of the SOLAS 2009 and the SOLAS 2020 showed that the consideration of intermediate flooding stages and the treatment of openings should be reconsidered.

---

<sup>1</sup> Institute of Ship Design and Ship Safety, Hamburg University of Technology, Hamburg, Germany \* Corresponding  
Author: krueger@tuhh.de

- In some aspects, the existing stability standard was found to be unnecessarily prescriptive, and it was suspected that this might prevent novel designs of Navy Surface Ships.

When reviewing recent developments in the stability assessment of commercial ships, the following problems were identified which should be definitively avoided when assessing the stability of Navy Vessels:

- Due to the more demanding damage stability requirements in the SOLAS, the limiting GM is strongly dominated by damage stability, but the ships shall operate most of the time in intact conditions, and they should be designed for intact conditions.
- Some types of ship (e.g. large Container vessels) operate with GM- Values which are far away from those the ship was designed for.
- The commercial standard allows to make use of additional operational guidance if problems in the fulfilment of the stability are identified (2<sup>nd</sup> Generation Intact Stability Criteria). This is certainly not an adequate option for Navy Ships.

Overall, there were several reasons identified which made a revision of the Navy Stability Code necessary. The following sections explain why certain amendments of the code became necessary and how the identified problems were solved. These amendments are compared with existing stability standards and it is shown where elements of these standards (e.g. SOLAS, IS-Code) could be used and where alternatives needed to be developed. The impact of these amendments on the future design of Navy Surface Ships is demonstrated afterwards.

## INTACT STABILITY

### A brief Introduction into the Intact Stability Part of the BV 1030-1

A detailed description of the BV 1030-1 (now DMS 1030-1) is given by Russel (2024). Explanations about the development of the original stability code are given by Wendel (1964). The governing principle of the BV1030-1 is the determination of ship specific individual heeling levers, which are then checked against the righting levers of the ship as lever balances. The code does not make explicit differences between Auxiliaries and Combatants, but it specifies service categories where a ship is intended to operate. Depending on the defined service area, loading conditions, external forces and groups of stability criteria are then defined. If any German Navy Ship shall operate in a region which is characterized by a higher service category than the one the ship was originally designed for, a decision of the German Parliament (Deutscher Bundestag) is required to permit the operation of the ship. For ships in unrestricted service, which are solely treated in this paper, these lever balances have to be determined for the still water condition as well as for the ship in waves, where the two situations “ship on wave crest” and “ship in wave trough” are to be analysed. Several loading conditions including reserve deadweight for future service have to be analysed during the stability assessment, and, before each voyage, the individual loading condition has to be individually checked against the criteria by the crew by making use of the stability booklet and, if available, the loading computer. It should be noted in this context that typically, the stability booklet and the loading computer are not provided by the industry, but by the German Navy Arsenal. As the BV 1030-1 deals with explicit loading conditions, no  $GM_{\text{required}}$  (or  $KG_{\text{max}}$ ) curves are in use. For the still water condition (see Fig. 1, top right), the following heeling levers have to be determined:

- Shifting of fluids by heeling levers for each tank (the maximum permissible filling level for any tank is 95%)
- Beam Wind of 40 knots
- Turning circle at full speed (eventually, the permissible speed is limited during the operation of the ship)
- Icing
- Unsymmetrical loading
- RAS supply, if applicable

found that too many physical problems existed which prohibited to make further use of any of these criteria in the context of the BV 1030-1. The problems identified were the following (e.g. Krüger 2013, Gualeni 2015):

- The SGIT- Criteria do not sufficiently take into account that the real GZ-curve may deviate substantially from its linearization by  $GM\phi$ . As a consequence, it is neglected that the natural roll period of the ship varies with the amplitude of the roll motion.
- The natural roll period of the ship is calculated from the still water stability, but it should be calculated from the stability in waves. And it does additionally vary in waves, as the stability permanently changes.
- The criteria do not take into account any combination of parametric rolling and pure loss of stability on the wave crest, and they additionally fail if the initial stability on the wave crest becomes negative. But that is exactly the failure mode which is to be addressed by the BV 1030-1 (in following seas).
- The computation of the righting lever curve in waves in the SGIT-regulations is incorrect, as it shall be computed for several longitudinal positions of the wave crest with free trimming at the same time. This is certainly not correct, as the real trim of a ship in longitudinal wave comes from the pitching motion. And this has a strong effect on the phase shift between heeling and pitching motion and therefore on the stability alterations.

Besides the above mentioned deficiencies of the SGIT, the BV 1030-1 already includes a stability regime in waves, and the newly developed criterion should be developed as an addendum to the existing code.

The newly implemented addendum is explained in the following, and it is now a mandatory part of the new DMS 1030-1 which has replaced the BV 1030-1.

**Figure 2: Stability in waves (following seas)**

As the BV 1030-1 aims on minimum stability requirements, the critical situation for surface ships is certainly their operation following seas. This is due to the following reasons:

- The most critical resonances (two or one pitch cycle(s) per roll cycle) occur only in following seas if the stability is low or moderate.
- In following seas, the ship stays sufficiently long on the wave crest which makes a large roll angle more probable.
- Due to the low relative velocity between ship and waves, roll damping (e.g. from bilge keels) is less effective.

For these reasons, the addendum shall focus on the stability behavior in following seas. Fig. 2 shows a typical stability situation in following seas, and it shows the righting lever curves for crest (red), trough (green) condition as well as the still water

condition (blue). The latter is not relevant for the problem addressed, nor is the linear representation of this curve. In Fig. 2, the initial stability on the wave crest has become negative, which means that the upright equilibrium is not stable anymore. If we assume for a moment that the wave crest situation would remain forever, then the ship will start to heel towards the stable equilibrium on the wave crest (EQ). If the ship reaches this equilibrium, she has taken up an energy level which is equivalent to the area under crest curve A2 (if dissipation by roll damping is neglected). As the remaining energy under the crest curve (A3) is larger than  $|A2|$ , the ship will not heel over the angle of vanishing stability and she will (after some time, damping included) return to the stable equilibrium EQ and she will then remain there. As long as A3 is larger than  $|A2|$ , the ship will not capsize due to pure loss of stability alone. The relation of A2 and A3 is mainly dominated by the wave height (for a given stability).

If one takes into account now that the ship is permanently oscillating between the wave crest and the wave trough situation, it is well known that this oscillation can build up a large and sudden roll motion (parametric roll). If the ship experiences such a roll motion, she sees the maximum roll angle when she is in the wave trough situation (green) and she is always close to the upright position when she is on the wave crest. In Fig. 2 we assume that when the ship is in the wave trough condition, she may have rolled to a certain roll angle, denoted by “1” in Fig. 2. If the ship is accelerated from the heeled position (1) to the upright position again, the wave passes by until the ship stays on the wave crest again in the upright position. During this heeling motion toward the upright position, the sea state feeds energy into the ship which can be expressed as the difference of the areas under the crest and the trough curve. In Fig. 2, this area difference is denoted by “A1”. When the ship reaches the upright position on the wave crest, she has taken up an energy equivalent to A1. When the ship now heels on the wave crest towards the crest equilibrium EQ, her energy level equals  $A1 + |A2|$  when she reaches this equilibrium. As the sum  $A1 + |A2|$  is certainly larger than A3, the ship will be forced over the angle of vanishing stability and she will capsize due to a combination of parametric rolling and pure loss of stability on the wave crest.

This concept was for the first time put forward by Kluwe (Kluwe 2009). He suggested 15 Degrees for the roll angle denoted by “1” in Fig. 2 and 40 Degrees as the maximum permissible roll angle. It is of further interest to underline that the Area A1 solely depends on the individual hull form of the ship and not on the stability (as this area is basically a difference between two righting lever curves, the  $ZCG\sin\phi$  and  $YCG\cos\phi$ - terms cancel out themselves), whereas the areas A2 and A3 depend on both the hull form and the stability. This criterion is therefore a strong motivation for the ship designer to minimize the righting lever alterations in following seas during hull form design. If he is not able to do so, the designer has to accept that the ship requires larger values of stability (on the crest) as a consequence.

In the context of the BV 1030-1 this criterion can easily be implemented if it is applied for the design wave which is already included in the BV. Rinke (Krüger 2014) has applied this criterion to several existing Navy Ships of the German Navy and he concluded that the Area A3 should have twice the value of the sum of the areas A1 and  $|A2|$ . Further, it was found that the GM on the wave crest must never become negative, which does then result in a crest righting lever which must be positive from zero to 40 degrees. (A3 then disappears, and A3 should amount  $2A1$ ). Concluded, the revised requirements of the DMS 1030-1 are the following (Russell, 2024):

- For the given design wave of  $\lambda$  equalling ship length, and the related wave height  $H=\lambda/(10+0.05\lambda)$ , the area under the wave crest curve up to 40 Degrees must amount to two times the area difference between trough and crest up to 15 Degrees (where the wave crest righting lever curve must be corrected for free surface effects).
- The stability on the wave crest (including free surface corrections) must meet a minimum value of 0.05m, which must occur before 40 Degrees. From the equilibrium up to 40 degrees, the righting lever on the wave crest must be positive.

It is further recommended to present the stability results in form of  $GM_{Required}$ -Curves. This is to prevent the situation that only one single criterion dominates the whole ship design or that damage stability deviates significantly from intact stability.

**Openings.** Originally, the treatment of openings was not foreseen in the BV 1030-1 as the hull (and the superstructure) needed to be watertight up to 60 degrees. During all stability calculations the only criterion was that the side of the bulkhead deck must never be submerged in any equilibrium (intact or damaged). This requirement was found to be too stringent, impeding to many interesting design alternatives. Consequently, the side of deck criterion was deleted and replaced by exactly the same opening concept as it is part of the SOLAS. Openings are subdivided into weathertight and not weathertight openings. During any equilibrium (the balance between heeling and righting levers), no openings are allowed to be submerged. Not weathertight openings may limit the range of stability if they become submerged. For the stability evaluation in waves, the freeboard of weathertight openings in the equilibrium is calculated as the average value between the crest and the trough condition. The means that a weathertight opening may be submerged either in crest or trough condition, provided, that the sum of both freeboards is clearly positive.

**Ballast water.** The DMS 1030-1 requires that no additional ballast water shall be taken in any loading condition for stability reasons. This means that the designer of a Navy Ship must be aware of the operational profile of the ship.

**GM<sub>Required</sub>-Curves.** The DMS 1030-1 requires that curves of GM<sub>Required</sub> are to be computed for the intact and the damaged ship during the planning phase of any Navy Ship. These curves shall be computed without taking into account fluid shifting moments. It must be demonstrated that the limiting GM- values for the damaged condition do not differ significantly from those obtained for the intact condition. If there is a significant difference found, the design should be revised, otherwise it must be demonstrated by appropriate calculations that in none of desired operational conditions, excessive accelerations do occur.

## DAMAGE STABILITY

### A brief Introduction into the Damage Stability Part of the BV 1030-1

Other than the SOLAS, the damage stability part of the BV 1030-1 examines the same predefined loading conditions as the intact part (or part of them). This includes not only the exchange of fluids in case a filled tank is damaged, but also the correction for the free surface effects of all partly filled tanks which are not damaged. One should note that the BV does not permit filling levels of more than 95% of a tank, which results in the fact that especially Auxiliary Navy Vessels may have large initial free surface corrections. The BV 1030-1 damage stability standard is a deterministic standard with a maximum damage length  $L_1$  of

$$L_1 = 0.18 L_{DWL} - 3.6\text{m, but not more than 18m.} \quad [3]$$

The maximum penetration depth is assumed not to breach the center line of the ship, the damage height is infinite. Like the SOLAS, any combination of lesser extent is to be examined. The BV generally requires to minimize the amount of longitudinal bulkheads, as the flooding should be kept as symmetrical as reasonably possible. During the damage stability evaluation, the following heeling levers have to be computed:

- Beam wind of 40 knots
- The shifting of fluids in tanks

The resulting equilibrium (including the heeling levers) must be less than 25 Degrees, and the residual righting lever must be larger than 0.05m up to 40 degrees or the submergence of a not weathertight opening. The range of positive stability from the equilibrium must be larger or equal to 15 degrees, for details see Russell 2024. Fig. 3 shows an example of the damage stability assessment according to BV 1030-1. It should be noted that the output of the stability assessment (both intact and damage) is quite extensive as this information is not only part of the stability booklet of the ship, but it is also used for crew training purposes in stability matters.

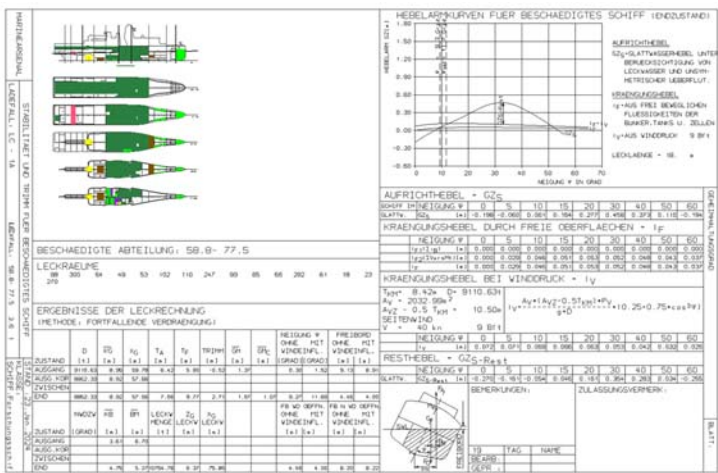

Figure 3: Damage stability assessment according to BV 1030-1

## Improvements the BV 1030-1 Damage Stability Part

**Intermediate stages of flooding.** In the BV 1030-1, the assessment of intermediate stages of flooding was not explicitly mentioned. Nevertheless, the BAAINBw could request that intermediate stages should be analysed, but this was typically not done. The reason is that the BV requires that flooding shall be kept as symmetrical as ever possible, and the use of longitudinal bulkheads was restricted to the absolute minimum. For the same reason, cross flooding devices were not fitted. Another assumption was that the investigation of lesser extent damages was typically restricted to investigate only the effect of double bottom compartments. The effect of A- class bulkheads on the possible flooding sequence was never requested to analyse, although Navy Ships have quite complex internal subdivisions in this respect, see Fig. 4.

**Figure 4: A-class sub-compartments of a single watertight compartment**

The revision of the SOLAS with the 2009 and 2020 edition has put more emphasis on intermediate stages of flooding (see Russell 2024), and now, also cross flooding arrangements of cargo ships have to be checked against intermediate stages of flooding. Consequently, it was found that there was a certain gap between the commercial standard, represented by the SOLAS 2020, and the damage stability part of the BV 1030-1. In contrast to the IS-Code developments, it was found to be useful to integrate the most important updates of the SOLAS 2020 more or less directly into the damage stability part of the BV 1030-1 as follows:

- If cross- flooding devices are fitted, intermediate stages shall be considered and cross flooding times shall be computed. The procedure is equivalent to the former A266.
- If A-class bulkheads are fitted, the most critical lesser extent combination of not flooded sub compartments has to be determined and investigated, eventually together with cross flooding examinations.
- In cases of large compartments with unrestricted floodwater flow, these may be additionally investigated as being partly filled.

The maximum permissible heeling angle of any intermediate stage must not exceed 25 degrees (including wind and shifting of fluids in partly filled tanks), the maximum residual righting lever must be 50mm. This is roughly equivalent to the SOLAS 2020 requirement for passenger ships.

**Openings.** The consideration of openings was originally not foreseen in the BV as it was required to design the complete hull and superstructure watertight until 60 degree. During the stability assessment (both intact and damage) it had to be checked that the deck edge must never be submerged. This concept was replaced by the opening concept which is used in the SOLAS 2020 standard, distinguishing between weathertight and not weathertight openings. None of these openings might be submerged during any equilibrium floating, but weathertight openings are allowed to submerge during the calculation of the righting levers.

**Watertight doors.** The new stability standard DMS 1030-1 does generally not permit the installation of watertight doors below the bulkhead deck.

## APPLICATION TO NAVY SHIP DESIGN

### Intact stability

**Figure 5: Navy Ship in wave crest condition of the design wave and a hull form optimized for righting lever alterations**

The newly implemented stability criterion puts an additional challenge on the hull form design of all Navy Ships built according to this new standard. Besides optimizing the hydrodynamics with respect to minimum speed power requirement and optimal underwater pressure signature, the designer must now additionally try to minimize the righting lever alterations in waves (see Fig. 5, left, and Fig. 2). This is certainly an additional design constraint for the development of the hull form and the subdivision. To keep the good hydrodynamics (also with respect to the underwater noise signature) of existing designs, it was found beneficial to conduct the following strategy during hull form design, which increases the stability on the wave crest and reduces the stability in the trough at the same time, while keeping the basic hydrodynamic efficiency of the hull:

- The LCB should be as far aft as reasonably possible. This leads to an increased trim down by stern in the wave crest condition and this increases the phase shift between rolling and pitching motion. At the same time it is also beneficial to design the ship in such a way that the ship will always operate with slight trim down by stern. This should be taken into account when optimizing the hydrodynamics of the aft body.
- The bilge radius should be as large as reasonably possible. This increases the immersion of the ship on the wave crest and increases the effective water plane moment of inertia.
- Where ever possible, buoyancy should be moved to the outer parts of the hull which are immersed in the crest condition.

Hulls which have been designed according to this strategy easily comply with the area ratio requirement. An additional problem now arises for all Navy Supply Vessels: As these ships have large tank capacities for aircraft fuel and marine diesel, this results in substantial free surfaces at small heeling angles, resulting in a righting lever curve which immediately deviates from its initial GM (see Fig. 6).

**Figure 6: Righting lever curve (red) of a Navy Auxiliary for a loading condition with large free surfaces**

In this context it must be noted that all fluid shifting moments have to be directly calculated, taking into account heel and free trimming. As the maximum permissible filling level of all tanks is 95%, this leads to large initial free surfaces which decrease with larger heeling angles. The wave crest curve in the area ratio criterion must be corrected for free surface effects. This may result in a situation where it is reasonable to subdivide large tanks to reduce the initial free surface.

It is further well possible that the ship may be sensitive with respect to trim. This mostly holds for Navy Auxiliaries which have a larger variety of possible loading conditions compared to Navy Combatants. For these ships, the tank arrangement must be well designed for all possible operating conditions as only limited possibilities exist to use extra ballast water.

## Damage stability

The revised damage stability regulations of the DMS-1030 result in two major challenges and opportunities for the design of the hull and the internal subdivision: First of all, the position of the bulkhead deck can be selected freely now, as it is explicitly allowed that the bulkhead deck becomes submerged during a damage case, provided, no openings become submerged. Secondly, it puts a hard challenge on the ship design if no water tight doors are allowed below the bulkhead deck. This is hardly a problem for Navy Combatants, but some Navy Auxiliaries are strongly restricted in their operability when heavy goods need to be transferred longitudinally below the bulkhead deck.

Figure 7: Possible location of the bulkhead deck (red)

This leads to one possible solution that the bulkhead deck must not necessarily be the uppermost water tight deck. It is now well possible to lower the bulkhead deck and to extent the watertight transversal bulkheads into the superstructure, see Fig. 7. This leads to an increased reserve buoyancy on one hand and allows the installation of water tight doors on the bulkhead deck and the superstructure decks. Due to the increased reserve buoyancy, the compartments can become longer which is cost effective. Below the bulkhead deck of Navy Auxiliaries, there may exist the possibility to install water tight doors in the main traffic routes, provided, the ship fulfils all damage stability requirements when the doors of interest are assumed to be open, see Fig. 8.

Figure 8: Damage stability assessment and  $GM_{\text{Required}}$ - Curves

Fig. 8, left, shows the results of the damage stability assessment where it is assumed that the most critical water tight door is open. Due to the large reserve buoyancy, this does not pose large problems for the damage stability assessment. The curves of  $GM_{\text{Required}}$  (Fig. 8, right) show that the required values of GM are not substantially larger compared to the intact stability values, even if the most critical water tight door is assumed to be open. The damage stability curve denoted by “Damage WTD closed” shows the effect of the most critical open watertight door on the damage stability.

## CONCLUSIONS

The present paper has given an insight into recent developments of the German Navy Stability Code DMS 1030-1 (former BV 1030-1) and to the resulting effects on Navy Ship design. The necessity to update the code was shown, and it was also discussed when it seemed to be reasonable to integrate well proven elements of stability standards for commercial ships into the BV code. It was also shown that for the problem of intact stability in waves, it seemed to be useful to deviate from available commercial standards. The idea that the limiting values of GM shall not differ substantially between intact and damaged condition, which is not reflected in commercial standards, assures that the design of a Navy Ship is well balanced with respect to stability. For typical ship design problems, recommendations have been presented how to deal with this new standard. Most important is that the stability assessment of a Navy Ship is thoroughly performed during the very first stages of the planning phase.

# The importance of first-principles tools for safety enhancement in the design of passenger ships in the case of flooding events.

Dracos Vassalos<sup>1,2</sup>, Francesco Mauro<sup>1,\*</sup>, Donald Paterson<sup>1</sup> and Ahmed Salem<sup>1</sup>

## ABSTRACT

*The design of a passenger ship is a complex process covering multiple aspects of naval architecture and marine engineering to address performance, functionality safety, and cost as primary objectives. Between them, safety is a key element focusing on the people on board. In this sense, ship safety in the case of flooding events needs proper estimation from the first stages of the design process employing an appropriate metric. To this end, safety can be evaluated as a risk by calculating the Potential Loss of Life. Thanks to a multi-level framework developed during project FLARE, it is possible to calculate the risk associated with an accident, increasing the level of reliability as the design process advances. The framework aims at employing first-principles tools from the early stages of the design process, abandoning static calculations and empirical formulae as soon as data is available to set up advanced calculation techniques. Then, the framework adopts rigid-body time-domain calculations for the flooding simulations, advanced evacuation analysis tools, and direct crash simulation to evaluate collision damages. The process allows for testing alternative design solutions for the ship to enhance safety. Investigating risk control options is also possible, considering active or passive systems such as fixed foam installations, deployable barriers, or crashworthiness. Such an approach allows for evaluating safer solutions, respecting other design constraints and cost-related aspects. The present work describes the risk assessment framework for the case of flooding events, together with the different levels of accuracy that can be achieved, showing the improvements that could be reached by employing alternative risk control options.*

## KEYWORDS

Risk-based design; flooding risk assessment; passenger ships; risk control options.

## INTRODUCTION

The design of passenger ships is a complex process involving the concurrent evaluation of multiple aspects of Naval Architecture and Marine Engineering. Between them, damage stability is a key part of the design process, providing a lifecycle flooding risk management for the vessel (Vassalos, 2020). Consequently, the estimation of flooding risk is a relevant attribute for the design of new passenger vessels (Atzamos, 2019, Papanikolaou et al., 2013, Vanem et al., 2007). However, the approach to risk has never been deeply applied by designers, who prefer to adopt a compliant-based approach to damage stability. In recent years the trend has changed, giving more importance to the application of first principles tools in the design process of passenger ships (Vassalos, 2016), and providing designers with suitable guidelines for their application (Mauro et al., 2023a).

The application of this different kind of approach led to the formulation of a multi-level flooding risk assessment framework during the EU-funded project FLARE (Vassalos et al., 2022a), suitable for the flooding risk estimation through the whole

ship lifecycle. The advantages of this framework are given by the implementation of a multi-level approach to risk, allowing a designer to choose the most appropriate tools to use during the design process, starting from simple assumptions and simulations up to perceiving fully first-principles-based predictions. The application of first-principles tools concerns principally three aspects of the flooding risk assessment, namely the damage generation, the survivability analysis and the evacuation analysis. For each topic, suitable options are available to achieve different levels in the reliability of predictions as indicated by the multi-level framework for risk assessment. Furthermore, the flexibility of the provided framework allows for the use of the first-principles tools as a design instrument for the identification and evaluation of the benefits of suitable risk control options (RCOs).

This paper presents the main concept of the multi-level framework for risk assessment for the specific case of the design phase of a passenger ship. A description of the main first-principles tools is provided for the generation of breaches, flooding simulations and evacuation analysis. To demonstrate the applicability and flexibility of the multi-level framework, a worked example is presented on two reference ships, a cruise and a Ro-pax, highlighting how first-principles-based tools can be used also for the design of RCOs, like the implementation of fixed foam installations, deployable barriers, and crashworthy structures. Simulations are performed with different levels of reliability, highlighting how the application of first principles tools influences not only the general estimation of the risk level but also the impact of each selected RCO on the reduction of risk. Finally, the obtained results raise questions on the actual praxis in passenger ships' design, highlighting how the application of active or passive RCOs may change the attained flooding risk level of a vessel without the need for searching for more capillary compartmentation of the internal layouts.

## FLOODING RISK ASSESSMENT FRAMEWORK

The assessment of flooding risk during the design phase of a passenger ship (or ship in general) passes through the recursive execution of the following main points:

1. Definition of calculation scenarios and ship main particulars.
2. Flooding risk evaluation.
3. Identification of suitable vulnerability mitigation measures.
4. Reassessment of the flooding risk.

These steps relate to the design of a new unit as well as to the retrofitting of an existing vessel or a change in the operational profile of the ship.

The risk can be measured through the Potential Loss of life ( $PLL$ ), which follows the general formulation of risk as given by the following equation:

$$PLL = p_f \cdot c_f \quad [1]$$

$p_f$  represents the probability of flooding and  $c_f$  is the consequence of the flooding event. For the evaluation of risk during the project of a passenger ship it is necessary to identify an attained index  $PLL_A$  to be compared with a tolerable level of risk. In case all the vessel life-cycle has to be taken into account, a more general model for  $PLL_A$  can be considered, evaluating the attained  $PLL_A$  per year of service ( $PLL_A^*$ ), which provides more flexibility to assess multiple operational scenarios. Then, the definition of  $PLL_A^*$  for every single scenario has the same form of equation [1] but with a more in-depth definition of  $p_f$  and  $c_f$ .

$$PLL_A^* = \sum_{i=1}^{N_{hz}} \sum_{j=1}^{N_{op}} \sum_{k=1}^{N_{ld}} \sum_{h=1}^{N_c} p_{f_{i,j,k,h}} \cdot c_{f_{i,j,k,h}} \quad [2]$$

In equation [2],  $N_{hz}$  is the number of possible hazards (which corresponds to collision, bottom and side groundings, i.e.  $N_{hz}=3$ ),  $N_{op}$  is the number of operational areas (open seas, restricted or port areas),  $N_{ld}$  is the number of loading conditions and  $N_c$  is the number of flooding cases (depending on the ship subdivision). Consequently, the associated probabilities and consequences of an event have the following formulations:

$$p_{f_{i,j,k,h}} = p_{hz_i} \cdot p_{op_j} \cdot p_{ld_k} \cdot p_{c_h} = p_{hz_i} \cdot p_{op_j} \cdot p_{ld_k} \cdot p_{c_h}^* (1 - s_{c_h}) \quad [3]$$

$$c_{f_{i,j,k,h}} = FR_{i,j,k,h} \cdot POB_{i,j,k,h} \quad [4]$$

The probabilities described by equation [3] result from the statistical analysis of damage databases, specifically for passenger ships. The probabilities of the damage case can be described by employing the common definition of the p and s-factors (Pawlowski, 2004, IMO,2009, Vassalos et al., 2022b). On the other hand, equation [4] describes the consequences of a hazard, which are given by the fatality rate  $FR$  and the number of people onboard  $POB$ . All the quantities change scenario by scenario, thus, the final risk assessment requires the execution of  $N=N_{hz}N_{op}N_{ld}N_c$  scenarios to be assessed with flooding survivability and passenger evacuation tools.

The resulting number of scenarios is considerably high as is the computational load, but they can be reduced by applying the concept of a multi-level framework, employing different types of tools according to the level of accuracy required by different stages in the vessel life cycle. This is of utmost importance, especially for the design phase.

## Multi level-framework

The studies performed during Project FLARE led to the definition of calculation frameworks, initially oriented to survivability only and subsequently extended to risk. Such frameworks provide a connection between the research-oriented vision of the flooding problem and the designer and operators' practical point of view (Mauro et al. 2023a). A global first-principle characterization of flooding risk is difficult to achieve because of the calculation time and availability of suitable codes. Therefore, a multi-level approach, with consequent multi-fidelity results, significantly improves in-force damage stability frameworks for passenger ships.

The main assumptions of the multimodal framework refer to three characteristics of the flooding process determination: the occurrence, the survivability and the fatality in a given scenario. Therefore, the definition of  $PLLA^*$  of equation [2] assumes the following form for the case of a single scenario:

$$PLLA_{A_{i,j,k,h}}^* = p_{i,j,k,h}^* (1 - s_{i,j,k,h}) c_{f_{i,j,k,h}} \quad [5]$$

According to equation [5], the probabilities and weights associated with the scenario occurrence are identified by  $p^*$ , while  $s$  describes the scenario's survivability and  $c_f$  the consequences as per equation [4]. Concerning the probabilities, the occurrence is identified during the input preparation phase of a Level 1 survivability assessment. Level 1 or Level 2 damage stability calculations determine survivability, while evacuation analyses determine fatality.

Therefore, the definition of the levels in the multi-level framework is as follows:

- *PLL Level 1*: the approach is fully based on static damage stability calculations. The expected number of fatalities depends on the time it takes the vessel to capsize, and the static analysis does not account for time. Then, the estimation of fatality rate in this stage needs some approximation. To keep the methodology as simple as possible and to account for the dependencies between survivability and fatality rate, the following extremely simplifying assumption is made:

$$FR = \begin{cases} 0.8 & \text{if } s < 1 \\ 0.0 & \text{if } s = 1 \end{cases} \quad [6]$$

This simple and conservative approach follows the method used in the EMSA III Project, the results of which were used to support political decisions at IMO, leading eventually to SOLAS 2020 regulations for damage stability.

- *PLL Level 2*: The main additional parameters distinguishing Level 2 from Level 1 flooding risk estimation are the Time to Capsize  $TTC$  and the Time to Evacuate  $TTE$ . The  $TTC$  describes the time it takes the vessel to capsize/sink after a flooding event occurs. Therefore, the use of  $TTC$  requires the execution of time-domain flooding simulations, thus neglecting the static approach. The  $TTE$  defines the time necessary for an orderly evacuation of passengers and crew onboard a passenger ship after a flooding hazard occurred. Hence, the  $TTE$  determination implies the execution of time-domain evacuation analyses. However, according to the multi-level framework, also simplified methods oriented to a fast  $TTE$  evaluation are available, providing two sub-levels for the Level 2 analysis. Such options are:
  - *PLL Level 2.1*: for this level of approximation, only time domain flooding simulations are required to determine  $TTC$ . Evacuation analyses for  $TTE$  evaluation are omitted; therefore, an empirical formulation is needed to derive  $FR$  as follows:

$$FR = \begin{cases} 0.0 & \text{if } TTC > n \\ 0.8 \left( 1 - \frac{TTC - n}{30 - n} \right) & \text{if } 30 \leq TTC \leq n \\ 0.8 & \text{if } TTC < 30 \end{cases} \quad [7]$$

where  $n$  is the maximum allowable evacuation time in minutes according to MSC.1/Circ. 1533. The assumption on  $FR$  intrinsically considers the nature of the capsize event as a function of the  $TTC$ , assuming the impossibility of evacuating the ship during fast transient capsizes cases.

- *PLL Level 2.2*: In this level the direct evaluation of  $TTE$  is considered. Starting from significant cases described by time-domain flooding simulations, where it is realistic to proceed with an evacuation analysis, ship motions and floodwater can be imported in the evacuation software. Such a coupling allows comparing the evacuation process and the associated  $TTC$ .

The full details, justifications and also applied examples for the FLARE multi-level risk framework are provided by Vassalos et al. (2022b) and are not rediscussed here for the sake of brevity. The individual definition of probabilities and values associated with occurrences, survivability and fatality changes not only with the selected level between the above-presented options but is also depend upon the phase of interest during the vessel life-cycle. Here the focus is on the design phase.

## Design Phase framework

The application of a risk framework for the design phase of a passenger ship implies the definition of the main inputs and all parameters in equation [2] to allow the evaluation of  $PLL_A^*$ , with input and information available in this specific stage of the vessel life cycle. Moreover, the application of the framework during the design phase requires to refer to regulations, assumptions, and outputs relevant to the statutory damage stability framework. This reflects in the selection of the frequencies and probabilities associated with the occurrence, survivability and fatality of a scenario and, consequently, in the generation of the cases to be analysed. The focal points can be summarised as follows:

- *Possible hazards*: the framework handles three kinds of casualties ( $N_{hz}=3$ ); collisions, side, and bottom groundings. These hazards imply the adoption of specific frequencies of occurrence  $p_{hz}$ , corresponding to the relative weights  $w$  used to define the A-index in the damage stability frameworks. Suitable values for  $p_{hz}$  derive from database analyses and are reported in Vassalos et al. (2022b) with the associated  $w$ .
- *Operational areas*: Only the open sea ( $N_{op}=1$ ) is taken into account for design purposes, restricting the wave conditions to a representative sea state that corresponds to a significant wave height  $H_s$  of 4 metres. When assessing risks at Level 1 or Level 2, such an assumption is taken into account.
- *Loading conditions*: the framework adopts two drafts  $T_1$  and  $T_2$  with the same weight on the final assessment and corresponding to 0.45 and 0.75 times the design draught of the ship, respectively. Such an assumption is maintained across the levels and does not follow the SOLAS standards, which are based on three draughts. The assumption has been promoted by designers during the activities of Project FLARE (Vassalos et al, 2022c).
- *Calculation scenarios*: Depending on the level chosen for the risk assessment, there are a different number of scenarios. 10,000 breaches are created for every type of danger in order to produce a Level 1 prediction, sampling the location and dimensions from relevant cumulative distributions. The number of scenarios is lowered to 1,000 breaches for each danger since time-domain simulations take longer to complete than a static approach. The damage distributions mentioned in Levels 1 and 2 are the same as those in SOLAS for collisions and EMSA III for bottom and side groundings.

According to the given assumptions, equation [2] can be modified by rewriting the occurrence terms provided by equation [3], resulting in the following final formulations valid for Level 1 and Level 2 predictions, respectively:

$$PLL_{A\text{Level}1}^* = \sum_{i=1}^3 \sum_{k=1}^2 \sum_{h=1}^{N_c^*} p_{hz_i} p_{ld_k} p_{ch}^* (1 - s_{c_h}) FR_{i,k,h} POB_{i,k,h} \quad [8]$$

$$PLL_{A\text{Level}2}^* = \sum_{i=1}^3 \sum_{k=1}^2 \sum_{h=1}^{1,000} p_{hz_i} p_{ld_k} p_{ch}^* (1 - s_{c_h}) FR_{i,k,h} POB_{i,k,h} \quad [9]$$

the two equations differentiate themselves mainly in the determination of the scenario's occurrence  $p_c^*$  and the final number of scenarios  $N_c$ . Such differences are strictly connected with the level of damage stability calculations. The generation of breaches is equivalent between Level 1 and Level 2, following a non-zonal approach requiring the sampling damage characteristics with an enhanced Randomised Quasi-Monte Carlo technique. But by using a static assumption (Level 1), it makes no sense to make a distinction between instances that harm the same set of internal compartments. Therefore, the final amount of scenarios to evaluate is  $N_c^* < 10,000$  and strictly depends on the ship's internal layout. All cases referring to the same damaged compartments are grouped to determine the scenario occurrence  $p_c^*$ . Conversely, when using dynamic simulations (Level 2), the grouping becomes impossible because the breach's diameter affects how much water enters and exits the system. Then, for Level 2 calculations, all cases are equiprobable and all the 1,000 scenarios are considered with the same  $p_c^*$ . The Level 2 framework permits a hybrid approach, taking into account only the case with the higher breach longitudinal area resulting from static calculations (Mauro et al. 2023a). Regardless, FLARE's recommendations and advancements are meant to standardise the use of dynamic analyses in the damage stability evaluation of passenger ships, leading to the selection of Level 2 flooding risk assessment.

Concerning evaluating the consequences and  $FR$  in particular, preliminary calculations performed during the FLARE project highlight small differences between Level 2.1 and Level 2.2 assessments (Vassalos et al., 2022c). The application of Level 2.2 design phase evaluation on one cruise ship and one Ro-pax highlights the significant equivalency of the final risk level that is reached, whether or not sophisticated evacuation analyses are used.

However, it is of utmost importance to encourage the application of first principle tools for increasing the reliability of the results since the first stages of a design, promoting their application for the generation of breaches, the flooding simulations and the evacuation analyses. This will be discussed in the following sections, together with the applications of measures to mitigate the risk and how to use first-principles tools to reduce the global risk onboard a passenger ship.

## FIRST PRINCIPLES TOOLS FOR FLOODING RISK

The determination of flooding risk during the design process of a passenger ship implies the evaluation of different components of risk, both for the frequencies and consequences estimation. In dealing with the flooding of ships, the first step is determining the source of the flooding, which means establishing how the flooding breach has been generated. Secondly, the flooding process needs to be analysed for the associated environmental conditions, determining the flooded compartments and the time to a possible sinkage/capsize event. Finally, in case there is sufficient time before a capsized event, it is necessary to simulate the evacuation process for the ship.

For all the issues mentioned above, there are different available solutions for identifying the associated relevant quantities, with different levels of approximation. Here, the focus is on employing first principle tools for the prediction of risk; therefore, the principal direct method for modelling breach dimension, flooding dynamics and evacuation will be shortly described.

### Breach generation

The generation of breaches derived from collisions with other ships or grounding has a serious implication on the evaluation of flooding risk in the design process of a passenger ship. The common practice is to use simplified breach models, referring to box-shaped damages or unrealistic prismatic damages which follow the shape of the waterline of the ship (Mauro et al. 2023a). The breach dimensions and location are derived from statistical distributions based on database analyses of real accidents (Bulian et al. 2019).

However, to generate the breaches necessary to perform risk analysis, a first-principles approach can be pursued by performing a set of crash analyses. Such kind of approach implies the execution of a large number of Finite Elements Methods (FEM) analyses, considering a proper population of potential striking ships (Conti et al., 2022). Using conventional FEM simulations to assess the internal mechanics of the collision problem would be prohibitive in terms of total computation time. Therefore, the simulations can be carried out based on the Super Element Method. This method, which was introduced by Lützen (2001), consists of splitting the ship into very large-sized independent structural units (the so-called Super-Elements), for which closed-form analytical formulations are available. These formulas, which describe the resistance and energy dissipation of the Super-Element based on its type and deformation mechanism, are derived from experimental and numerical data.

Regarding the ship's external dynamics (rigid body movements of the ship due to the action of the hydrodynamic loads and the collision forces) during the collision event, they are addressed using a semi-coupled approach via the use of the MCOL solver (Le Sourne et al., 2001), the ships hydrodynamic properties being obtained using Bureau Veritas seakeeping analysis code Hydrostar (BV, 2019).

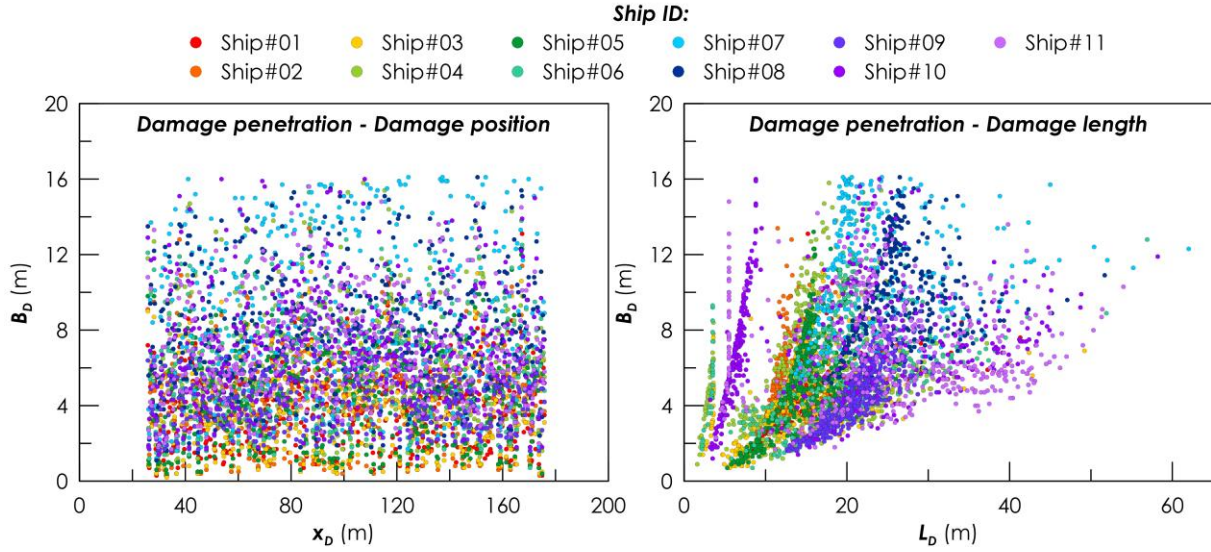

Figure 1: Example of super-element model for crash analyses.

**Figure 2: Example of damage dimensions derived from super-element calculations.**

These two principal features are considered in the software SHARP, which allows for performing fast collision simulations. The accuracy of this method was recently reconfirmed during Project FLARE, by benchmarking against Finite Element codes (Kim et al., 2022). Furthermore, the methodology allows for building damage databases suitable not only for the generation of damages in the design stage (Conti et al., 2022) but also for the estimation of risk in real-time applications (Mauro et al., 2023b). Figure 1 gives an example of the super-element modelling of a passenger ship, while Figure 2 shows an example of the damage penetration derived from crash analyses as a function of the damage position and length. The adoption of this direct technique to estimate the damage dimensions permits the generation of a reliable input for the damage simulations, but still following the approximation of box-shaped damages.

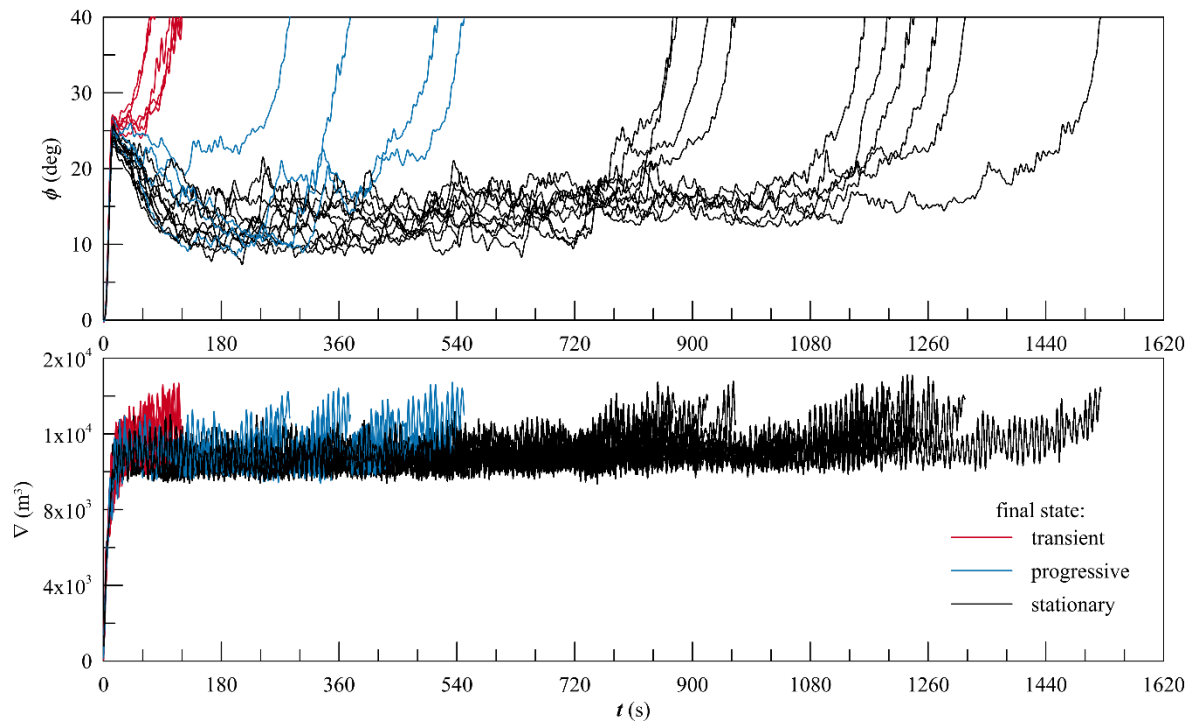

## Flooding simulations

The assessment of the flooding process after a casualty with direct calculations implies the modelling of a complex phenomenon, coupling the motion of the ship with the behaviour of the flooding process and their relative interaction with the ship and the wave environment (Vassalos, 2020). Different levels of simplification apply to the problem modelling with associated different levels of confidence for the obtained results.

Among the possible solutions, the adoption of time-domain simulations on rigid bodies offers a good compromise between calculation time and the accuracy of the provided results. The damaged ship motions derive from fundamental motion equations as the law of conservation of linear and angular momentum. These laws normally apply to rigid bodies, thus systems where the mass is constant during the simulations; here, the floodwater changes at each time interval. The problem is approximated by extending the rigid body motion equation to the internal fluid mass, resolved in a body-fixed reference system. Then, six scalar equations are defined for linear and angular motions having the following vector form in the case of angular motions:

$$\begin{aligned}
 & \left( I'_s + I'_w \right) \cdot \frac{d}{dt} \vec{\omega}' + M_w \cdot \left[ \vec{r}'_w \times \frac{d}{dt} \vec{v}'_{Gs} \right] + M_w \cdot \left[ \left( \vec{\omega}' \times \vec{r}'_w \right) \times \vec{v}'_w \right] + \\
 & + M_w \cdot \left[ \vec{r}'_w \times \left[ \frac{d}{dt} \vec{v}'_w + \vec{\omega}' \times \left( \vec{v}'_{Gs} + \vec{v}'_w \right) \right] \right] + \\
 & + \frac{d}{dt} M_w \cdot \left[ \vec{r}'_w \times \left( \vec{v}'_{Gs} + \vec{v}'_w \right) \right] + \left( \frac{d}{dt} I'_w \right) \cdot \vec{\omega}' + \vec{\omega}' \times \left[ \left( I'_s + I'_w \right) \cdot \vec{\omega}' \right] = \vec{M}'_{Gs}
 \end{aligned} \tag{10}$$

where  $I_s$  and  $I_w$  are the ship and internal fluid mass moment of inertia,  $\omega$  is the rotational velocity vector,  $M_w$  is the internal fluid mass and  $r_w$  and  $v_w$  are the position and velocity vectors of the internal fluid mass centre.  $v_{Gs}$  is the ship velocity vector and  $M_{Gs}$  is the external moment acting on the ship. A more detailed explanation of all relevant terms together with the complete model in six degrees of freedom is available in Jasionowsky (2001). The right-hand side of equation [10] represents the external forces and moments acting on the ship with respect to its centre of mass. The sloshing motions of the floodwater can be modelled as a lumped mass (Papanikolaou et al, 2000), while water ingress/egress, the water accumulation and progression follow a simplified model based on the Bernoulli equation. These methods are implemented in the software PROTEUS3, used in this study, which has been recently tested and compared with other software during project FLARE (Ruponen et al., 2022a, 2022b), highlighting its suitability for the modelling of critical scenarios in waves for passenger ships

**Figure 3: Example of roll (up) and floodwater (down) time histories derived from flooding simulations.**

(Mauro et al., 2023a). Figure 3 shows the outputs of a set of dynamic simulations, representing the roll time history from the occurrence of the hazard until the ship capsizes and the amount of mass water entering/leaving the ship.

The time-domain simulations imply the modelling of water ingress/egress from/to the ship; therefore, the breach dimensions strongly influence the dynamics of the flooding process and the evaluation of the time to a possible capsize/sinkage event (The time to capsize).

## Evacuation analysis

Another aspect of a risk assessment is related to the evacuation of the ship. Once there is sufficient time before an upcoming sinkage/capsize event, it is worth assessing the time needed to evacuate the ship. This, in turn, allows for evaluating how many fatalities may occur by comparing the Time to capsize obtained by flooding analyses and the time to evacuate derived from the evacuation analysis.

There are different approaches to the evacuation analysis, employing different kinds of simplifications and modelling of the evacuation path. In fact, it is possible to perform the evacuation with simplified methods by employing the hydraulic analogy (Nasso et al., 2019), assuming that corridors are like pipes and the passengers are the mass flow flowing through them. This method is admitted by the MSC.1/Circ. 1533 for evacuation analyses of passenger ships; however, the methodology is too simplified to capture well the evacuation process and the possible occurrence of some congestion points during the evacuation path. For such a reason, it is convenient to employ more advanced methodologies based on the direct evaluation of the pedestrian path of each evacuee, considering the interaction with the rest of the environment (Vassalos et al., 2003, Azzi et al, 2011, Kwee-Meier et al, 2016).

Among the different software that provides the possibility to perform the advanced evacuation analysis of a passenger ship, there is software EVI. EVI, developed by the University of Strathclyde and distributed by Safety at Sea, is based on the concept of “evacuability”, meaning the ability of an individual to evacuate the ship. The resulting evacuation index takes into account a wide range of parameters, which can be collected in two separate groups, namely the Initial Conditions and the Evacuation Dynamics. The first group considers the layout of the ship, the demography of the population its initial distribution and the response time to danger, while the second group takes into account the walking speed of each agent, the interaction between passengers and crew and between agent and layout of the ship. Figure 4 shows the modelling layout of a Main Vertical Zone in EVI for a passenger ship.

**Figure 4: Example of modelling a Main Vertical Zone with software EVI.**

Furthermore, the evacuation analysis could be performed by imposing the dynamic motions and the flooding progression determined by dynamic flooding analysis. Such a coupling allows for extending the reliability of evacuation results as the dynamics of the ship and its interaction with the evacuees are implicitly considered.

## **RISK CONTROL OPTIONS**

The safety of a passenger ship is strictly related to its internal layout, as highlighted by dynamic flooding analyses and evacuation simulations. Nonetheless, a passenger ship's interior design must take into account unique considerations for passenger comfort as well as safety regulations pertaining to additional potential death threats, such as fire. Increasing internal layout restrictions in an attempt to reduce flooding may compromise the ship's ability to make money. Therefore, it is necessary to look at possible solutions aimed at increasing safety in a possible accident during the ship operation, thus increasing ship resilience to a failure event. Such solutions are usually referred to as Risk Control options (RCOs), as they aim to the reduction of the risk, i.e., in our case, of the Potential Loss of Life.

The risk control options can be passive, thus fitted permanently on the ship like fixed foam installation in ship voids or the adoption of a crashworthy structure, or active like watertight deployable barriers used only during emergencies. The following section describes a set of possible solutions to be installed onboard or to be considered during the design phase of a modern passenger ship.

### **Permanent foam installation**

In order to increase the ship's initial stability and restoration forces in the event that these areas are directly or indirectly flooded after an incident, permanent foam is installed in the void spaces of the ship as part of a passive flooding protection system.

These installations function similarly to buoyancy tanks and have the extra advantage of being impermeable, which allows them to provide buoyancy in the damaged region instantaneously. Reducing the likelihood of transient capsize cases, which are also closely linked to insufficient reserve of stability during the early stages of flooding, is the goal of this type of improvement in initial stability and additional reserve of stability. Figure 5 shows a possible site for foam installation in available void spaces on the lower decks of a passenger ship.

to restrict the main arteries. Deployable barriers are a good way to prevent flooding in this situation without changing the interior design of the ship. Deployable barriers consist of two lightweight shutters spaced 30 cm apart, usually composed of steel laths or GRP with an A-class fire rating. Shutters can be deployed also in case of fire casualties or drills. In case of flooding, the cavity between shutters is filled with expanding foam delivered from a compressed foam canister. In order to comply with specific local structural characteristics and arrangements, the shutters can be mechanically adjusted to be deployed either vertically (see Figure 6b) or horizontally (see Figure 6c). In addition, the barrier may be extended up to 30 metres over intermediate supports in a matter of minutes, limiting and managing floodwater channels that were previously determined to be crucial.

In this way, an appropriate damage control plan may be established and adequately carried out based on the outcomes of time domain flooding simulations, perhaps with the help of an appropriate decision support system. This makes it possible to isolate the affected area after any critical flooding event that is predicted and for which progressive flooding is the cause of the loss. The implementation of evacuation evaluations for certain important instances is implied by this technique, which aims to determine whether deployable impediments impede the evacuation process. This provides a clear benefit over current damage control strategies, which are mostly based on fixed design measures and are therefore less flexible and effective in likely critical loss circumstances.

## Crashworthy structure

Another kind of RCO is crashworthiness, studied as a mitigation measure for damage stability since early 1990s. However, the lack of suitable tools to undertake this analysis as a routine has discouraged its application by designers since the early stages of the design process of passenger ships. In fact, crashworthiness is the ability of a structure to protect its occupant during an impact; therefore, the determination of a crashworthy structure for a passenger ship implies the dedicated study of a new layout for the main longitudinal and transversal elements of the ship.

In project FLARE, a dedicated study has been performed in an attempt to implement crashworthiness as a suitable risk control option to mitigate flooding risk. The scope was to derive a general scaling method from the conventional distributions used for damage dimension determination (Mauro & Vassalos, 2022) to new distributions considering the implementation of specific reinforcement to the hull (Cardinale et al. 2022). Thanks to the application of super-elements codes, as mentioned earlier, it was possible to derive corrections for specific damage dimensions according to the damage type:

1. Collisions: damage length, damage penetration, damage height.
2. Bottom groundings: damage length.
3. Side groundings: damage length

The correction has the form of a scaling function as reported in the following equation:

$$d^* = \lambda \cdot d \quad [11]$$

Where  $\lambda$  is the scaling function,  $d$  is the original breach dimension derived from pertinent distributions and  $d^*$  is the new breach dimension.

The following possibilities have been analysed in the study, pertinent to different damage types:

1. Doubling of hull thickness: for collision only.
2. Increase of side shell plating thickness by 10 mm: side grounding only.
3. Installation of the double hull at B/20 with transversal web frames and an inner plate of 12 mm: collision and side groundings.
4. Installation of the double hull at B/10 with transversal web frames and an inner plate of 12 mm: collision and side groundings.
5. Installation of the double hull at B/30 with transversal web frames and an inner plate of 12 mm: collision and side groundings.
6. Installation of the double hull at B/20 with transversal web frames and an inner plate of 7 mm: collision and side groundings.
7. Installation of the double hull at B/20 with transversal web frames and an inner plate of 17 mm: collision and side groundings.
8. Doubling of inner bottom plating thickness: for bottom groundings
9. Doubling the number of girders within the inner bottom: for bottom groundings.
10. Increase of bottom structures material grade to AH36: for bottom groundings.

The above 10 possibilities have been implemented on a reference ship, considering possible collisions with a database of 11 striking ships (Conti et al., 2022, Mauro et al., 2023b).

Thanks to this modelling it is possible to take into account the crashworthiness of the new structure in all the levels of approximation of the risk assessment framework, as the correction for crashworthiness is directly applied to the inputs, thus allowing assessments from Level 1 up to Level 2.2.

## RISK MITIGATION EXAMPLES

The present section presents two test cases for the implementation of RCOs on passenger ships. The cases refer to a Cruise Ship (Ship A in the following) and a Ro-Pax (Ship B). The general particulars of the ships are reported in Table 1, while the general overview is given in Figures 7 and 8. The two cases present the evaluation of different RCOs according to the following scheme:

1. Ship A:
  - 1.1. Change of internal layout with the installation of passive permanent foam
  - 1.2. Insertion of a double hull at B/20 with a plate shell thickness of 12 mm.
2. Ship B:
  - 2.1. Change of internal layout with application of permanent foam.
  - 2.2. Insertion of deployable barriers with foam.

The resulting combination of the two examples covers all the mentioned RCOs possibilities, having fixed foam applications (Cases 1.2 and 2.1), deployable barriers (Case 2.2) and crashworthiness (Case 1.2). For all the conditions, the PLL has been calculated at Level 1 and Level 2.1. No calculations have been performed at Level 2.2 because studies in project FLARE highlight that the differences between Level 2.1 and Level 2.2 are negligible for the tested vessels (Cardinale et al. 2022).

Figure 7: General Overview of Ship A

Figure 8: General Overview of Ship B

Table 1: Main particulars for Ship A and Ship B

Parameter	Symbol	Ship A	Ship B
Length overall	$L_{OA}$	300.00 m	211.30 m
Length between perpendiculars	$L_{PP}$	270.00 m	195.30 m
Subdivision length	$L_S$	296.74 m	212.25 m
Beam	$B$	35.20 m	25.80 m
Draught	$T$	8.20 m	6.70 m
Construction height	$D$	11.00 m	9.40 m
Number of passengers		2750	2315
Number of crew		1000	185
Gross tonnage	$GT$	95,900	36,822
Deadweight	$DWT$	8,500 t	5,581 t

### Ship A

Ship A is an example of a large cruise ship. The ship was first assessed in its original configuration employing static and dynamic analyses for flooding risk assessment. The first round of calculations allows for identifying the attained PLL at both Level 1 and Level 2.1 according to the process described in the previous sections. However, the execution of detailed analyses offers also the possibility of identifying the most critical and vulnerable areas for flooding, thus giving the possibility to select the most suitable zones for the implementation of risk control options.

Figure 9 gives an overview of the critical damage location with the associated penetration resulting from the first analysis. The graph reports in a non-dimensional form the penetration  $L_y$  and the location  $x$  of the damage highlighting the presence of two main vulnerable areas located in the presence of the ship aft and fore shoulder. Those locations correspond to the presence of the heeling tanks in the fore shoulder and of the engine room in the aft. Due to the internal configuration of the ship, it is easier to fit risk control options in the aft shoulder instead of in the fore shoulder. For such a reason, two solutions have been applied to the re-design of the aft-shoulder space: the implementation of a crashworthy structure and the installation of permanent foam.

Figure 10 presents the first option, which means the creation of a crashworthy structure consisting of a watertight double-hull located at B/20 with local reinforcements with a thickness of 12 mm. The configuration gives a significant improvement in terms of achieved PLL, indicating a decrease of 14.6% compared to the original value for Level 1 and a decrease of 15.5% compared to the original for Level 2.1 prediction.

Figure 11 reports the second option, consisting of the installation of permanent foam inside void spaces in a double hull positioned at B/20. Such a technique allows for reducing the permeability of the void space in the double hull, thus increasing the “floatability” of the vessel. The configuration gives a lower reduction compared to the previous solution, providing a decrease of PLL of 11.9% compared to the original configuration for Level 1 and a decrease of 12.3% compared to the original configuration for Level 2.1 prediction.

Figure 9: Critical damages location and penetration for Ship A.

Figure 10: Crashworthy structure for Ship A.

Figure 11: Double hull with foam installation for Ship A.

## Ship B

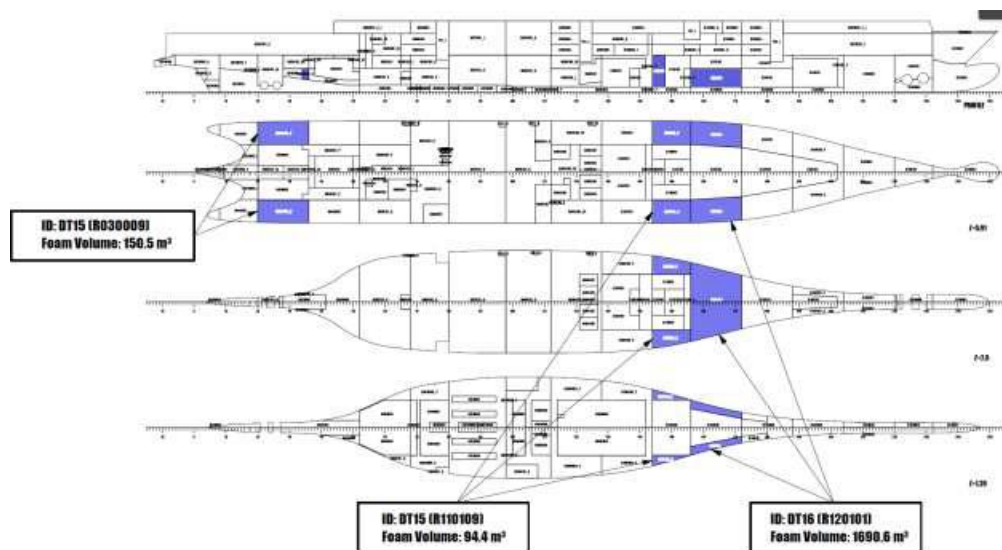

Ship B is an example of a Ro-Pax vessel. As for the previous ship, the vessel was initially assessed for its original configuration through static and dynamic analyses, providing Level 1 and Level 2.1 predictions for the attained PLL. Also, in this case, the execution of detailed analyses allows for identifying the most vulnerable areas of the ship, allowing for providing the correct location of possible RCOs.

Figure 12 shows the most vulnerable areas of the ships, highlighting two main areas of risk, one in the fore shoulder and one in the aft shoulder. Compared to Ship A, most of the critical damages lie in the fore-shoulder, thus, this is the most critical area to be re-engineered by employing suitable risk control options. In this case, having the configuration of the Ro-pax 2 full car decks, it is not possible to change the volumetry in that space or change the structures of the decks, therefore it is possible to use deployable barriers as a risk control option in combination with fixed foam installation under the car decks.

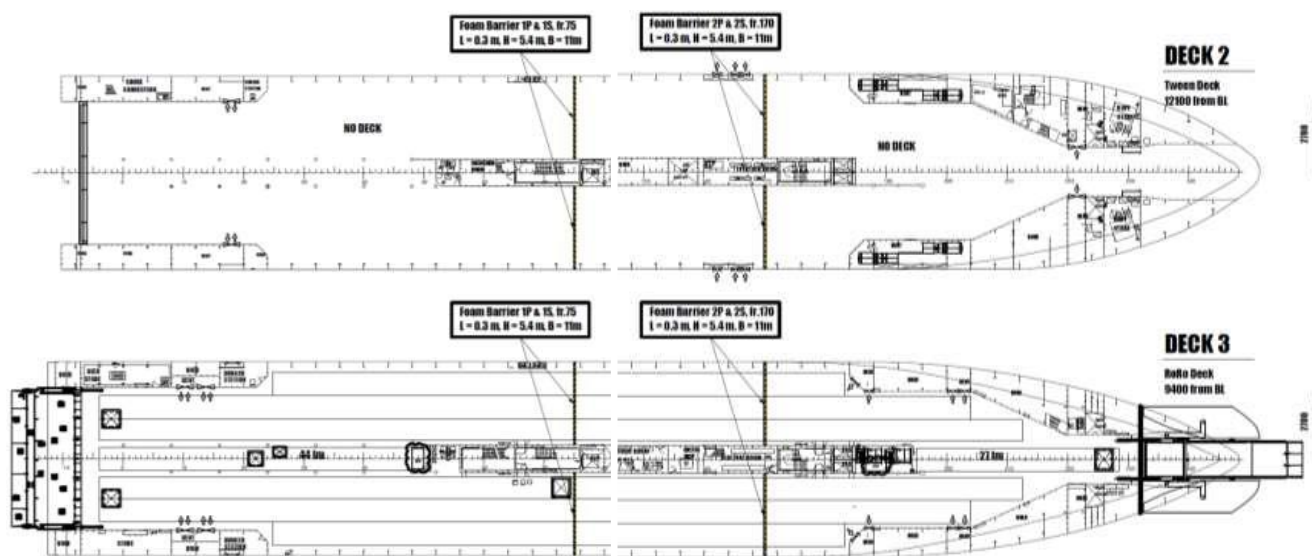

Figure 13 shows the first risk control option implementation, consisting of the installation of permanent foam in void spaces under the car deck. The location of foam is concentrated in the fore shoulder, where most of the criticalities have been detected by initial analysis. It is these cases in particular that can benefit the greatest from the introduction of passive foam, as such installations work to significantly increase damage GM (restoration). Furthermore, as a passive system, the permanent foam is immediately available following the opening of the damage breach and is therefore effective during the transient phase. As void spaces have been targeted, the resultant solution is non-intrusive by nature and converts what is essentially “dead space” into an asset. The configuration gives a considerable improvement in terms of achieved PLL, registering a decrease of 47.04% compared to the original value for Level 1 and a decrease of 42.57% compared to the original for Level 2.1 prediction.

**Figure 12: Critical damages location and penetration for Ship B.**

**Figure 13: passive foam installations on Ship B.**

**Figure 14: Deployable barriers in the car deck for ship B.**

Figure 14 shows the second risk control option implementation, consisting of the installation of deployable barriers. In determining where best to locate the foam barriers, the first consideration has been to target areas of heightened vulnerability within the vessel design. These can be identified where there are concentrations of loss scenarios. Secondly, the barriers have been located to limit, as far as possible, the number of breaches overlapping the barriers. This works to maximise the number of cases that will be positively influenced by the presence of the barriers, whereas if they were to lie within the breach extent, they would offer little to no protection. The resultant configuration has seen the implementation of 4 barriers, protecting both the fore and aft shoulders in pairs across the car deck. The configuration gives an improvement in terms of achieved PLL, registering a decrease of 15.74% compared to the original value for Level 1 and a decrease of 22.94% compared to the original for Level 2.1 prediction.

## Concluding Remarks

The previous sections presented the implementation of three different kinds of RCOs to the two reference ships. The implementation results in evaluating the PLL with both simplified and advanced methodologies. More precisely, Level 1 considers only static calculations while Level 2.1 employs dynamic simulations, thus a first principle tool. Table 2 reports a resume of all the PLLs evaluated for the reported cases for Level 1 prediction, while Table 3 reports the results for Level 2.1. The implementation of RCOs led to different results comparing Ship A and Ship B, especially for the installation of the passive fixed foam system. This is essentially due to the differences in the amount of foam installed in the two designs. For Ship A, the quantity of foam is limited to the small space of the double hull in the engine room area (see Figure 11) thus ensuring few reserves of buoyancy compared to Ship B, where the total amount of foam is about 1935.5 m<sup>3</sup>, equivalent to almost 30 % of the volume in deadweight conditions. Such a massive installation of foam was possible on Ship B because of the large number of void spaces available under the car decks, something not possible to achieve for Ship A or a cruise vessel in general. Other studies on foam application highlight that there is some margin to put more foam volume on cruise vessels, just by slightly changing the internal layout of the ship (Vassalos et al., 2021, 2022a).

**Table 2: PLL Level 1 values for Ship A and Ship B.**

	Damage type	No RCO	Passive foam	Crashworthy structure	Deployable barriers
<b>Ship A</b>	Collision	0.3549	0.3182	0.2716	-
	Side grounding	0.5349	0.4555	0.4721	-
	Bottom grounding	0.1990	0.1859	0.1859	-
	<b>Total</b>	<b>1.088</b>	<b>0.9596 (-11.90%)</b>	<b>0.9296 (-14.60%)</b>	-
<b>Ship B</b>	Collision	0.3412	0.1862	-	0.2622
	Side grounding	0.1603	0.0820	-	0.1546
	Bottom grounding	0.0357	0.0163	-	0.0358
	<b>Total</b>	<b>0.5372</b>	<b>0.2845 (-47.04%)</b>	-	<b>0.4526 (-15.74%)</b>

**Table 3: PLL Level 2.1 values for Ship A and Ship B.**

	Damage type	No RCO	Passive foam	Crashworthy structure	Deployable barriers
<b>Ship A</b>	Collision	0.3173	0.2674	0.2268	-
	Side grounding	0.3353	0.2956	0.3086	-
	Bottom grounding	0.1809	0.1683	0.1686	-
	<b>Total</b>	<b>0.8334</b>	<b>0.7312 (-12.30%)</b>	<b>0.7040 (-15.50%)</b>	-
<b>Ship B</b>	Collision	0.3284	0.1894		0.2281
	Side grounding	0.1041	0.0632		0.0988
	Bottom grounding	0.0352	0.0161		0.0334
	<b>Total</b>	<b>0.4677</b>	<b>0.2686 (-42.57%)</b>		<b>0.3604 (-22.94%)</b>

In any case, with the application of foam being really effective in reducing flooding risk, it could be reasonable to start thinking about different layouts for the passenger ship interior design and abandon the actual trend of extensively capillary compartmentation aimed to increase asymptotically the static A-index, which of course is not possible as saturation is reached after a small increase of the empirically determined number of bulkhead spacing of  $0.03L_s+10$  m.

On the other hand, the crashworthy structure for Ship A and the deployable barriers for Ship B highlight comparable levels of flooding risk reduction while considering a Level 1 assessment. The difference between the effectiveness increases while considering the Level 2.1 characteristics where the effect of the deployable barriers in the car deck became more effective due to the reduction of water progression in the car deck, something that can be reliably evaluated with dynamic simulation only as highlighted by recent benchmarking activity on several flooding simulation codes (Ruponen et al. 2022a).

It is important to underline the differences between the PLLs evaluated with Level 1 and Level 2.1 for both ships as it underlines the relevance and impact of using first principle tools for the flooding risk assessment. All the PLLs evaluated with dynamic simulations have lower values than those obtained by Level 1. The differences arise both for Ship A and Ship B, regardless of the RCO adopted for the calculations. For the Ship A original configuration, the Level 2.1 risk is 23.40% less than the Level 1.1. For Ship B the difference in the original configuration is in the order of 12.94%. Considering the fixed foam installations, the difference for Ship A is about 23.80% and for Ship B 5.5%. For the crashworthy structure, the difference attests to 24.27% while for the deployable barriers in Ship B is 20.37%.

The difference between the values obtained with the two prediction levels is not negligible as it is always above 5%, reaching peaks around 25%. Such a matter stresses the importance of using first principle tools for flooding risk assessment in the design process of passenger ships. Furthermore, the obtained results suggest how different strategies should be pursued to design safer passenger ships, thanks to the adoption of proper cost-effective risk control options instead of relying only on the excessive compartmentation of internal spaces.

## CONCLUSIONS

The present work details the application of a multi-level flooding risk assessment framework for the design phase of passenger ships, highlighting the possibility of implementing different kinds of risk control options to reduce the final risk. The paper describes the primary first-principle tools that can be used to increase the reliability of the risk analysis during the design phase of a passenger vessel, focusing on the adoption of super-element methods for breach generation and design of crashworthy structures and the application of dynamic flooding simulations to estimate the vessel survivability to a given hazard. The execution of advanced evacuation analyses has also to be taken into account to pursue a fully first-principle-based risk analysis, however, the study within project FLARE demonstrates that the gain in terms of PLL by using evacuation analyses or analytical approximation is negligible. Therefore, the implementation of a risk assessment framework for flooding is achievable by using first principle tools up to Level 2.1, thus employing dynamic simulations for vessel survivability.

The paper offers also the possibility to appreciate the flexibility of the given framework to implement different design solutions for risk mitigation. The example provided on a cruise ship (Ship A) and a Ro-pax (Ship B) allows for the testing of three different risk control options: fixed foam installation, deployable barriers and crashworthy structure. Calculations have been performed for all the configurations highlighting the efficacy of the proposed measures to the reduction of risk, always above 10% compared to the original configuration. At the same time, the calculation provided at both Level 1 and Level 2.1 for the PLL highlights differences from 5 to 25% in the final value of attained risk. Such a matter underlines the importance of using more reliable tools (thus at least a Level 2.1 prediction) in the flooding risk assessment of passenger ships.

Finally, the paper underlines how the adoption of a risk control option may increase the safety of a passenger ship and how the use of first principles tools allows for the quantification of the risk reduction provided by the RCOs themselves. The results show how active or passive solutions may significantly reduce the flooding risk on a ship, without the need for

increasing the capillarity of the internal compartmentation of the vessel. Therefore, the adoption of such tools in the design process of passenger ships may result in a new design strategy for the achievement of a generation of safer passenger vessels. It is important to stress that the first-principle tools employed for the reference study have all been validated against experiments in the last 20 years, with continuous activity of benchmarking. Such a matter gives confidence in the reliability of the final results.

## **Part 9:**

# **DESIGN EDUCATION**

# Designing a marine systems design specialization track at NTNU

Stein Ove Erikstad<sup>1,\*</sup>, Per Olaf Brett<sup>1,2</sup>, Benjamin Lagemann<sup>1,3</sup>

## ABSTRACT

*In this paper we describe and discuss the current and future MSc specialization programme in marine systems design at the Norwegian University for Science and Technology (NTNU). We follow the structure of a design process. First, we identify relevant stakeholders. That includes industry, society and the students themselves, and we discuss what are their key needs and requirements for a master level education. Further, we outline what can be considered a conceptual solution for the marine systems design specialization programme's structure and content. We apply two basic types of learning elements. First, a set of focused topic blocks covering central systems design models and methods to develop the required theoretical competence platform. Second, the students perform a series of creative, 'use case'-oriented collaborative development projects based on CDIO (Conceive, Design, Implement, Operate) principles. We discuss the "educational design solution" in terms of learning objectives vs. achieved results and evaluate the impact both from an academic and an industrial perspective.*

## KEY WORDS

Marine systems design; Education; Study programme

## INTRODUCTION

"Everyone designs who devises courses of action aimed at changing existing situations into preferred ones" (Simon 1996). In this paper the "situation" refers to our marine technology study programme, unlike in most IMDC papers, where the design object is typically a ship.

Globally, there are only a few universities offering an integrated five-year MSc track in marine technology. Our marine technology programme at NTNU graduates around 120 MSc students each year. This reflects the importance and size of the maritime industries in Norway, traditionally being shipping and fisheries, shipbuilding, ship equipment systems, later including offshore oil & gas and aquaculture in the 70s, and more lately offshore energy, autonomous ocean space surveillance and now also deep-sea mining.

NTNU is also among the even fewer universities having a dedicated specialization in marine systems design (MSD). In our MSc programme, about 20-30 students each year have chosen this specialization, alongside those specializing in marine structures, hydrodynamics, cybernetics, or energy systems. The historical roots of the MSD programme date back to the late 60s, with the establishment of a separate department of *ship design*, and with Professor Stian Erichsen pioneering the development of *design* as a research and education field at NTNU beyond what was then considered a typical naval architecture and shipbuilding programme. Later, with the advent of the new ocean industries both in Norway and beyond, the specialization changed its name to *marine systems design*. This was reflecting both the shift of importance to "industry Norway" expanding from shipping to offshore oil and gas related design objects<sup>1</sup>, but also the importance of a *systems* focus in developing everything from integrated multi-modal logistics to the installation and operation of subsea oil & gas fields, aquaculture, offshore wind farms, to name a few.

<sup>3</sup> SINTEF Ocean, Trondheim, Norway

As will be discussed in more detail later in this paper, we have a current string of both more general systems analysis courses as well as marine design methodology courses that is the backbone of the MSD specialization. However, we steadily see the need to review and re-design this track. There are several reasons for this. One is simply to critically evaluate the status quo at regular intervals as part of a continuous education quality process. Further, internal factors such as student exchange periods (80% of our student go abroad for at least one semester), changes in human resources and internal organization, and changing expectations from industry, all drive change and require adaptation. Finally, external developments such as the focus on sustainability and net zero emissions towards 2050, and developments in digitization and artificial intelligence, are additional instigators for change.

Asbjørnslett et. al. (2022) presented much of the concept ideas and some more details about the NTNU perspective on educating the next generation marine system design engineer. The NTNU future technology studies project was reviewed and discussed as to its consequences and implications for the organization and upgrades of the marine technology study and outline of the study plan. It was also explained how the trajectory of human expansion into the ocean represented by new and expanded ocean activities like marine aquaculture, deep-sea minerals, offshore wind energy generation, etc. in addition to the more conventional and well-established ocean activities like shipping, offshore oil & gas, fisheries, and others, may be seen as an accelerated demand for marine systems design architects and engineers. The CDIO (Conceive, Design, Implement, Operate) approach introduction in the study syllabus, the use of field studies to improve the understanding of operational matters, the introduction of sustainability and digitalization into the study plan, and finally, a short review and argumentation for the introduction of the marine system design (MSD) "diamond" as a realization and implementation tool of the needs-function-form mapping in engineering design, on different levels, meeting the diverse stakeholders' demand, were all addressed.

Thus, the overall objective of this paper is to *outline the goals, structure and content of a marine systems design MSc specialization track that meets anticipated needs and requirements for the next decade(s)*. Based on this, the important questions we want to address here and discuss at IMDC are as follows:

- Who are key stakeholders for such a programme, and what are their needs and requirements?
- How can we map these needs and requirements into specific learning objectives for the specialization programme in marine systems design?
- What should be the corresponding learning content, in terms of theory, models, processes, tools and skills?
- What should be the structure of the study programmes?
- How do we handle and include the interdisciplinary challenges of future study programmes?
- What should be the role of industry and industrially relevant design business cases in this education track?
- What is a good balance between a classical naval architecture approach and the exploration and implementation of new topic areas and technologies, such as artificial intelligence, digital twins, model-based systems engineering?

## Needs and requirements

Before we start to define needs and requirements for a revised MSc education track, we must define *who* are actually our "customers". What immediately comes to mind for most technical universities is the industry and their needs since they are the main receivers of graduates which they subsequently turn into value-creating employees. This "what-the-industry-want" is also easily accepted by the students, since an education targeted towards their needs, make them attractive in the labour market after graduation. It is here important to keep in mind the tendency of industry to be short-sighted and very topical in their demands and expectations' setting. From experience, we know that study programmes are not that quickly to change and sometimes topics and expectations of industry can only be met by inter-departmental (institutes) set-ups, because they are multi-disciplined by nature and the universities and departments are not necessarily arranged such that cross-discipline challenges experienced by industry, can easily be handled by existing course programmes and syllabuses. Industry demands and expectations must, therefore, be carefully scrutinized and evaluated, and study programmes gradually adapted to these needs if at all possible. So, not all industry expectations can necessarily be met by universities.

Beyond the value-creating employee perspective, the students themselves are important stakeholders. A master level education is essential for the formation of an intellectual and competency platform for the individual that gives meaning, mastery and self-realisation throughout their life. The report "Worth knowing" (NOU 2000) points out that "higher education should not only provide society with competent professionals, but also aim for developing independent and insightful people." The first sets of Generation Z have arrived and already finished their MSc study at the universities. More student groups have or are about to finish their studies. As the first social generation to have grown up with access to the internet and portable digital technology from a young age, members of Generation Z, even if not necessarily digitally literate, have been dubbed "digital natives" (McKinsey 2023). Moreover, the negative effects of screen time are most pronounced in adolescents, as compared to younger children. Members of Generation Z tend to live more slowly than their predecessors when they were their age. This is

reflected in being more concerned than older generations with academic performance and job prospects and spend more time on electronic devices and less time reading books than before, with implications for their attention spans, vocabulary, academic performance, and future economic contributions.

For the society as such, it is desirable that we train master level engineers who can contribute constructively to the public debate with understanding, perspectives and opinions that stretch out over narrow commercial interests. This will be both a counterweight and a complementary voice in a public debate which is characterized to a greater extent by social scientists and economists than by engineers. Such a public debate will demand engineers who dare to challenge and question existing structures and to use their knowledge to point out errors and shortcomings in a world characterized by technology - including topics that may not always be in the industry's interest to raise. Most of the students we educate will, to a greater or lesser extent, work with research and development. Here, in addition to solving technology challenges in a short-term perspective, they must be trained to address more long-term, fundamental issues that often fall outside the industry's interest, but where a holistic understanding is important. The importance of this has increased by the need to curb greenhouse gas emissions. The solution is multifaceted, but technology does play a vital role - both in creating the problem in the first place, but also for developing solutions. And it should be said that industry representatives have told NTNU that we should listen to what they say – but we should not listen too carefully.

We are part of a knowledge society, where knowledge is perceived to have an intrinsic value beyond its usefulness from an industrial perspective. Knowledge is a crucial pillar in an enlightened, rational, and democratic society. The interaction between technology and society, and technology and humanity, is as such an important perspective which, both directly and indirectly, must be communicated as an important end goal for an education.

### **What is then the future role of the naval architect?**

Previous IMDC contributions have addressed and seriously challenged the future role of the naval architect – to be strengthened and expanded upon as an integrator or manager of the ship design project – sometimes even administering the new building project development on behalf of the customer from idea to ship in operation. Thus, the naval architect becomes an integral part of the customer's business development process – as in current project-making activity (Ulstein & Brett et al. 2012, 2015). In addition, it has been argued that it is paramount that the naval architect retains his or her expertise and skills, and even continually improves them, in designing the better ship or marine object to meet all stakeholders' expectations.

Andrews (2018b) approaches the challenge by asking the question "is a naval architect an atypical designer – or just a hull engineer?" He continues: "It seems appropriate...to question whether the engineering discipline – that of naval architecture – which has to date dominated ship design practice, still remains best placed to continue in that role." In the conclusion, it is said that: "...despite the increasingly demanding safety (and decarbonization) regime in ship design, that emphasizes the naval architect's role as "the hull engineer", the naval architect's role remains that being the overall ship (solution) designer." In short, Andrews (2018a) put forward three main reasons for that assertion: a) "Everyone's problem is the naval architect's problem," b) "There is a need to have a whole ship perspective to ensure design balance is achieved from the initial synthesis and maintained through-out design development and through life", c) "Architecture is seen to be the key to both initial ship design synthesis and to achieving and maintaining design balance".

In addition to the appropriate academic qualifications a naval architect needs to also expand from wider engineering practice with a set of additional applied and social science expertise and skills such as finance, human resources, organization, marketing and communication and finally, project leadership and management skills, (Ulstein & Brett, 2015, 2018). Thus, more naval architects need to expand their multi-disciplinary expertise and skills to better support and be able to respond better to increasing industry demands. Again, it is suggested that "the ship designer of the future" must master equivalent expertise and knowledge within the fields of commercial, operational, and technical challenges related to a new building project realization. Thus, a new type of competent naval architect must be developed by academic education and training and put into practice situations different from the past.

### **Marine systems design - a managerial process**

Over the years, it has become clearer to us that handling the whole process of a ship design project, with its apparent complexity, uncertainty, and ambiguity are more of a managerial mastery task rather than a classic naval architecture and marine engineering-based ship design and ship-hull engineering task. Another challenge is the conflict-oriented situation, which often arises in the ship design approach and how to turn it into something positive for the process and the parties involved. Conflict situations are generated within or among stakeholders in the ship design process as a manifestation of contesting differences in viewpoints, competence, and experiences. They occur when the views that are involved in the ship design discussions collide to produce cognitive turbulence, which can result in instable patterns of conflicting behaviour. Typically, three classes of conflict situation can arise in a ship design approach: i) tensions that may have no discernible cause, ii) disputes caused by

misreading and interpretations *and* minor provocations, and iii) conflicts represented as a manifestation of differences in opinions, experience, and expertise. Consistent with the systems viewpoint, it has been suggested that a conflict modelling cycle can contribute to the exploration of the undesirable behaviour patterns and inherent attitudes among the participants in the ship design process.

Under such a regime, we believe that traditional ship design approaches will gradually become an extended project management process to be offered owners rather than a given design package. Classic naval architecture and marine engineering skills and expertise will rather become an integral part of it. Hence, state-of-the-art naval architect education must gradually reflect these challenges.

### **New challenges – time for change**

In line with RINA, it seems as if the traditional naval architecture and marine engineering basic bachelor and or master's degree educational disciplines and existing study programmes do not suffice as the basis for further enlightenment and proper handling of appearing multi-faceted, "wicked" problems. The wicked problem(s) being described by typically 10 propositions put forward by Rittel and Weber, (1973): "1. There is no definite formulation of a wicked problem. 2. Wicked problems have no stopping rule. 3. Solutions to wicked problems are not true or false, but good or bad. 4. There is no immediate and no ultimate test of a solution to a wicked problem. 5. Every solution to a wicked problem is a 'one-shot operation'; because there is no opportunity to learn by trial-and-error, every attempt counts significantly. 6. Wicked problems do not have enumerable set of potential solutions, nor is there a well-described set of permissible operations that may be incorporated in the plan (business concept). 7. Every wicked problem is essentially unique. 8. Every wicked problem can be a symptom of another problem. 9. The existence of a discrepancy representing a wicked problem can be explained in numerous ways. The choice of explanation determines the nature of the problem's solution. 10". The planner (naval architect) has no right to be wrong. Head and Alford (2015) propose some strategies for dealing with wicked problems – such as going beyond technical/rational thinking, collaborative working, new modes of leadership, and reforming the managerial infrastructure. These strategies can enable partial and provisional responses to problems, amounting to shared understanding about the nature and about ways of dealing with them, they conclude.

RINA (Andrews, 2018) suggests that such additional problem-solving expertise and skills training should take place after the formal degree-based education is finished. The authors of this article argue that such training is not only a question of future on-the-job training for a certain period but requires proper education in relevant non-technical subjects too.

It is, therefore, time to reconsider how we educate and train future naval architects. Future technology study programmes (Asbjørnslett et al., 2023) should expand their knowledge territories and or let other complementary trained expertise, team up with them each time and in such a way to create the necessary inter-disciplinary expertise and skills to advance the relationship between academic staff and students. Project-related work where students can achieve valuable collaborative experience, go beyond technical/rational thinking, take real leadership of their innovation projects, ensure that the different subjects of the marine technology study-programme is fully explored and utilized, seem to be in line with contemporary plans for the future of technology studies. Complementarity, openness and improved interpretive schemes for interfacing different subjects and study programme approaches and their corresponding project tasks and course work are most likely what we need. NTNU IMT is moving quickly in this direction. It will be interesting to see whether other academic marine design schools move into the direction of broadened and multi-disciplinary study programmes too.

## **THE CURRENT STUDY TRACK TO MEET NEW CHALLENGES**

### **Programme structure**

The integrated Master of Science programme extends over five academic years (10 semesters) and constitutes a course load of 300 ECTS credits. All 5-year master's programmes offer a combination of compulsory and elective courses. To graduate from a Master of Science programme a student must have completed all compulsory courses, as well as enough elective courses to achieve the total 300 ECTS credits required to complete the programme.

For a student that will graduate with a master's in marine technology, with a specialization in marine systems design, the study will comprise the following, see Table 1:

- There is a string of marine technology courses starting from the first semester, that is meant to cover all basic naval architecture topic areas, such as hydrostatics and stability, hydrodynamics, structures, cybernetics & power systems. This string is compulsory for all students. It converges towards the 6<sup>th</sup> semester with a capstone design project that will synthesize and integrate the different marine technology disciplines, providing hands-on training for the students to apply their knowledge in a realistic design setting.

- In parallel, the first three years will develop a sound foundation in mathematics (4x 7.5 ECTS), physics and chemistry, as well as covering basic engineering topics such as mechanics, fluid dynamics and thermodynamics.
- In the last part of the study, the students are obliged to dive deeper into selected marine technology topics, such as sea loads, advanced structural analysis, propulsion, etc.
- Additionally, a number of non-technical topics are compulsory, such as technology management and electives from economics, finance, or social sciences.

Table 1: The five year MSc programme in marine technology at NTNU. Yellow cells are common cross-specializations naval architecture courses, while the blue are courses specifically for the marine systems design specialization

Year	Sem	7.5 ECTS	7.5 ECTS	7.5 ECTS	7.5 ECTS
5	10	Master's Thesis			
	9	Complementary	MT elective	Simulation/Fleet design	Specialization Project
4	8	Experts in Team	MT elective	MT elective	Design methods II
	7	Complementary	MT elective	Other elective	Design methods I
3	6	MT elective	OR & Optimization	Machinery systems	MT6 Capstone design
	5	Mathematics 4N	Techn management	MT5 Marine dynamics	MT4 Propulsion&control
2	4	Statistics	Thermodynamics	Material Technology	MT3 Hydrodynamics
	3	Mathematics 3	Physics	Fluid Mechanics	MT2 Structures
1	2	Mathematics 2	Programming	Mechanics 2	Philosophy of science
	1	Mathematics 1	IT Introduction	Mechanics 1	MT1 Intro

The specialisation in Marine Systems Design starts off after the capstone design course. According to the learning goals, the specialization shall provide the students with knowledge and competence for the design and realization of complex, innovative marine systems, such as ships, marine transportation systems, offshore platforms, offshore logistics and systems for offshore energy production. After completing this specialisation, the candidates shall be able to:

- perform a technical analysis of relevant marine systems, such as stability and hydrostatics, resistance and propulsion, strength, reliability, and availability.
- analyse the economic, environmental, risk and safety-related performance of a vessel or fleet in a life cycle perspective.
- design and verify systems for operation in harsh marine environments, with a particular focus on Arctic conditions.
- use methods from operations research and risk analysis for optimization, simulation and decision support.
- apply a holistic perspective to the development and realization of marine systems, based on methods from design theory and systems engineering.

They should also develop skills that make them able to:

- develop holistic, complex innovative systems solutions both individually and as part of teams.
- make relevant ICT tools for computer aided design, technical analyses, optimization, simulation and risk and safety analysis.
- verify design solutions with respect to regulations and requirements from trade, customers, and society as such.
- efficiently present and communicate the final design solutions and corresponding documentation, both written and orally.

## The overall programme

The new study programmes in marine systems design must be structured in such a way that not only "filtered" industry needs are catered for but also some of the needs of the incoming Generation Z students. Compared to previous generations, the alternative characteristics of Generation Z: live more slowly, more concerned with academic performance and job prospects,

more time spent on electronic devices and less time reading books, with implications for their attention spans, it is argued by the authors of this paper that in many ways, a perfect situation is now to make a new marine design course programme work based on the following synthesized assertions:

1. Traditional course time thieves, like making computer programmes work, and traditional library-oriented data-source searches can be replaced by more creative project 'use case'-oriented collaborative development work – idea creation, comparing different solution alternatives by performance indexed benchmarking and massive, big data web-based information solicitation – a real collaborative project expectation elucidation process.
2. Take a broader stand to a full project realization, get in charge with the project team and argue your project team's case and pursued project business proposition – a full practical project work and findings communication process – read less and do more innovation work – take leadership.
3. Use all subject disciplines related to commercial, operational, and technical matters, by engaging all the subject disciplines of a marine technology institute and thereby – make use of the knowledge infrastructure and network - apply the full CDIO (Conceive, Design, Implement, Operate) principles.
4. Prepare and document a real time series of decision-making related to the project development and ship design solution drawings, specification, and analyses – practical application of lessons learned to date and beyond.

## CORE METHODOLOGY MODULES OF THE SPECIALIZATION

Still, “the proof lies in the pudding”. Given the needs and requirements developed so far, and the statements on the high-level learning objectives, what should be the specific content of the core specialization track? We have chosen to take a modular approach to this. At NTNU, the standard course is 7.5 ECTS<sup>4</sup>. We have chosen to break this up into 2.5 ECTS “virtual” modules, thus giving us 9 topical building blocks as a replacement for the three courses considered. The question then becomes: What should be those 9 modules?

We are still in the process of developing these modules. Our first draft contained the modules outlined in Figure 1. Each of these is supposed to provide one or a few tangible tools to the designer's toolbox, both from a theoretical and an application-oriented perspective. These modules will of course need to build on the other basic courses that the students have already covered, both generic topics (mathematics, mechanics, etc.), NAME topics and basic systems analysis (e.g. operations research, data analysis, statistics, etc.). In the following, we will briefly describe each of these and discuss the rationale for including them:

	Learning objectives	Main topics
1 Design theory & methodology	Theoretical foundations for engineering design in general, and marine systems design in particular	<ul style="list-style-type: none"> <li>• Design strategies</li> <li>• Design methods</li> <li>• Design procedures &amp; tools</li> </ul>
2 Shipping logistics & economics	Know how to model maritime logistics systems (fleets, operations, infrastructure) and analyse KPIs related to economics, transport service levels	<ul style="list-style-type: none"> <li>• Macroeconomics of shipping, shipping markets</li> <li>• Ship size &amp; speed (microeconomics)</li> <li>• Ports and waterways, queues</li> </ul>
3 Optimization methods for marine systems design	Modelling real life design problems as optimization problems for insight and decision support	<ul style="list-style-type: none"> <li>• Vessel design problems</li> <li>• Fleet configuration and utilization</li> <li>• Transport problems using networks</li> </ul>
4 Systems simulation and data analysis	Learn to capture real operations into simulation and data analysis models to derive system level performances	<ul style="list-style-type: none"> <li>• Operation models from AIS MetOcean data analysis</li> <li>• Simulation model development and analysis</li> <li>• Visualization and animation</li> </ul>
5 Designing digital twins and digital services	Develop digital services based on digital twin platforms according to engineering design principles	<ul style="list-style-type: none"> <li>• The digital service design process</li> <li>• DT architectures and design patterns</li> <li>• Sensors and data channels/edge</li> </ul>
6 Design for sustainability with focus on uncertainty and flexibility	Designing for LC sustainability, with focus on low and zero emission shipping solution	<ul style="list-style-type: none"> <li>• Low emission regulatory context towards 2050</li> <li>• Energy efficient ships, logistics, low emission fuels</li> <li>• Uncertainty and flexibility theory</li> </ul>
7 Risk-based design	Learn basic risk analysis concepts, models and methods, and how they can be used as an integral part of complex marine systems design	<ul style="list-style-type: none"> <li>• Basic risk models and methods</li> <li>• Risk-based design principles (safety equivalence)</li> </ul>
8 Modular architectures, configuration-based design	Learn fundamental principles of modular architectures and product platforms, and their application in product and systems design	<ul style="list-style-type: none"> <li>• Modularization, modular architectures</li> <li>• Product platform development</li> <li>• Configuration-based design, mass customization</li> </ul>
9 Introduction to RAMS	Explore basic concepts of reliability, availability maintenance and safety (RAMS) applied to marine systems design and operations	<ul style="list-style-type: none"> <li>• Basic RAMS concepts</li> <li>• Optimal inspection and maintenance policies</li> <li>• Fleet design for inspection and optimization</li> </ul>

Figure 1: A preliminary outline of core theory and method modules as part of the systems design specialization

<sup>4</sup> European Credits Transfer System

## Design theory and methodology

This module will cover the theoretical foundations for engineering design in general, and marine systems design in particular. This includes different design models, the design processes at shipyards and ship designers, and provide a basis for understanding of design as a mapping from needs via functions to form. From before, the students have covered most topics related to marine systems analysis pertaining to hydrodynamics, structures, power systems, etc., and they have already a “hands-on” experience of a guided and relatively complete design process from their capstone project in the 6<sup>th</sup> semester.

The “function-to-form” principles in engineering design requires a fundamental logical shift for the students. Their previous engineering subjects typically has a form-to-function approach (“given this description, analyse the performance using this method algorithm”). They have already been exposed to the practical reality in the 6<sup>th</sup> semester capstone subject, which provides a good starting point for reflection and a more theoretical understanding of fundamental design principles. This includes the realization that there is not one “deductive” correct solution for real world design problems, motivating for the introduction of system architectures and corresponding conceptual choice theory. This is akin to “style” being a fundamental element of design according to Andrews (2018a), both as a mental and practical construct of design classes as archetypes that can be further developed and optimized by prototype refinement, (Coyne et al. 1990).

## Shipping logistics & economics

A systems perspective on marine design requires a fundamental understanding of the operating context in which the ship will operate. The ship is typically part of a fleet, and the fleet a part of a logistics system. Further, we see the need for a deeper understanding of both the ship and fleet operations, as well as the operational context in terms of e.g. regulatory framework, economics & financing, fuel infrastructure, and technology development – and this from a lifecycle perspective.

This module should link relevant topics from the technical disciplines with topics from operations research and economics, with an emphasis on the strategic design decisions towards fleet renewal and retrofit under a high degree of uncertainty.

## Optimization methods for marine systems design

Intrinsically, *design is about finding the best possible solutions* within a set of constraints. Thus, optimization is naturally a core topic for the marine systems design specialization. This includes reflections towards the challenges of capturing large, complex, multi-faceted problems, as real-world design problems typically are, into the relatively strict and formalized framework of mathematical optimization (Simon 1973, Ackoff 1979). Still, our experience is that the students gain considerable insight into a design problem by the modelling process itself, independently of the final optimal solution. This module is planned on the assumptions that all students have a basic course in operation research and optimization from before, so that the focus can be on application-oriented modelling of industry-relevant design problems.

## Systems simulation and data analysis

*We always design for operation.* To understand, visualize and be able to analyse operations that are complex, dynamic, and typically stochastic, simulation and data analysis models become an important part of a designer’s toolbox as a means to derive system level performances.

## Designing digital twins and digital services

Recent advancements in digitalization and the Internet of Things (IoT) have enabled various digital twin (DT) solutions, facilitating closer collaborations among ship designers, equipment manufacturers, and shipbuilders throughout the vessel's lifecycle. An important aim of DT solutions is to offer value-added services by based on real-time data streams from onboard sensors. For instance, one such service could involve monitoring the vessel's inventory from its inception to decommissioning, actively providing docking services for maintenance, upgrades, and retrofits as needed. Another example includes the establishment of online shore-based operation centres, capable of delivering specialized expertise and economies of scale through the simultaneous management of multiple vessels. These examples illustrate how digital twins become an import outcome from a systems design process, alongside the delivery of the physical vessel. Furthermore, these DT-based value-added services should be *designed* based on the same underlying principles and using a similar methodology as for the ship design itself (Erikstad 2019b).

## **Design for sustainability with focus on uncertainty and flexibility**

*We always design for the future, and the future is intrinsically uncertain.* Still, we do not have the luxury of waiting for these uncertainties to be uncovered. Design decisions must be made today, increasingly for the long horizon to meet sustainability goals following the 2050 zero emission target defined by IMO. At NTNU, we have an ongoing process towards defining and developing what should be the curriculum related to sustainability, both for the engineering education as such, as well as for the marine technology programme. We believe this topic should be combined with teaching theory, models and methods for designing for uncertainty, flexibility and changeability, such as real options, stochastic programming, epoch-era analysis, scenario development, combined with lifecycle analysis methods.

## **Risk-based design**

Understanding fundamental concepts of risk is a necessary element in all systems-oriented programmes. Many students will take elective courses covering this topic in depth, predominantly from other perspectives than design. A basic module here should cover fundamental risk analysis concepts, models, and methods, and how they can be used as an integral part of complex marine systems design process. It is already central to core topics in naval architecture, e.g. probabilistic damage stability, (Papanikolaou 2012), and it will be increasingly important for developing new and innovative solutions for which there is a limited existing regulatory framework, say, new zero emission fuels, new energy-saving technologies, etc. Here, principles of “equivalent-risk” and “equivalent-safety” are needed for validating design solutions.

## **Introduction to RAMS**

Covers basic concepts of reliability, availability, maintenance, and safety (RAMS) applied to marine systems design and operations. RAMS concepts are important for the operation of the system as such, but also for understanding and modelling important service operations (say, service vessels/fleet for wind farm inspection and maintenance).

## **Modular architectures, configuration-based design**

This module covers fundamental principles of modular architectures and product platforms, and their application in product and systems design, (Erikstad 2019a).

## **Alternative modules**

The nine modules proposed here were the first attempt to define a specialization track for marine systems design. With each module covering 2.5 ECTS, this corresponds to three normal courses, which is our current planning constraint. There will be good arguments for including other topics in this track, though this will have the consequence that one of these nine will have to be removed. Some of the alternatives considered are:

- Project-making and business development, focusing on how shipping and maritime projects are initiated and matured from both technical, commercial/financial and operational perspectives. This includes stakeholder’s perspectives, requirements elucidation, and analysis of markets and competitors using tools like Accelerated Business Development (ABD), (Ulstein & Brett, 2015).
- Strategic business models for the design firm. In the DREAMS<sup>5</sup> project, NTNU and Ulstein have investigated the relation between strategic business models, the organisation of the design firm, the structure and content of alternative design processes, and the technical and commercial outcome of the process. It remains an open question to us whether this should be a part of a systems design specialization curriculum.
- Model-Based Systems Engineering (MBSE). This is an approach to systems development that has strong historical roots, as well as having received renewed attention lately. It puts emphasis on the explicit modelling of all central aspects of the system using formal, standardized models, and thus have a relevance to the students beyond systems design. MBSE could be a separate module in our 9-module collection, or it could be integrated as a common modelling framework in most of the other modules.
- Artificial Intelligence in design. At present, with AI application beyond “classical machine learning” is still relatively immature, this would basically be raising relevant discussions and exploring opportunities towards using

---

<sup>5</sup> Design Re-Engineering and Automation for Marine Systems

AI in design. Though with the present pace of development in this area, it is likely that more substantial models, methods, skills, and applications will have reached a level of readiness to be an unavoidable part of the curriculum.

This list could have been longer. A key point is that we live in an uncertain dynamic world, thus we should design our study programme so that we can continuously adapt – and to the extent possible open up for a certain degree of choice for each student. Over time, it is expected that this list of complementary study modules will be expanded upon to for example meet special contemporary topical needs of the industry and political trends. Other existing modules might be frozen for some years if demand and student interests do not prevail and later on to be revised and revitalized if need be.

### From subject theory to project making - Capstone design course

NTNU IMT decided in fall 2023 to adjust and enhance their 3<sup>rd</sup> level 6<sup>th</sup> semester TMR4256 Design of Marine Systems Course (previously PMS) into a capstone project that became compulsory for all specializations. The capstone project being a unique opportunity to carry out independent group work to devise an innovative solution for a real-world problem. Figure 2 depicts the international development and search for a modernization approach to existing and traditional training of engineers, particularly at MSc level. Table 1 showed how the Capstone initiative is positioned in the middle of the 10-semester long MSc-course structure of NTNU. In this way, it is thought that students after 5 semesters of basic theoretical training of engineering subjects like maths and physics and others, will need and experience a challenging course in the 6<sup>th</sup> semester where they will have to develop their innovative skills, handle commercial, operational and technical aspects related to a real problem-solving project.

An important change was that this course was made compulsory for all specializations – so that, e.g., a student who wants to study hydrodynamics should understand the setting for supporting the hull form and propeller design as part of an integrated process.

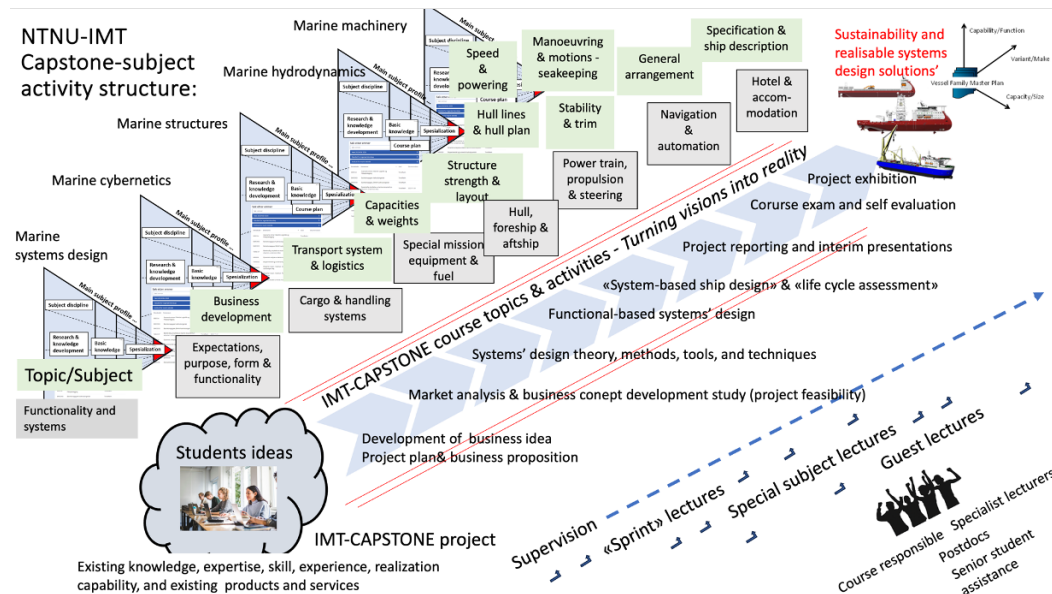

Figure 2: The outline of the new capstone design course

The idea is that students with their 6<sup>th</sup> semester start background and with additional core lectures, external guest contributions and many "sprint" training sessions can make the students develop an idea almost into a "sellable" and "producible" marine system design solution.

All the traditional naval architecture and marine engineering disciplines are there and applied by the students. In addition, they must also expand their horizon in the early part of the course project work in being introduced, for the first time, with market, business, commercial, and operational matters that influence their project problem solving process. A new important feature of the Capstone initiative is that academic staff (subject specialists) from other main subject disciplines are directly involved in the course execution by particularly running the ad hoc "sprint" training sessions on subject matters arising as the progress of student work takes place and project problems arise – "problem solving at your fingertips". A comprehensive course project

plan is needed and a tight control of course time-plan is executed. Continual facilitation of project work and supervision of student students are practiced.

Interaction with industry is important and is encouraged. Industry representatives are, therefore, involved by web, telephone or physical presence. A lot of emphasis is placed on presentation of ongoing and final work and the course finish off with a two-day oral exam and a two-week exhibition of project work done at the end of the semester.

Almost midway through the Capstone effort, it is still too early to summarize the experiences so far. We, therefore, promise to return to IMDC at a later stage and report on more thought through and well documented experiences.

## CONCLUSIONS

In this paper we have outlined a revised plan for a specialization track in marine systems design at NTNU. This is indeed a complex design process, starting with defining the needs of multiple stakeholders, such as students, industry, and society at large, and ending up with, though somewhat fragmented, propositions for what should be part of a marine systems design master-level specialization. We have further described our revised Capstone design course that serves as the introduction to a holistic systems design thinking.

We live in a time where new areas are being opened for exploration, energy production and extraction, where typically deep water, long supply lines, and challenging climatic conditions require new expertise and technology. Energy shortages and a focus on the environment pave the way for profitable exploitation of wind power far offshore. Global warming demands significant reductions in emissions to the air from maritime transport, where a vision of zero emissions from the industry itself sets high expectations for technology that has not yet been developed. Our northern areas are becoming more accessible for marine activities, with associated challenges for vessel technology, logistics, risk, and environment, and where commercial exploitation of a trans-Arctic route is increasingly seen as a real possibility. Aquaculture is moved out into exposed waters. All this paints a picture of an industry where the most important constant factor is change. And the pace of change seems to be accelerating. The future for which we are educating our engineers appears, however, unpredictable, unclear, and complex. We, therefore, see the need to understand multidisciplinary and complex issues, while important areas of knowledge continue to be developed, accompanied by a need for bringing fragmented expertise within narrow areas closer together. This creates significant challenges in terms of what knowledge and skills we should convey so that our students are as well-prepared as possible for a 40-year plus career after completing their education.

# Educating for an unknown future: How to prepare students of ship design for the propulsion of tomorrow

Carmen Kooij<sup>1,\*</sup>

## ABSTRACT

*It is very likely that the students that we educate today will work with what we currently refer to as modern propulsion or alternative fuels in their career. As educators, the goal is to best prepare our students for their working life. This article looks into what a naval architecture student would need to know about these modern propulsion systems and fuels when they graduate. In this article, two types of knowledge are defined; adaptive knowledge, knowledge that spans multiple areas, and routine knowledge, that addresses a specific case. By identifying what competencies fall under the adaptive knowledge and which fall under routine knowledge, it is possible to advice on changes that should be made to the curriculum in order to best prepare students for the future.*

## KEY WORDS

Design education; green propulsion; green shipping; marine engineering

## INTRODUCTION

Last year, in 2023, the IMO published the common ambition of its member states to bring the greenhouse gas (GHG) emissions close to zero. Additionally, they made a commitment to use more alternative, zero and near zero GHG fuels by 2030 (IMO, 2023). These goals, together with the general trend towards cleaner and greener fuels and propulsion methods means that the students we educate today will need to work with these alternative fuels and propulsion systems in their career. However, as we are still at the beginning of the green revolution in shipping there are many different types of fuel and corresponding propulsion systems to choose from. Unfortunately, we cannot simply address them all in detail.

Education has always had to deal with adapting to innovations made in the industry. Especially in the last decades, technology and tools used in industries are changing rapidly, making educational institutions play catch-up. There is a field of tension between teaching students traditional skills and adding new skills. This is influenced by the wishes of the industry, but also by the skillset of the lecturers and the available time to set up a curriculum surrounding these new technologies.

In this article, we look at how we can best prepare students for the unknown future, allowing them to excel regardless of how a ship's propulsion system will look in the future. We start of with an analysis of the current curriculum for the marine engineering. From there, we define the competencies that a student who graduates with a bachelor degree has. Next, we make the transition to identifying what competencies students should have in the future. This is based on three parts; the first is an analysis of a project performed by our third year students who were tasked with designing a Crew Transfer Vessel (CTV) powered by fuel cells, without them receiving specific training in this area. Additionally, a literature review is performed to find if a trend can be found there. Finally, the industry is asked for their input to see what competencies recent graduates lack. Together, this leads to an overview of what changes should be made to better prepare our students for the future. The article ends with an advice on where the focus should lie.

<sup>1</sup> Maritiem Instituut Willem Barentz, NHL Stenden, Leeuwarden, The Netherlands

\* Corresponding Author: [carmen.kooij@nhlstenden.com](mailto:carmen.kooij@nhlstenden.com)

In this article the focus lies on modern propulsion systems such as batteries and fuel cells and different (low flash point) fuels. Other methods to reduce GHG emissions on ships such as scrubbers and wind assisted sailing also exist. However, the use of these types of systems is assumed to not be as disruptive for the industry and therefore the curriculum. This means that they are out of scope.

## **CURRICULUM MAPPING**

Currently, the curriculum at NHL Stenden mostly focusses on ships powered by conventional propulsion. In the first year, students are introduced to the main drivers and auxiliary systems. They learn about the most important values of the propulsion systems and make some basic calculations to determine the type and size of engine a ship requires. In the second year, as part of a project, students are asked to make a more detailed design of the engine room. They determine the required power to propel the ship, calculate the amount of additional power that is required and make technical drawings of the engine room such as a detailed design of the engine room and a one line diagram. In the third year students are tasked to design a more complex ship design which requires a better understanding of the required power on board.

To identify the skill that students now have when they leave their study program a method known as curriculum mapping is used. Generally, it is used to identify how generic skills, such as literacy, numeracy and interpersonal skills of students are evaluated, however, it also works for technical skills. Curriculum mapping is used to identify in which subject specific competencies are taught. For example, it can be used to identify where students learn to present their work orally, or where they learn to write a comprehensive report (Sumsion & Goodfellow, 2004). For this article, the method was inverted. Using the study guide of the NHL Stenden University of Applied Sciences as well as input from the lecturers for the different subjects and projects the current competencies within the bachelor curriculum related to the propulsion of ships is investigated.

## **Defining main educational themes**

The mapping of the competencies leads to a long list of different skills related to the propulsion of the ship. In many cases the competencies could be directly derived from the learning outcomes of the different subjects, leading to well defined competencies. The competencies are then grouped together under overarching themes. By identifying the different themes, it is easier to define where changes to the curriculum are required and what elements can remain the same.

The themes are identified conceptually, as is a common approach in this type of research (Male et al., 2011). For this research six themes have been defined; technical theory, design; knowledge of systems and components; operations and economics; safety and fit for 2050. Within these themes, the competencies are identified. Below, each of the six themes are explained further, explaining which current competencies would fall under the relevant theme. The full list of the competencies belonging to the six themes can be found in Table 1. These competencies are used in the end of this article to identify what changes need to be made to the curriculum and what can remain the same.

### **Technical theory**

Technical theory is a very broad theme than encompasses the general knowledge students should have to understand the working principles of the propulsion systems. This includes a general understanding of basic thermodynamic principles but also electrical engineering. The competencies in this theme form the basis on which students build with the other themes.

### **Design**

The theme design covers the competencies related to the design of the engine room. This means that students are able to select the required machinery based on a set of requirements, place it in the allocated space and identify how their choices might influence the rest of the design. As this study only looks at the design of the engine room. Design strategies, although a key part of education of a naval architect, are left out of the scope of this research.

### **Knowledge of systems and components**

This theme covers the understanding of different components that make up the propulsion system. In a traditional system, this would include the diesel engine, (shaft) generators, gearbox etc. Additionally, it includes, but might not be limited to, auxiliary systems and fuel systems. In addition to understanding the different propulsion types, this theme also covers the ability to connect ship types with common or favourable propulsion types.

### **Operations and economics**

It is not enough for a naval architect to be able to design an engine room, they should also understand the effects the chosen propulsion has on the operational profile or building cost of the ship. This theme covers the effect that the choice of propulsion type will have on the operation of the ship, as well as the influence on building cost and operational cost.

### **Safety**

Safety is always a key aspect in any operation, but is also a very broad term. For this article, safety is everything that has to do with safe operation of the ship, with regards to the propulsion system. A main competency in this area is the understanding of the dangers of different propulsion and fuel types. This also includes a basic understanding of the rules governing the design of the engine room and knowing how to apply them.

### Fit for 2050

The final theme already looks towards the future. The current curriculum already has an aspect that looks into elements of modern propulsion. Covered in this theme are calculations regarding the emissions of a ship, knowledge of the EEDI, EEOI and EEXI and benefits of electrification on board of ship. However, the competencies within this theme are still fractured and not very well defined.

**Table 1 Summary of the themes and corresponding competencies**

Theme	Included competencies
Technical theory	<ul style="list-style-type: none"> <li>- The student can apply the basis laws of thermodynamics (e.g., first and second law, ideal gas law etc.)</li> <li>- The student can apply basic electric principles (e.g., Kirchhoff, AC, DC, Lorentz force etc.)</li> </ul>
Design	<ul style="list-style-type: none"> <li>- The student can translate functional requirements to system solutions which are subsequently integrated into a ship design that meets the requirements of the client.</li> <li>- The student can select required machinery based on system requirements.</li> <li>- The student can perform a matching procedure to determine the required propeller and main driver characteristics.</li> <li>- The student is capable of placing the selected propulsion system and auxiliary systems into the general plan of the ship.</li> <li>- The student understands the logic behind the general plan of different types of cargo ships.</li> <li>- The student can compare different types of conventional propulsion systems with regards to performance, efficiency, manoeuvrability, comfort, design and cost.</li> </ul>
Knowledge of systems and components	<ul style="list-style-type: none"> <li>- The student can explain the components and processes that are part of the following propulsion systems: <ul style="list-style-type: none"> <li>o A conventional internal combustion engine</li> <li>o A gas turbine</li> <li>o A blue fuel system</li> </ul> </li> <li>- The student knows the capabilities of the following propulsion systems <ul style="list-style-type: none"> <li>o A conventional internal combustion engine</li> <li>o A gas turbine</li> <li>o A blue fuel system</li> </ul> </li> <li>- The student knows the auxiliary systems of a conventional propulsion system.</li> </ul>
Operations and economics	<ul style="list-style-type: none"> <li>- The student is aware of the different operational profile of conventional propulsion systems</li> <li>- The student can determine the operational cost of conventional propulsion systems</li> </ul>
Safety	<ul style="list-style-type: none"> <li>- The student knows and is conscious of the technical, human and organisational dangers and risk of different propulsion systems</li> </ul>
Fit for 2050	<ul style="list-style-type: none"> <li>- The student knows the different types of ship emissions and the influence of the environment.</li> <li>- The student can determine the environmental impact of a specific design.</li> <li>- The student knows the advantages and disadvantages of different modern propulsion types.</li> </ul>

### Comparison with other study programs

While a detailed analysis of other study programs has not been done at this time, a cursory comparison is made to see if there are large differences. Within the Netherlands, two other universities offer a bachelor's degree in naval architecture; the Delft

University of Technology and the Rotterdam University of Applied Sciences. The study programs are not the same, Delft has a more theoretical focus, and in Rotterdam they specifically mention marine engineering as separate subjects instead of being integrated into projects as is the case at NHL Stenden (Delft University of Technology, 2023; Hogeschool Rotterdam, 2023). However, based on the short study guide descriptions and discussions with lecturers from the other schools it can be concluded that many of these competencies overlap.

### Adaptive expertise

Adaptive expertise is a term first introduced by Hatano and Inagaki (Hatano & Inagaki, 1984). They stipulate that in learning one can have two types of expertise; routine expertise and adaptive expertise. Routine expertise means a person is highly skilled at a specific task, but lack the flexibility to use the skills and knowledge related to this tasks to new problems. Adaptive expertise on the other hand means that creativity and flexibility are used to solve a problem. This also means that the “standard” procedures for solving a problem are not always followed. To allow for students to thrive not only in the current state of technology but also in the future, they should gain adaptive expertise. However, educational institutes struggle with how to help students develop the creativity and flexibility to become an adaptive expert when needed, without forgoing the need for standardised routine expertise (McKenna et al., 2006). An efficient study program prepares students to have both areas of expertise (Pierrakos et al., 2016).

### COMPETENCIES IN PRACTICE: DESIGN OF A FUEL CELL POWERED CTV

In the second semester of their third year, the marine technology students at NHL Stenden are tasked with the full design of a vessel for a specific client. They will run through the entire design process, from identifying the clients wishes to the drawing of the general plan. Last year (2022/2023) the students were tasked with designing a crew tender vessel that was powered by fuel cells. They did not receive any specific training or lectures on the detailed workings of the fuel cells, they had to find the relevant information for themselves. This project therefore provides a good insight into what further information the students would require to fully understand how to design a ship with this type of propulsion.

The final report of the project shows that the students are capable of performing the calculations that determine the required power that needs to be installed on the ship. This is, of course, no different when designing a ship with conventional propulsion. They also calculate the amount of energy they can get out of a m<sup>3</sup> of hydrogen, giving them a reasonable assumption in the amount of hydrogen they would need to take. This, once again, is no different from designing for HFO or MDO. In the next step the students select a fuel cell, as they have been taught.

Figure 1 - general plan of the CTV designed by the third year students

The steps the students take up to here show that they have the competencies that one would expect them to have given the list presented in Table 1. However, after this, we see what happens when students try to apply routine expertise as adaptive expertise. It becomes clear that the students have not understood the different equipment that is required for a fuel cell system to operate. The choice they made in the design and the general arrangement show that they do not know enough about the set-up of a system that uses fuel cells. Additionally, the report shows that they have a limited understanding how a fuel cell system generates energy and how this energy is used to power the ship. One example of this is the battery pack. Although the report mentions the fact that a battery pack of 45 batteries is required and it is also drawn into the general arrangement of the ship (see

Figure 1), it is never explained how much power can be stored in these batteries. The confusion seems to stem from how a system with a fuel cell works. Basically, they have designed a system that gets its power from the fuel cell, and provides this to an electrical engine and the propellor directly, as can be seen in Figure 2. This shows that they have a very good understanding of how a propulsion system with a diesel engine works, but that they failed to make the translation towards a fuel cell system. Figure 3 gives a very basic representation of the main components of a fuel cell system.

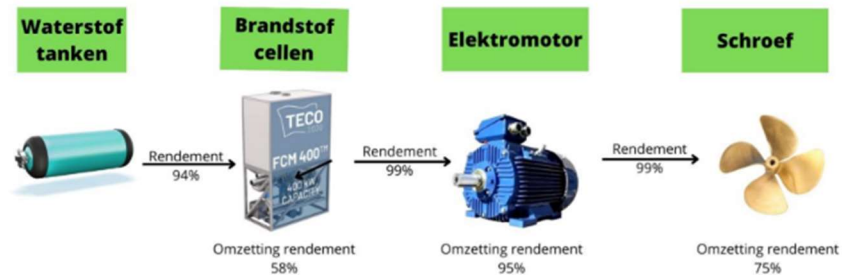

Figure 2 - Basic setup of a fuel cell system according to the students, showing that they designed it as they would a diesel direct system and misunderstood the fundamental differences between these systems.

Figure 3 Very basic overview of the main components of a propulsion system with fuel cells

The analysis of this project shows that the competency regarding the matching procedure; *the student can perform a matching procedure to determine the required propellor and main driver characteristics*; can be classified as adaptive expertise. Regardless of the requirements of the propulsion system, the students can perform the required calculations. The students also show that they can change from conventional fuel types to different types of fuel to calculate the consumption and thus the size of the tanks. The students also made a reasonable estimation of the production cost of the system, based on basic figures they had found. However, for a functioning design, the theme of Knowledge of systems and components should be expended with knowledge of the fuel cell and its corresponding systems. Likely, the same argument can be made for a system that runs on batteries.

It would be beneficial for the students to not only learn about the different systems that a modern propulsion system consists of, but also work with them in a project. By applying the knowledge they have gained in practice it cements. Additionally, they might run into situations not covered by the theory, leading them to use what they have learned creatively, making the step towards adaptive knowledge.

## REQUIREMENTS ACCORDING TO LITERATURE

In literature, the terms green propulsion, automation and digitalisation are often used together when it comes to the future of the shipping industry (Skillsea, 2022). As we are still at the beginning of the transition to other types of propulsion, much of the literature focusses on the possibilities and capabilities of different types of batteries and fuel cells and the systems that manage them. To the authors knowledge, no research has been published on what naval architecture students should know.

There are however, articles that look into very specific calculations or estimations that can be done to determine specific details about, for example, determining the power demand or determining the degradation of batteries in a system. In these articles machine learning and AI is used to perform the calculations or the analysis. A bachelor student of naval architecture is not required to understand the machine learning and AI that is used, but might, at some point be working with the resulting programs, tools, or calculation methods. This means that some understanding of the working principles of machine learning and AI might be required or beneficial.

## Existing training and documentation in modern propulsion systems

Although there is seemingly no standard or advice in what naval architects should know about modern propulsion, there is a wide variety of introductory courses, books and other documentation available that cover different types of modern propulsion. In general, everything seems to follow the same set-up. It starts with an introduction on the main engineering principles of the technology that is discussed. From there the operating characteristics are introduced and finally the link is made to the system operating in a maritime context (Baldi et al., 2022; MAN Energy Solutions, 2019; Maritime Hydrogen Safety (MarHySafe) Joint Development Project, 2021; Netherlands Maritime Technology, 2024; Stoiber & Valøen, 2016)

This makes sense. Before being able to grasp the benefits and abilities of a propulsion type, one should have a basic understanding of how this works. The main difference in this case will be the electro-chemical propulsion, as it is substantially different from the current propulsion systems. Both the chemistry required to grasp the working principles of these types of propulsion systems and the electrical engineering required to understand how the power is distributed throughout the ship are not currently part of the standard curriculum.

## Adjusting requirements for seafarers

The training and education of the seafarers that work on the ships is much more regulated than that of the designers. The IMO is looking to make large changes to the International Convention of Standards of Training, Certification and Watchkeeping for Seafarers (STCW). In a large review of the current STCW code it was decided that a committee should look into how the changes in propulsion should be anticipated (IMO Subcommittee on Human Element Training and Watchkeeping, 2024).

A large European project, Skillsea, looked into the skills that seafarers should have now and should have in the future (Oksavik et al., 2020; Zec et al., 2020). They mainly identify a skill gap in digital skills, such as understanding the complex digital architecture of modern systems, and green skills, which focusses on energy efficient and environmentally friendly ship operations.

In the results of this project, it is suggested that additional specialisation can be offered, without (currently) making changes to the STCW. They suggest, among others, the following technical skills (Oksavik et al., 2020):

- Knowledge of logistic and optimisation methods in terms of the operation of ship and machinery
- Operation of complex hybrid and zero-emission machineries
- Measurement, calculation and documentation of emissions
- In-depth knowledge of the complex systems on board
- Advanced skills in analytics and use of data in optimisation of the fleet

There is an overlap between the observation made regarding the student project and the skills that are suggested here. The Skillsea project finds that the knowledge and understanding of the modern systems on board is lacking for seafarers, as we also found during the student project. The measurement and calculation of emissions is already covered in the curriculum and mentioned under the theme Fit for 2050 in Table 1.

The optimisation methods have not come up yet. For the seafarers, this mostly focusses on the operation, for example by sailing at ideal speeds, or having the propulsion system function at peak efficiency. At the moment, there is not a lot of focus on the operational profile of the ship, as a diesel engine does not offer a lot of flexibility in operational modes. However, an electrical system has much more adaptability and flexibility, making use case calculations more important (Klein Woud & Stapersma, 2008).

## THE WISH OF THE INDUSTRY

Finally, we look at the wishes of the industry. As ships powered by modern propulsion systems are already operating and with more in the order books, companies that work with these systems are looking for personnel that has knowledge of these systems. To determine what companies require, informal interviews have been held. During these interviews the competencies of the students were discussed, to see if the list of competencies is complete, and more importantly, if they feel that knowledge should be added.

One of the main findings is that companies that design and install modern electro-chemical propulsion systems in house find it difficult to find recent graduates that have the required knowledge and interest to work at their company. In general, these companies state that the lack of knowledge with regards to electrical engineering is lacking. They do not generally expect student to be completely familiar with different types of modern propulsion systems but having a stronger basis in theory would help them be better prepared to work with these systems. Many of the companies provide in house training, either on the job or as a course for their new employees to make them more familiar with modern propulsion systems. Interestingly one company stated that they were also hiring engineers from ships who have a specialisation as an Electro Technical Officer, because they

are currently the best qualified to understand how the systems work. Companies have also branched out, hiring mechanical or electrical engineers who have no direct knowledge of ships, training them in that area, as they cannot find employees who have both knowledge of electrical engineering and ships.

## HOW TO BEST PREPARE OUR STUDENTS

With the analysis completed, it is time to look at the competencies defined at the start of this article. This is the current starting point for bachelor students, but from the analysis, several changes can be proposed. The summary of the findings can be found in Table 2.

Table 2 Summary of the findings per defined theme and suggested changes to the competencies within the theme

Theme	Type of expertise	Summary and suggested changes
Technical theory	Adaptive expertise	<p>Talking with industry shows that the interest and knowledge with regards to electrical engineering is lacking. While it is listed as a competency, the students' knowledge in this department is generally not sufficient to work with more electrified systems.</p> <p>Suggested change: A broader focus on the theory of electrical engineering and chemistry to help students better understand how electrochemical propulsion works.</p>
Design	Adaptive expertise	<p>The analysis of the design of the CTV shows that most of the competencies in this theme are adaptive knowledge that translates very well to other types of propulsion.</p> <p>Suggested change: Adapt the final competency: <i>The student can compare different types of conventional propulsion systems with regards to performance, efficiency, manoeuvrability, comfort, design and cost</i> to also include modern propulsion systems.</p>
Knowledge of systems and components	Routine expertise	<p>From the analysis it has become clear that this theme requires some changes. While other types of fuel do not seem to be a problem for the students, as the design process remains the same, the systems that are not based around an internal combustion engine are more difficult. Therefore, these should be added to the list for both of the competencies listed under this theme. At this point, this seems to be fuel cells and batteries, however, this could be completely different in the future.</p> <p>Suggested change: knowledge of a system working with fuel cells and or batteries should be added to both competencies.</p>
Operations and economics	Adaptive knowledge	<p>The operational profile of a system with a modern propulsion system can be very different from that of a system with a conventional propulsion system. However, with the additional knowledge provided in the previous two theme, the skills and methods taught in this theme should translate well enough for students to work with modern systems as well.</p> <p>Suggested change: The competencies should be adapted to include modern propulsion systems, however, this does not necessarily change the content of this theme.</p>
Safety	Adaptive and routine knowledge	<p>Safety has not been a significant area within this article. Every different power generation configuration has different safety risks. However, the process of identifying and handling these risks remains the same. Some additional attention could be paid to specific risks of other types of propulsion and fuel, but a change to the competency is not required.</p> <p>Suggested change: When focussing on the working principles of modern propulsion systems, additional attention should be paid to additional risks that are present when a ship is equipped with different fuel and/or propulsion systems.</p>

Fit for 2050	Adaptive knowledge	There are not many changes required to this theme. The effects of the emissions and the influence of shipping on the environment will remain a factor. The fact that we are teaching students about low and no carbon fuels doesn't mean that learning about emissions is suddenly obsolete.
--------------	--------------------	--

## CONCLUSIONS

Table 2 shows that the competencies in most of the themes can be classified as adaptive knowledge. The competencies that require the most attention are the once under the theme knowledge of systems and components. This knowledge very much counts as routine knowledge, meaning that each type of new propulsion needs to be addressed separately. In addition to the specific knowledge regarding the working principles of the new propulsion types and the required auxiliary systems, the connection between the themes *operations and economics* and *safety* might need additional attention. However, the competencies here does not necessarily change, it is mainly using the competencies from the theme *knowledge of systems and components* in a different way.

# “Are You Sure About That?": Handling Uncertainty in an Early-Stage Ship Design Process

Rachel Pawling<sup>1,\*</sup>

## ABSTRACT

*UCL teaches ship design at postgraduate and undergraduate level, using a combination of spreadsheets and commercial computer aided ship design tools. These tools produce single values for a given input and so uncertainty is only incorporated via margins. Experience has shown that students do not develop an effective understanding of engineering uncertainty using the current tools and approaches. This paper describes ongoing work to develop an “add on” to the existing UCL toolset to allow the representation of various ship parameters as uncertainty distributions. This is with the aim of better understanding of uncertainty in ship design, primarily for ship design education but with broader applications for concept design tasks.*

## KEY WORDS

Design methodology; design education; uncertainty; margins

## INTRODUCTION

UCL has taught ship design since 1967 when the RCNC course moved to the Department of Mechanical Engineering from the Royal School of Naval Architecture in Greenwich. The Naval Architecture and Marine Engineering (NAME) group, part of the Department of Mechanical Engineering (UCL, 2024a) teaches ship design at two levels; MScs in Naval Architecture or Marine Engineering; and a Maritime Design module as part the “Integrated Engineering Programme” (UCL, 2024b). The author has run the undergraduate module since its inception in 2018 and, after providing support for several years, took over the running of the postgraduate module in 2019. With a background in early-stage design methodology research, frequently presented to IMDC (Andrews & Pawling 2003, 2006, 2009, Pawling et al 2015) the author has sought ways to combine research and teaching interests. This paper briefly describes the UCL postgraduate course, focusing on observations regarding the way in which uncertainty manifests in the teaching of twentieth century students. The concepts of uncertainty, margins and design robustness are explored, and a possible approach illustrated via a modification to existing UCL design tools.

## SHIP DESIGN TEACHING AT UCL

This paper mainly focusses on the postgraduate course, as it is a longer module (450 hours commitment) with time to explore design in detail. The course and some of the details of the various design tasks are described in more detail in Pawling et al (2018). The Ship Design Exercise (SDX) module follows six months of taught modules covering aspects such as ship stability, structures, resistance and powering (for naval architects); thermodynamics, power electronics and control (for marine engineers). Students on the course are generally industry sponsored but may be early in their employer’s graduate schemes so have little practical experience. The module sees the cohort split into small groups of 2-4 naval architects and marine engineers. Design requirements for each group are generally warships and service vessels and they are characterized by being challenging and relatively open. Table 1 provides some examples of recent design requirements. The SDX requires the students to integrate the subject specific technical knowledge gained during the MSc into a coherent design. Emphasis is placed on decision making and justification, and the understanding of influences and interactions in the design.

**Table 1: Examples of UCL MSc SDX design requirements**

Year	Title	Summary
2020	Optionally Crewed Territorial Defence Vessel	A small, high speed vessel for patrol and defence of home waters against a numerically superior adversary.
2021	Family of Zero Emissions Island Ferries	An adaptable design for a Ro-Pax ferry serving island routes around the British Isles
2022	Seaplane Logistics Mothership	A ship to act as a hub for logistics seaplanes including large ground-effect machines.
2023	Adaptable Export Patrol Combatant	A trimaran vessel designed for export and to be completed in several roles via design and construction modularity.

## A Typical UCL Design Model

Both undergraduate and graduate design exercises involve the construction of a parametric model composed of a number of line items for weight and space, with the general iterative structure shown in Figure 1.

**Figure 1: The general structure of a UCL student sizing model**

This model is then used to examine different capability variants (cargo, speed, weapons etc.), and also the impact of different technology options, e.g. directed energy weapons or all-electric machinery. The students are provided with a template Excel file with the UCL Weight Breakdown System and various housekeeping functions such as the generation of summary tables already implemented. This spreadsheet becomes not only a design tool but also a method of managing work allocation between design team-members, integration with simplified analysis tools such as initial resistance estimates, prior to later development of Paramarine or Maxsurf design models. Screenshots of the spreadsheet are shown in Figure 2 overleaf.

## MARGINS, UNCERTAINTY AND ROBUSTNESS IN SHIP DESIGN

Within the UCL SDX, general uncertainty in design is handled in a relatively simplistic manner. Margins are added to weight, space and other characteristics. Stability is generally assessed in the extremes of deep and light load, and many systems such as propulsion or electrical generation will be designed to meet the worst-case scenario. Students are expected to consider more general operational scenarios, but there is not a formalised process to specify what these should be, other than some very specific cases (e.g. harbour load is a specified condition for electrical generation).

## Fixed Design Margins

The use of various types of margins is an important part in any engineering design activity, however these margins have different conceptual meanings. Design and build margins are used to account both for possible changes that \*may\* occur with the design but also for weight growth that \*will\* occur during detail design but is not captured in the early-stage design estimates. In the theoretical case of perfect and complete detailed data collection and perfect and completely detailed design models, this latter type of design and build margin would not be needed, or at least could be limited to that required due to mechanical variation (e.g. plate rolling). Growth margins are also applied to prevent design limits being exceeded through life.

UCL ship design education employs several types of design and operational margins, and these are summarised in Table 2. These are ultimately derived from UK naval practice and experience in the post war period. For example, the “Board Margin” refers to the RN Admiralty Board who would authorise additional equipment to be added during the ship’s life (Brown, 1991), whilst the electrical load margin originates in the rapid growth of shipboard electronics in the post-war period (Gates & Rusling, 1982). Growth margins for UK warships were derived from historical experience of 0.5% per year between major refits (Brown, 1991). It can be seen that these are all linear, additive margins that simply make the initial design larger, heavier and more expensive, firstly to account for changes in detail design and build and then to account for changes through life.

**Table 2: Typical UCL MSc SDX margins**

Group	Name	Weight %	Space %
<b>Design and Build Margin</b>			
1	Hull	5-10	0
2	Personnel	0-5	5-10
3	Ships services	5-15	2-10
4	Propulsion	4-10	0-2
5	Electrical services	5-10	0-10
6	Payload	5-25	5-25
7	Variables	4-7	4-7
Board margin, for additions through life		2-10% light weight @ no 1 deck	5% volume
Growth margin, for unattributed growth through life		5% light weight	
Sea margin, to prevent overloading engine		25% on shaft power	
Fuel margin		5% on fuel tankage	
Electrical load margin, for design and build		25% on design load	
Electrical growth margin, for additions through life		20% on design load + design margin	

Simply adding linear margins to design characteristics is not the only solution, and can cause problems with compounding margins (Hockberger, 1976). A ship with excessive stability margins may in fact be too stable early in life or in some light load conditions. A generator with the total margins applied in the traditional UCL approach will be lightly loaded much of the time, with consequences for efficiency and reliability. This was illustrated in Lyster and Pawling (2019) where a Monte-Carlo analysis applied to a statistical model of ship through-life operations showed that the conventional approach of designing for the worst-case, or a set of specific loadings, was poorly matched to the wide range of possible displacements and load cases that would occur once the total range of variability was incorporated into the model. This is illustrated in Figures 3 and 4 which show the probability distributions of displacement and fuel consumption for a light frigate / OPV type vessel.

**Figure 3: Probability distribution of displacement over ship life (Lyster & Pawling, 2019)**

**Figure 4: Probability distribution of fuel consumption for different machinery types applied to a statistical through-life model (Lyster & Pawling, 2019)**

Design and build margins can however be consumed by uncertainty due to new technologies not developing as first estimated. As exceeding design margins can have undesirable consequences, the appropriate margin to be applied can be related to not just the novelty and confidence in a design estimate, but also the acceptable risk (ISAW, 2001). Both design and through life margins can be regarded as similar in some respects to the safety margins applied when calculating loads, as they ensure a system remains within a safe (or low risk) region. However, risk here is a broad case including financial and programmatic risk rather than only structural failure or stability problems. As risk is probability multiplied by consequence, this suggests margins should be selected using an approach that examines a range of consequences for different margin choices, as different outcomes may be permitted; as noted by Brown (1991) RN practice was that the vessel had to meet its performance requirements with all design and build margins consumed, but growth margins were permitted to degrade performance but not safety. The importance of considering a range of possible outcomes increases if margin policy is derived from historical designs, technologies and operational practices which may not be appropriate for modern systems. An example is a fuel-cell based generator system. Given the higher UPC for fuel cells compared to diesel engines, oversizing the generator is undesirable. But if a large fuel cell generator is composed of multiple smaller modules, it becomes possible to remove the growth margin by allowing for easy addition of more modules later in life.

## Uncertainty

Uncertainty and variation in design can take many forms and have many implications, and it is not truly captured by simple linear margins added to properties such as weight and space. Hockberger (1976) used a probabilistic approach to describe design margins in general, with the demand and supply both being probability distributions as illustrated in Figure 5.

**Figure 5: Representation of design demand and capability as probability distributions with associated range of uncertainty (Hockberger, 1976)**

Uncertainty can be inherent in the mathematical models used in ship design, as the final product produced via detailed design may vary from estimates due the vast range of possible detail solutions that can be produced to meet the same high-level requirements. Some items such as recreation spaces may also be regarded as “rubber” in that they can expand to fill available space or be compressed if the design is cramped. Table 3 illustrates this with a sample of cabin areas for five ships (all service

vessels), for the same rate of cabin on that ship, normalised to the smallest example for that ship, with variations as high as 90% on the smallest size. The distribution of the ratios-to-smallest is summarised as a histogram in Figure 6.

**Table 3: Example of variation in cabin sizes for the same rate**

Ship	Cabin Sizes, Normalised to Smallest				
A	1	1.5	1.9		
B	1	1.2	1.1		
C	1	1.2	1.1	1.3	
D	1	1.2	1.1	1.2	
E	1	1.2	1.2	1.2	1.1

**Figure 6: Histogram of ratios-to-smallest cabin**

Much of the design data in the UCL database is derived from multiple datapoints with subsequent curve fitting and this type of model leads to an uncertainty of plus or minus some percent, as illustrated in Figure 7 for a generic linear diesel generator. Based on specific machinery data, the Excel trendline (using the default least-squares method built into Excel) is only around +/-20% accurate to any specific item. Figure 7 also shows the error between the linear estimator and individual data points as a histogram, with a maximum error of +/-32%.

**Figure 7: Example of a UCL single line sizing algorithm and error distribution**

Uncertainty can also manifest as a type of prediction, i.e. a new technology might be expected to become cheaper or lighter as it is refined, thus having a wider “-%” than “+%”. Porche et al (2004) described the use of BetaPERT distributions, more typically used to describe uncertainty in task durations for project management, to evaluate the effect of uncertainty in propulsion machinery technology. Figure 8 below shows such a distribution applied to the case where a trendline has been fitted to a set of data points.

**Figure 8: An example of a trendline fitted to data being the “most likely” value in a Beta distribution (Porche et al, 2004)**

The Beta distribution was adopted by Porche et al as it can be used to represent a three-point estimate, itself being a simple way of describing the error or uncertainty in a numerical evaluation. In particular a Beta distribution, for the same three inputs (minimum, maximum, most likely value), weights the most-likely value more heavily. This approach can be particularly useful in comparing various options, such as electric motor technologies as shown in Figure 9, where both general trends and the potential for different technologies to have very similar outcomes can be shown.

**Figure 9: Representation of different motor technologies having different power density and different uncertainty ranges (Porche et al, 2004)**

Whilst most mathematical and procedural methods for incorporating uncertainty have focused on the detail design and component level, e.g. structural design (Claus & Collette, 2018) or planing craft resistance (Brefort & Singer, 2018), other approaches have looked at higher level aspects, such as market and regulatory uncertainty has also been considered (Zwaginga et al 2021), (Puisa, 2015) extending to through life operation (Plessas et al, 2018). Olivier et al (2012) used a structured approach to capture subject matter expert input and develop a probabilistic model of ship cost at the weight group and total ship level. They illustrate the major difference between uncertainty inherent to the ship design (“epistemic factors”) and uncertainty due to external factors (“aleatory factors”), with quite broad ranges as illustrated in Figure 10, where were then used to define the sample ranges in a Monte-Carlo analysis using a ship costing model. The importance of working with SMEs and stakeholders was also described by Brett et al (2022), in their comprehensive survey of the subjects of uncertainty and complexity in ship design.

**Figure 10: Broad ranges of uncertainty resulting from design and environmental factors (Olivier et al, 2012)**

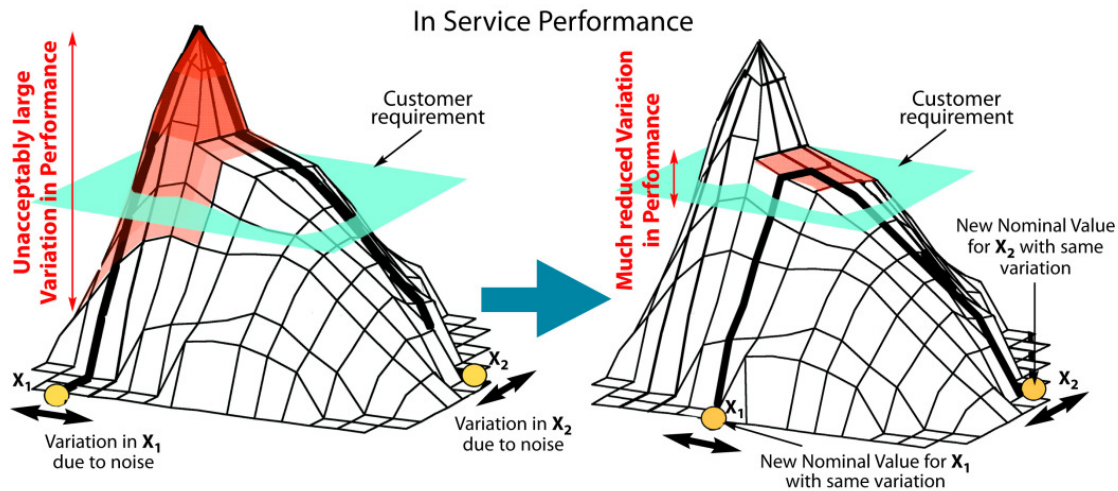

Whilst this paper focusses on the UCL postgraduate course, which mainly covers warship design, uncertainty and robustness were introduced to the undergraduate course, specifically concerning the assumed values of container or vehicle weight. Provided with data such as that illustrated in Figure 11, taken from Kristensen (2013), the students were expected to justify their assumptions for tonnes per unit cargo and discuss the likelihood and consequences of variations in service. Similarly, the students are provided with representative data on vessel utilisation and operational speed profiles and expected to consider scenarios where these differed from the theoretical optimum.

**Figure 11: Example of variation in probability of occurrence with laden container mass in tonnes (n = 1013, digitised from Kristensen (2013), 0-5300 TEU range)**

## Robustness

Design margins and uncertainty also relate to the concept of robustness in design. The concept of robust design originated with Taguchi's robust design method, developed in Japanese manufacturing, which sought to create "a design that has minimum sensitivity to variations in uncontrollable factors" (Simpson, 2000). A graphical representation of design robustness is provided by Karl et al, (2011) and shown as Figure 12. This shows a notional design space with a surface representing possible solutions. On the left, a solution is shown that has been selected for peak performance. Whilst it easily meets the customer requirement, the steep shape to the local solution space means that any change in design or operational characteristics leads to its performance rapidly falling to below the requirement. To the right of the figure is an example of a more robust solution, which may not have such high performance, but will remain above the customer requirement for a range of design or operational characteristics.

**Figure 12: Example of highly optimised (left) and robust design (right) (Karl et al, 2011)**

Summarising literature on robust design methods that would of interest in ship design, Puisa et al (2014) outlined four ways of dealing with uncertainty:

- Resistance: plan for the worst possible case of future situation – this is similar to the conventional approach used in the current UCL MSc SDX.
- Resilience: whatever happens in the future, make sure that the system can recover quickly – this is a key part of warship survivability, being the crew-centric concept of recoverability.
- Static robustness: aim at reducing vulnerability in the widest possible range of conditions.
- Dynamic robustness (or flexibility): plan to change over time in case conditions change.

Various mathematical approaches have been applied to the problem of robust design, including real options valuation (Puisa, 2015), the use of response surfaces providing meta-models of more complex engineering models (Karl et al, 2011), Epoch-era analysis (Gaspar et al, 2015) whilst the US Department of Defense’s Engineered Resilient Systems (ERS) effort sought to improve the resilience and robustness of US defence procurement through the application of high-performance computing tools (Neches, 2012).

## Adaptability and Changing Design Styles

The design of both warships and commercial vessels has changed in recent years, with cargo vessels, previously having been seen as the perfect example of a ship “optimised” for a single operational point, now having a much broader range of operational speeds (Banks et al, 2013) and in general a greater understanding of operational variation in the design, leading to changes in hull design for example or considerations of designing for adaptability through later refits (Puisa, 2015). The long operational life and rapidly changing strategic and technological environments mean adaptability has long been of concern for warship designers (Andrews, 2001) and recently warships have seen ever greater use of modularisation e.g. Doerry (2014), an approach introducing substantial uncertainty as to system weight and service demands, even if volume is constrained (Abbott, 1977).

Whilst some items in the UCL ship design database are derived from a technologically similar set of datapoints, such as a range of high speed marine diesel engines from one or two manufacturers, the majority of the scaling algorithms were generated using weight and space data from RN warships of the 1970s and early 1980s and so inherit the design style of those vessels. Pawling et al (2013) proposed a definition of “Style” in the engineering context of warship design as “a cross-cutting concept, where one decision explicitly influences a wide range of solution areas”, with one example being how the approach to survivability will impact the number of bulkheads and detail design to resist shock. Some stylistic aspects of warship design have changed since this database was defined, such as the adoption of “Naval Ship Rules” and semi-commercial approaches, that do not explicitly call for heavier structure, but frequently lead to it. That warships are subject to change in their general style and proportions is well documented, e.g. Gates & Rusling (1982), implying a need to capture possible (but not certain) changes in general design style from current concept design algorithms.

## THE PERCEIVED NEED FOR A NEW APPROACH IN THE SDX

Whilst the UCL design process features several stages of option exploration and selection, ultimately it results in a single point design assessed over a limited set of operational conditions. Although students are expected to consider aspects such as uncertainty and robustness in their designs, and justify their choice of margins, it is generally difficult to ensure they do so purely through lecture material and discussion – if default margins are provided, students will usually adopt them. There is thus a need for a method and toolset for students to examine possibilities and determine margins as a structured part of the exercise. Another reason for introducing improved handling of uncertainty within an educational concept is an observed trend for many engineering students to view engineering as simply "applied mathematics", with any value calculable with high precision. It can be a challenge to assist students in internalising the changes in engineering systems with increasing detail, and the difference between a sizing algorithm applicable to a wide range and data representing single points, i.e. the importance of being "approximately right" rather than "precisely wrong".

Against this educational and engineering background, as the co-ordinator for the two UCL ship design modules, the author has been examining how concepts such as uncertainty, robustness and margin selection can be better examined in the course, through the use of software tools. The author has previously presented some aspects of software tools for ship design education (Pawling et al, 2015), with specific attention to teaching general arrangements design. Nine properties were identified as being important for tools to be usable by students. Based on these, the approach has been to take the existing Excel spreadsheet templates and add additional functionality;

1. Wide availability:
2. Low learning and familiarisation overheads:
3. Fast operation:
4. Not type ship based:
5. Task focused:
6. Not automated:
7. Integration of models, datasets and evaluation:
8. Flexible levels of detail:
9. Appropriate levels of precision:

## THE MODIFIED MODEL

The existing UCL MSc ship sizing template Excel sheet was modified with additional characteristics for each line item and VBA macros to carry out various studies. The most visible change is that the weight, space, cost etc. defined for each item becomes the “most likely” value in a beta distribution, with a percentage +/- defined for each item. This is illustrated in figure 13 below.

**Figure 13: Top: modified table with +/- percentages for weight and volume. Middle: Resulting Beta Probability Density Function (PDF). Bottom: Cumulative Density Function (CDF).**

Sampling was carried out using the Cumulative probability Density Function (CDF). For a required number of samples, the CDF was sampled at a random point within each sample window. Figure 14 below illustrates a sample taken at 0.275 within the sample window 0.2-0.4 (i.e. the window resulting from a sample number of 5).

**Figure 14: Example of a sample taken from a CDF**

At the time of writing, the following studies have been implemented using VBA macros:

***MOST LIKELY Run:*** This macro sets the values to their most likely value and balances the design.

***MAX Run:*** This macro sets all values to their maximum value and balances the design.

***MIN Run:*** This macro sets all values to their minimum value and balances the design.

***X% Run:*** This macro sets all values to their Xth percentile value and balances the design. Currently this is set to the 50<sup>th</sup> percentile. The aim of this function is to allow students to quickly identify a “most likely” outcome.

***Weight Group X Sensitivity Study:*** This macro conducts a simple sensitivity study for a selected weight group “X”, varying each item from its minimum to maximum value and recording the impact on the design. The aim of this function is to assist students in determining which items have the most impact on the overall design.

***Special Item Study:*** This macro conducts a sensitivity study on specified variables. This is intended for variables such as hullform coefficients, specific fuel consumption etc. It requires more input from the user as they must specify the sheet and cell in which the variable is located.

***System Sensitivity Study A: Deterministic:*** This macro conducts a complex sensitivity study on multiple items, using the mid-point of each range within the CDF.

**System Sensitivity Study B: Random:** This macro conducts a complex sensitivity study on multiple items, using a random point within each range of the CDF. System sensitivity studies are defined in a tabular structure illustrated in Figure 15. Up to six line items can be defined. There is no restriction on the number of samples, other than user preference for run time.

Selected Items for System Sensitivity			
Item #	Item Name	Item Group	Samples
1	DG size 1	5	5
2	Electric Motors	4	5
3	GT GB	4	5
4	EM GBs	4	5
5	DG size 2	5	5
6			

**Figure 15: Definition of the system sensitivity study**

The tool currently uses a simple full factorial approach, examining every combination of every item. The tool generates 2 to 3 options per second, with typical run times for a study summarised in the table below. Keeping run times short is important to ensure student use, as unless they are directly assessed on the use of the tool, any activity that takes too much time will generally be deprioritised. The UCL design exercise emphasises interactivity and the explorative “sketching” model of concept design described by Pawling and Andrews (2011) where the design model is used to explore alternatives and aid in discussion. In this model of design, time spent developing and running models should be reduced as much as possible, as it can be an impediment to understanding.

**Table 4: Typical run times for the tool**

Items	Samples per Item	Run Time (minutes)
1	4	<1
	5	<1
2	4	<1
	5	<1
3	4	<1
	5	1
4	4	2
	5	5
5	4	7
	5	21
6	4	28
	5	105

## EXAMPLE DESIGN STUDY

To demonstrate the functions currently implemented, the sizing model was populated with data representing a generic frigate, with the broad characteristics outlined in Table 5.

**Table 5: Principal particulars of the example design**

Combat Systems	Baseline (most likely option)	
1 x 127mm and 2 x 30mm guns	Deep displacement	4338 tonnes
20 short range and 16 medium range SAM	Light displacement	3268 tonnes
Single face AESA radar	Internal volume	18088 m3
12 long range SSM	Waterline length	113.2m
10 tonne helicopter with hangar	Waterline beam	15.6m
3 x 1.5 tonne UAV	Depth amidships	12.5m

2m 7m and 2 x 11m boats  
Hull sonar  
Triple torpedo tubes  
Decoys  
16 x Embarked personnel  
Machinery

Draught amidships 4.8m  
UPC 398 M€  
Max speed 29.5 kn  
Cruise speed 15 kn  
Complement 139  
CODLOG – twin shaft, single boost GT with splitter gearbox

## Example Single Weight Group Sensitivity Study

In this study the tool sets all weights to their “most likely” value, then for each item in the selected weight group performs two runs – one with that item set to its maximum value, and one with it set to the minimum. Comparison charts are produced showing several metrics; the ratio of item change (in tonnes and m<sup>3</sup>) to overall ship change; the total range of variation (in tonnes and m<sup>3</sup> and as a percentage of the group totals); the percentage of the group total that that particular item makes up. These are presented in bar charts as shown in Figures 16-19 for weight group 2 (personnel).

Figure 16: Ratios of item to overall ship change for group 2

Figure 17: Composition of weight group 2 by percentage

Figure 18: Total range of variation for each item

Figure 19: Total range of variation for each item as a percentage of the group totals

## Example System Sensitivity Study

A trail was run on the main components of the propulsion system; gas turbines; diesel generators; electric motors and their power electronics. Figure 20 shows; a histogram of the deep displacements with the corresponding approximation of the CDF produced by compiling the runs. A generic beta PDF is also shown, generated by varying the specific components to their minimum and maximum values. Figure 21 shows the same plots for the overall ship volume. The current concept for use of the tool is that the CDF plots would be used to derive the design point to be used for analysis, based on a required level of certainty.

Figure 20: Displacement results

Figure 21: Volume results

Figures 20 and 21 show that the overall distribution is not necessarily well represented by a simple beta, or by a normal distribution (as would be expected as per the central Limit theorem). However, it should be remembered that this study only examined a small set of the many line items in the sizing model.

# SPECIFYING UNCERTAINTY RANGES

For this approach to be used in the design exercise, guidance will be required regarding the choice of uncertainty ranges. This should be linked to some characteristic to allow a reasoned selection. Some references may describe uncertainty using +/- values. These can range from specific components to entire weight groups.

## From Data

As noted previously, UCL sizing algorithms derived from multiple data points have an inherent uncertainty, and this can be provided in the existing design database. Histograms of the error between the actual values and fitted curve can be used to determine the most appropriate +/- values to generate the min and max inputs to the beta distribution. This is illustrated for the case of diesel generator weight in Figure 22.

Basis data, fitted curve and example limits

Histogram of errors between fitted curve and input data

Figure 22: Example uncertainty range for a fitted curve

To support the development of the new design tool, similar histograms have been developed based on reference papers containing historical values such as Kehoe et al (1983). A range of general arrangement drawings for commercial and naval ships have also been analysed to determine possible distributions for the area of certain spaces, some of which are shown in Figure 23. The figure also compares the area per rating for accommodation sizes in commercial and naval vessels in the database and whilst there is some overlap in the values, the distributions are quite different. This is due to the dominance of offshore support vessels and research vessels from the 1990s onwards in the commercial ship database, all being designed to broadly similar standards of crew comfort, whilst the warships database contains ships as old as the 1970s designed RN Type 22 frigate (with mess decks for accommodation) and as modern as the RNZN Otago class OPV (with cabins).

Operations rooms, area per operator

Galleys, area per crewmember

Ratings accommodation, area per rating, commercial

Ratings accommodation, area per rating, naval

Figure 23: Example histograms for spaces extracted from general arrangement drawings

# From Design Margins

The recommended weight and space margins summarised in Table 2 may also be used to generate a beta distribution, under some assumptions. If a weight margin is assumed to be the value that captures 90% of all possible outcomes (for example) then it is possible to define a Beta distribution that reflects this. Figure 24 shows how this might be represented for the assumption that the baseline value is the most likely value (left) or that the margin value is most likely (right). The margin value has a CDF of 90% in both cases. This approach has the advantage of aligning with the existing approach to design margins.

**Figure 24: PDFs derived from existing margins and assumption that margin = 90% cumulative probability**

# From Confidence Levels

Linking uncertainty values with standardised definitions of confidence, is attractive for a teaching environment as the definitions can be clearly stated and understood. The NASA Technology Readiness Levels (Manning, 2023) are already used within both the SDX and its sister Submarine Design and Acquisition Course at UCL, but do not have any formal margins or uncertainty values associated with them. Past NASA programmes have shown that novel concepts can experience huge weight growth as the design develops (NASA, 1971) however, a ship would usually not be entirely composed of new technologies so TRL-linked weight margins or uncertainty levels should be selected for the specifics of shipbuilding rather than aerospace. Pedatzur (2016) proposed specific ship weight margins associated with the Bonen scale – a similar concept to TRL – and stage of the design. These are shown in Table 6 below and could be used to generate a PDF as per other weight margins. The Bonen scale having four levels listed below.

- Level 1—Duplicating an Existing System
- Level 2—Upgrading an Existing System
- Level 3—Development of a New System
- Level 4—Technological Breakthrough

**Table 6: weight margins based on design stage and Bonen scale (after Pedatzur (2016))**

Complexity and risk level according to the “Bonen Scale”	Stage of the project			
	Feasibility study	Contract design	Detailed design	Construction
Level 1	5%	4%	2%	1%
Level 2	10%	8%	5%	2%
Level 3	15%	12%	8%	4%
Level 4	25%	15%	10%	5%

# DISCUSSION AND CONCLUSIONS

Within the UCL SDX, general uncertainty in design is handled in a relatively simplistic manner via margins added to various characteristics, and a limited set of operating conditions to be analysed. It has proven difficult to ensure students consider the concept of uncertainty in their design, either at the whole ship or system level, and this has, ironically, been made more difficult

by the greater numerical precision easily available with modern tools. This paper has described a work-in-progress on developing new tools and approaches to address this issue. Whilst a need for a different approach to educating future engineers about uncertainty in design has been identified, the tool demonstrated is only viewed as a step along the way. As the ship design exercise represents one quarter of the total credits for the MSc some caution is warranted when making changes to the tools or material. This paper is intended as part of the discussions on the way to improving ship design teaching at UCL. Implementation of an Excel based uncertainty model using the beta distribution at individual line-item and component level has proven relatively straightforward. More complicated is the development of the supporting material, such as recommended numerical uncertainty values associated with concepts such as TRL and the phase of the design process.

## FURTHER WORK

Currently the tool performs a simple analysis, generating all possible combinations of the selected items. This full factorial approach does not scale to larger numbers of samples or components of a system without an unacceptable run time. A further development would be to incorporate a method such as Latin Hypercube Sampling to generate a statistically representative set of results over a large range of design components. As a typical UCL sizing sheet would contain around 250 individual line items this would be a challenge to cover the entire design within a run-time acceptable to maintain the desired level of interactivity. However, it would permit the extension of single-system analyses to cover more components.

Additional visualisations and aggregations of results will be required for deployment, as experience with other UCL-developed tools has shown that students frequently output the results from multiple runs with the tool, to compare and discuss with teammates. A further area of development is to automate the process of generating the complete definition of a beta distribution from only a baseline and additive margin. The beta distribution is defined by three input parameters; minimum, maximum and most likely, so a method is required to derive the values such that the CDF reaches the required value (e.g. 90%) at the margin, as shown in Figure 24. Currently this is done by a pre-calculated set of ratios arrived at by numerical approximation.

# Empowering Adolescents through Hands-on Wooden boatbuilding Training: Adapting Javanese Wooden Boat Design and Construction for a Teenage-Friendly Training Experience

Daniel M. Rosyid<sup>1</sup> and Samodra<sup>2,\*</sup>

## ABSTRACT

*In the realm of educational and cultural enrichment, empowering adolescents through hands-on wooden boatbuilding training connects them with Javanese maritime heritage. This scholarly exposition outlines a modern path for youth to engage in traditional wooden shipbuilding, emphasizing tangible skill acquisition and intangible heritage appreciation. The curriculum navigates the confluence of woodworking, mentorship, and cultural identity, fostering youth empowerment. This innovative pedagogical approach views wood sculpting as a vehicle for empowerment, creating a framework for youth-friendly learning inspired by Javanese shipwrights. The proposed model not only crafts seaworthy vessels but also shapes resilient, confident, and empowered young minds, navigating the waves of growth and identity.*

## KEY WORDS

Empowerment; Adolescents; Training; Adaptation; Boatbuilding.

## INTRODUCTION

At the heart of adolescent development lies the need for an education that equips youth with more than just academic knowledge; it calls for the development of holistic skills that prepare young minds for the challenges and opportunities that await them in the future. Integral to this comprehensive educational experience is the incorporation of innovative, engaging, and practical teaching methodologies that groom adolescents into competent, creative, and culturally aware adults.

A paradigm that fulfills these criteria is the art of traditional Javanese wooden boatbuilding, an Indonesian cultural hallmark that is as much about craftsmanship as it is about heritage and communal identity (Clark et al., 1993).

Tucked away within the vast maritime expanse of the Indonesian archipelago, the island of Java quietly harbors a tradition that encapsulates both the essence of cultural ingenuity and the spirit of nautical exploration that has come to define the region for centuries. Javanese wooden boatbuilding is not merely a craft; it is a limbic narrative, interwoven with the lives of the people who build these vessels and the seas they navigate. It speaks of a symbiosis between nature and human endeavor, between the trees that furnish the material and the hands that mold it into form. This intrinsic relationship, filled with lessons of sustainability, resilience, and engineering, holds untapped educational potential, particularly for the youthful learner (Barker, 1993).

\* Corresponding Author: nfsamodra@gmail.com

The present paper endeavors to explore the transformative prospect of adapting the Javanese boatbuilding tradition for adolescent training programs with a particular emphasis on empowerment as a fundamental outcome. The need for such an interventional approach in educational systems cannot be overstated, especially in an era that is rapidly shifting towards abstract, disconnected modes of learning. By bringing this centuries-old maritime artisanry into training modules, the contemporary youth can be imbued with a rich concoction of hard skills such as woodworking, design, and physics, coupled with soft skills like teamwork, problem-solving, and cultural intelligence (Belasus & Daly, 2023; Ellis, 2009).

This fusion of practical know-how and socio-emotional development embedded within a cultural context promises to deliver a multi-faceted learning experience. Adolescents engaged in this hands-on woodworking journey will not only inherit the rich legacy of their forebearers but also arm themselves with a suite of applicable skills and competencies. Moreover, by crafting something tangible and enduring, such as a wooden boat, they participate in a rite of passage that instills a robust sense of self-efficacy, accomplishment, and pride (Bogucki, 2008).

However, the question remains: how does one translate an involved and intricate tradition such as Javanese wooden boatbuilding into an accessible, engaging, and rewarding experience tailored for the young modern learner? It is a task that involves a careful balance of respect for tradition with the pragmatism of educational application (Mitsuyuki et al., 2020).

Modifications and adaptations are necessary to cater to the learning requirements and safety of adolescents, all while ensuring the essence of the craft is not lost but rather emphasized and cherished (Roberts et al., 1994).

Moreover, the process must be cognizant of the current societal trends and the adoption of technological advancements. Youths today are digital natives, and the use of technology must be adeptly integrated into the learning process to heighten their engagement and to bridge the gap between traditional craftsmanship and contemporary learning environments (H. De Rosa et al., 2012).

Such an endeavor also brings forth considerations of pedagogical theory, instructional design, and curriculum development. It is about curating an experience that respects the cognitive and psychological developmental stages of adolescents (Hunt, 2012). It is about embracing a multidimensional teaching approach that fosters not just skills but also an awareness of environmental stewardship, an appreciation for cultural diversity, and a sense of connectedness with the global historical narrative (Allen, 2022).

Through a pedagogical lens, the paper examines the theoretical frameworks and educational underpinnings that support such an integration of tradition into teaching. It delves into constructivist theories, experiential learning models, and the latest in educational psychology to discern methodologies that both resonate with the targeted age group and deliver on instructional goals. The manuscript also explores the socio-cultural importance of maintaining such crafts, the potential impact on local communities, and how engaging the youth in this tradition can foster a new generation of custodians for intangible cultural heritage (Zhao et al., 2023).

In dissecting the role that this adaptation of Javanese boatbuilding can play in the broader scope of adolescent empowerment, the discussion extends to include the expected outcomes and deliverables of such a program. These include the development of technical acumen, enhancement of socio-emotional intelligence, promotion of cultural pride, and ultimately, the cultivation of a self-empowered individual ready to navigate the complex seas of the contemporary world (Allen, 2022; H. M. De Rosa et al., 2015).

As such, the paper sets the stage for a comprehensive exploration of how the ancient lore of Javanese wooden boatbuilding can be reframed and restructured as a potent instrument for modern education, a tool that does not merely impart knowledge but actively empowers the learner. It provides the foundation upon which a rich tapestry of cultural education can be woven, never losing sight of the ultimate goal: to mold adolescents who are not just learned but empowered, not just skilled but also enlightened; individuals who are the very embodiment of the fusion of tradition with modernity, of the past with the future.

## **THE RELEVANCE OF BOATBUILDING TRAINING IN ADOLESCENTS FORMATTING**

In the multidimensional world of education, specific approaches and disciplines serve as pivotal gateways to a spectrum of learning outcomes and skill development. Notably, among such methods, boatbuilding training has emerged as a remarkable platform that dissipates its echoes across diverse dimensions such as the mechanical, structural, aesthetics, and historical.

This craft, particularly as it unfolds in the context of traditional Javanese boat design and construction, possesses inherent potential to not only stimulate intellectual growth but also cultivate personal attributes and codify cultural connections for adolescents, a transformative experience that amalgamates the richness of heritage, the wisdom of age-old techniques, and the value inculcation of priceless transferable skills (Hunt, 2012).

When analyzed closely, the intricate process of boatbuilding offers numerous touchpoints of mechanical understanding for the learner. It introduces students to the basic principles of woodworking, from selecting and preparing the right materials to understanding the various types of tools, their uses, and safe handling methods.

Beyond learning the pragmatic value of creating something tangible and useful, young learners gain exposure to concepts such as buoyancy, load bearing, balance, and propulsion, which inadvertently steep them in the fundamentals of physics and engineering (Stammers, 2001).

The hands-on application of these principles not only serves as a practical demonstration of theoretical knowledge but also promotes an in-depth comprehension of how different mechanical aspects merge to give life to a complete sea-going vessel.

On a more sophisticated level, the design and construction of a boat demand an understanding of structural concepts. Students learn about the importance of creating a durable, robust framework that can withstand the elements, the steps to ensure symmetry and balance, and the elements that contribute to a boat's overall stability and functionality.

This exposure cultivates an appreciation for how integral the combination of various constituents, wood pieces, hull design, deck arrangement, is to the working of the complete, structural entity. Understanding these concepts prepares adolescents for potential interests and careers in architecture, structural engineering, and product design (Kahanov et al., 2012).

Inescapably, boatbuilding is not a process devoid of artistry. The craftsmanship requires an eye for detail and an aesthetic sense that ensures the finished product is pleasing to the eye. Javanese boat design is well-regarded for its distinct, intricate detailing that can be seen as an expression of cultural art inherited through generations.

The opportunity to learn, appreciate, and contribute to this retained aesthetic appreciation in adolescents can help foster a belief in the value of traditional art and the potential for its modern reinterpretation (Martín Seijo et al., 2021).

Equally significant is the historical facet woven into the very fabric of Javanese boatbuilding. As the adolescents attune to innovative building techniques, they inadvertently uncover layers of historical information lurking beneath. They explore a rich tapestry of maritime history, socio-cultural norms, and philosophical underpinnings that have shaped the very tradition they are engaging with. This understanding bridges generations and fosters respect for the wisdom and skills of ancestors, thereby building a profound connection with their cultural lineage (Domínguez-Delmás et al., 2023).

Delving deeper beyond academic growth, engaging adolescents in the process of boatbuilding offers a fertile landscape for the germination of essential character traits. The art of crafting a boat is a testament to patience since the process requires careful precision and does not permit haste. Dedication and persistence are instilled as the project demands time, effort, and a consistent commitment to see the craft move from an idea to reality (Grieco et al., 2020).

Moreover, since boatbuilding is rarely a solitary endeavor, students learn the essence of teamwork and cooperation. They experience the division of labor, the necessity of communication, and the shared responsibility that fosters a communal spirit. It births an understanding of collective responsibility and helps students grow into more collaborative, thoughtful individuals, attributes that are invaluable for personal growth and career success (Teo et al., 2021).

Simultaneously, the boatbuilding journey amplifies the spirit of determination and resilience. The path to completion might be strewn with failed attempts, challenging stages, and moments of self-doubt. However, overcoming these obstacles instills a sense of accomplishment, self-efficacy and nurtures the courage to persist amid adversity, an experience resembling the arduous but rewarding voyage of a boat on the sea (Imron & Abdullah, 2023).

By engaging youth in the Javanese tradition of boatbuilding, the educational prospect goes a step further, infusing cultural appreciation alongside practical wisdom. These adolescents gain first-hand insight into the philosophy and principles echoed in every curve, joint, and finishing touch of the boats they build. They unwittingly become custodians of a rich cultural legacy, appreciating, preserving, and potentially passing on their knowledge to future generations (Barker, 1993).

The acquisition of practical, transferable skills through boatbuilding initiatives imparts a unique edge to adolescents, preparing them for versatility in various fields in the future. They become equipped not only with technical knowledge but also insights into project management, problem-solving, and critical thinking, proficiencies that persist beyond the boatbuilding classroom and into their adult life (Allen, 2022; Szubska et al., 2023).

In its essence, the pedagogy of traditional boatbuilding embodies a worldview on education: a journey of self-exploration, discovery of heritage, initiation into adulthood, and protocols of community living. Simultaneously, it is an experiential journey that opens young minds to the infinity of their potential (Rodzala & Saat, 2018). A pathway to empowerment, the relevance of teaching Javanese boatbuilding to adolescents can be seen as a catalyst in their evolution: an evolution from learners to creators, from students to skilled practitioners, and ultimately, from adolescents to empowered adults ready to navigate the vast ocean of life's opportunities.

# ADAPTING THE JAVANESE WOODEN BOAT DESIGN FOR ADOLESCENT TRAINING

The encapsulation of traditional Javanese wooden boat designs within an adolescent training program brings about an intriguing challenge. It necessitates adapting an age-old craft, complex, nuanced, and routed in layers of cultural knowledge and skill, into an accessible, appealing, yet formative educational experience for youth. The process of adaptation needs to strike a thoughtful balance between preserving the essence of the craft and making the experience stimulating, relevant, and youth-friendly. This section explores addressing this challenge by simplifying complex techniques, incorporating technological integration, and enhancing engagement strategies for a holistic learning environment fostering adolescent development (Liu et al., 2019).

## The Boat Design

Javanese traditional wooden boats, known for their cultural significance and historical roots, provide a unique foundation for innovative adaptations in modern boat design. The general arrangement of Javanese traditional wooden boats can be creatively integrated with contemporary elements, fostering a harmonious blend of heritage and functionality. Adapting their design for contemporary use involves respecting and drawing inspiration from the cultural heritage embedded in these vessels. The general arrangement reflects a balance between preserving the authenticity of the original design and incorporating practical modern features.

Ergonomics in the general arrangement should be approached with a focus on preserving the traditional aspects of Javanese boat design. The arrangement should be strategically positioned to reflect the cultural context, ensuring a comfortable and authentic experience. This integration of ergonomic principles with traditional aesthetics contributes to a seamless fusion of old and new.

Building the wooden boat for this training purpose should also involve a commitment to sustainable construction methods. Emphasizing the use of locally sourced, renewable materials and traditional building techniques contributes not only to the authenticity of the design but also to the environmental sustainability of the vessel. This approach aligns with the ethos of Javanese craftsmanship, which historically prioritizes harmony with nature. The construction of this training wooden intentionally avoids the use of wood from natural forests and exclusively utilizes wood sourced from cultivation which are Teak wood (*Tectona grandis*) and Mahogany (*Swietenia mahogani*) harvested from managed cultivated forest.

Adapting the general arrangement of Javanese traditional wooden boats for contemporary use involves a delicate dance between heritage and innovation. Preserving cultural authenticity, optimizing spatial arrangements, infusing ergonomics with tradition, embracing sustainable construction methods, and integrating technology with sensitivity are crucial aspects of this transformative process. In doing so, designers can create vessels that not only pay homage to Javanese maritime traditions but also serve as a bridge between the past and the future of wooden boat design.

The frames are made using wood lamination techniques in which wooden materials are placed together to form a strong and water-resistant structure. Lamination techniques are employed to reduce the use of natural bent timber for the frames constructions and to improve structural performance. By utilizing lamination techniques, boats can be designed with better durability without sacrificing the sustainability of resources. This technique enables manufacturers to achieve an optimal combination of strength, lightweight construction, and resistance to environmental conditions in water.

The boat name is Putri Mayangmadu, translated into English as 'The Daughter of Mayangmadu.' The name originates from a local folklore featuring Prince Mayangmadu, whose name literal translation means Sugar Palm (*Arenga pinnata*). Prince Mayangmadu served as a prominent local chief during the Javanese classical era, possibly acting as the Harbor Master of the Paciran coastal area, where the boatyard for the training project is located.

Principal Dimension of the Boat:	
LOA	: 12.85 meter
LBP	: 11.10 meter
B	: 4.00 meter
H	: 1.65 meter
T(max)	: 1.10 meter

**Figure 1: General Arrangement**

**Figure 2: Midship Section**

**Figure 3: The Daughter of Mayangmadu is seen side by side with a traditionally built Javanese wooden fishing boat**

## **The Builders Team**

The boat was constructed in a traditional wooden boatyard in Kandangsemangkon Village, Paciran East, Java (Coordinates 6052'17.02"S - 112018'50.02"E) as a training project for a team of students from SMK Negeri 3 Buduran Sidoarjo – a state-owned Vocational High School – and students from SMK Sunan Drajat, Paciran – a local Islamic Vocational Boarding High School. The teamwork involved 45 male and female students, guided by 4 Master Boatbuilders as trainers. The training lasted for 8 months, with 6 months dedicated to fieldwork. Throughout the training period, the students stayed in provided housing next to the boatyard.

**Figure 4: The students are constructing the boat's laminated frames in the school workshop**

**Figure 5: The students are working on setting the frames in the boatyard.**

**Figure 6: Completing the hull construction**

**Figure 7: Pre-launching**

**Figure 8: Sea Trial**

## **Simplification of Technical Aspects**

An accurate replication of traditional Javanese boatbuilding techniques may involve intricate processes, high-end tools, and a level of skill mastery typically earned over years, if not decades, of practice. For an adolescent demographic, some of these aspects could appear daunting, unnecessarily arduous, or even unsafe, potentially hampering youth's buy-in into the learning process. Therefore, it becomes crucial to devise a simplified model of boatbuilding that retains the core elements of the tradition yet is streamlined, achievable, and safe for younger learners (Belasus & Daly, 2023).

The first step would be to distill the techniques into their most basic elements, ensuring that the fundamental concept, approach, or principle that drives the technique remains intact. This simplified design needs to be easily comprehensible to the adolescent mind, scaffolding upon students' existing abilities and understanding. By strategically reducing the complexity, it ensures the learners are not overwhelmed, thus promoting a sustainable and fulfilling learning journey that gradually grows in depth and sophistication (Indruszewski, 2008).

One example of simplifying boat construction involves utilizing lamination techniques for futtock constructions and designing jigs to facilitate students in forming the futtock and assembling other frame parts without excessive complexity.

While preserving cultural authenticity, the use of age-appropriate, modern tools becomes instrumental in maintaining safety, efficiency and reduced physical effort. Protective gear, accompanied by strict safety protocols, can ensure that the students can engage in the process without posing unnecessary risks. Moreover, the incorporation of simpler, ergonomically designed tools mitigates the risk of injury and drastically increases the students' sense of mastery and confidence in handling the tools, empowering them to explore deeper into the craft (Kahanov et al., 2012; Khalilieh, 2005).

## **Use of Technology**

In an era where adolescents are essentially digital natives, a crucial aspect of the adaptation process lies in integrating technology within the traditional boatbuilding training. This adoption not only makes the training more relatable to modern youth but also expands the horizons of their understanding, application, and interest in the craft (Ma et al., 2023).

One compelling tool for this purpose could be Learning Management System. This tool will enable online distance learning, anywhere anytime as long as the internet connection is available.

The learning management system employed is Moodle, an open-source platform software, complemented by instructional videos developed specifically for boat construction tasks. These videos guide students through various stages of the construction process, offering detailed demonstrations and explanations. By integrating video instruction into Moodle, students benefit from visual aids that enhance their understanding and retention of complex concepts and techniques involved in boat building. This multimedia approach not only facilitates learning but also allows students to review and reinforce their skills at their own pace, ensuring comprehensive mastery of the construction process.

In the intricate planning and design stages of boatbuilding, Learning Management System can provide an immersive way for students to understand and visualize the project before they even lift a single tool. They can study the technical and the 3D drawings of the proposed boat, inspect it from every angle, and comprehend the structural nuances, a previsualization process that could significantly intensify their conceptual understanding. The 3D Drawing could also provide a safe, virtual sandbox where students can practice certain construction methods or procedures before replicating them in the real world. This risk-free, immersive experience allows for learning through practice minus the risk, fostering a heightened sense of preparation and confidence when transitioning to real-world application.

Moreover, using modern software to design, simulate, and test the boats on a computer allows adolescents to align their insights about traditional craftsmanship with contemporary design principles. This computer-aided design (CAD) integration opens an engaging dialogue between tradition and technology, an exciting arena of exploration that could be massively appealing to technological affinities of modern youth. Introducing technology in the teaching of traditional boatbuilding is, therefore, about creating relevant bridges between the traditional and modern worlds of learning. It's about using tools that adolescents are familiar with, to teach them skills that have their roots in the distant past but are still as relevant today.

## **Enhanced Engagement**

The art of teaching, more so when it involves encapsulating culturally rich traditional skills within an adolescent learning net, lies in thoughtfully enhancing student engagement. The efficacy of the boatbuilding training program will pivot upon the ability to capture students' curiosity, sustain their interest, and motivate them towards continual growth in mastering the craft.

Consequently, designing the program thoughtfully with ample opportunities for hands-on activities, group collaboration and gamification could be the catalysts in transforming the experience into an engaging, empowering journey rather than a mere technical skill-learning endeavor (Grieco et al., 2020).

Firstly, hands-on activities present an experiential learning environment where students can tangibly interact with the processes and see the fruits of their efforts materialize in real-time. The amalgamation of 'thinking' and 'doing' fosters deeper comprehension, retention, and satisfaction stemming from active learning. It positions the students as active creators rather than passive receivers, thereby continually cultivating their intrinsic motivation (Eggenberger & Backes-Gellner, 2023).

Secondly, the incorporation of group tasks within the boatbuilding process fosters students' interpersonal and collaborative skills. Building a boat in teams not only lightens the workload but also births an atmosphere of mutual reliance, shared accomplishment, and communal kinship, values that resonate with the societal orchestration of traditional Javanese boatbuilders (Erstad & Siddiq, 2023).

Lastly, incorporating gamification elements in the boatbuilding process can convert learning tasks into challenges, making the process more enjoyable and motivating for adolescents. Leaderboards, progress bars, badges, or other rewarding elements can boost student motivation. Also, integrating positive reinforcements such as certifications, rewards, or school credits can serve as powerful incentives to spur interest and induce motivation, ensuring progress is recognized and valued, fostering a sense of accomplishment and ownership among the learners (Hassan et al., 2017; Omar et al., 2020).

Gamification can take the form of students circling the boat and playing while inspecting various parts of a ship's construction that are perceived to be incorrect. They are discussing and arguing about the result of the inspections with an instructor supervising and acting as the judge. Rewards can be given to those who identify the most errors. Rewards can also be given to students who provide arguments explaining why a particular error occurred.

In adapting the Javanese wooden boat design for adolescent training, an essential consideration remains harnessing the profoundness of formative skills nestled in cultural wisdom. It's about simplifying while preserving, modernizing without losing authenticity, and engaging without overwhelming. Continual careful calibration of these components can ensure that the resulting training program rhetorically communicates its relevance to adolescents, both as a tribute to their shared cultural heritage and as a skillset geared towards their future prospects (Ciarli et al., 2021).

## **OUTCOMES AND EMPOWERMENT**

The fruition of a well-adapted Javanese wooden boat design training program for adolescents must be seen not just in completed boats or acquired skills, but in the broad-sweeping developmental accomplishments, and ultimately, empowerment, of its participants. This experience is expected to yield multifaceted outcomes, propelling students into a realm where they are not only cognizant of the value of traditional craftsmanship but also possess enhanced capabilities that span the technical, social, and cognitive domains (Belasus & Daly, 2023; Roberts et al., 1994). They are likely to emerge with a fortified sense of accomplishment, cultivated teamwork dynamics, a deepened cultural understanding, and a profoundly entrenched sense of personal empowerment. This section delves into the expected outcomes from such a transformative educational journey.

### **Appreciation of Traditional Craftsmanship**

Upon successfully completing training that interlaces the historic threads of Javanese boatbuilding with innovative teaching methods aimed at modern adolescents, students are likely to develop a robust appreciation for traditional craftsmanship. This appreciation stems from understanding the effort, skill, and artistry involved in creating something magnificent from raw materials, all while honoring the time-tested practices of their ancestors. However, their admiration would extend beyond mere recognition; they will internalize the craftsmanship as part of their cultural identity and legacy, a precious heritage to be preserved and cherished (Indruszewski, 2008).

### **Enhancement of Technical Skills**

Naturally, through the detailed and immersive process of boatbuilding, technical skills are honed to a significant degree. Students learn to work with various tools, materials, and methodologies that are both traditional (in respect to Javanese designs) and modern (in relation to contemporary tools and safety practices). The practical knowledge encompassing woodworking, material selection, design principles, and structural integrity interwoven with the efficiency of modern technology provides these adolescents with a unique edge. They add to their toolbox of competencies an array of valuable skills that serve them in various fields, from engineering to design to environmental science (Kahanov et al., 2012).

## **Social Skills Acquisition**

A crucial part of the learning process during the boatbuilding training is the enhancement of social skills. Given that boatbuilding is often a communal effort, students learn valuable lessons in teamwork, communication, leadership, and cooperation. The necessity to collaborate with peers, respect different roles, and contribute effectively to a shared goal is a powerful life lesson that transcends the context and becomes a guiding principle for community life and work environments they will enter later on (Imron & Abdullah, 2023; Jaaffar et al., 2016).

## **Cultivation of Problem-Solving Abilities**

Problem-solving is an inherent part of any constructive or creative task, and boatbuilding is no exception. Adolescents engaged in building a boat face various challenges that demand innovative solutions, whether it's adapting a design to better suit materials at hand or rectifying a structural issue uncovered during a trial. Learning to troubleshoot in the workshop, students apply logical reasoning, critical thinking, and creativity, which becomes a habit of mind beneficial in all aspects of life (Hudnall & Kopecky, 2020).

## **A Sense of Accomplishment**

There is a monumental sense of accomplishment that comes from completing a boat. It's a tangible testament to the students' efforts and skills, a visible, floatable product of their dedication. This sense of accomplishment is profound and resonates deeply, often contributing to heightened self-esteem, a reinforced belief in one's abilities, and a validation of personal effort. The process from start to finish is a journey through which students confirm to themselves that they are creators, builders, and finishers (Messinis & Ahmed, 2013).

## **Teamwork Dynamics**

The collaborative nature of the boatbuilding process fosters not just an ability to work in a team but an intrinsic understanding of group dynamics. Students experience first-hand how a team functions efficiently with the distribution of tasks, reliance on fellow team members, and productive synergy required to achieve a common goal. These teamwork dynamics are invaluable not just in their immediate educational environment but as preparation for their professional life and as active citizens (Eggenberger & Backes-Gellner, 2023; Erstad & Siddiq, 2023).

## **Deepened Cultural Understanding**

By its very nature, the program is steeped in cultural education. By learning the traditional methods of Javanese boat construction, students gain more than just a superficial textbook understanding of their heritage. They gain hands-on, pragmatic comprehension of their cultural history, imbuing within them a respect for their cultural identity and a passion for its conservation and celebration (Hensel et al., 2021).

## **Personal Empowerment**

Finally, and perhaps most importantly, the experience of learning to build Javanese wooden boats culminates in a heightened sense of personal empowerment. Adolescents learn that they can wield tools, create complex designs, work collaboratively, overcome challenges, and complete significant projects. This empowerment transcends the immediate skills learned, it's the realization that these young individuals can engage with their tradition in meaningful ways and are equipped to contribute their inherited knowledge and novel insights to their communities and the wider world (Hassan et al., 2017).

In essence, the outcomes of Javanese wooden boat design training for adolescents are both immediate and enduring. Participants benefit from a unique confluence of skill acquisition and personal development. They are apprentices not only in the artistry of boatbuilding but also in the more subtle art of weaving their newfound skills, cultural understanding, and collaborative experiences into the broader tapestry of their lives (Omar et al., 2020). These outcomes do not just empower students as individual artisans or technicians; they empower them as custodians of a rich cultural heritage, responsible community members, and proactive contributors to society.

## **CONCLUSIONS**

Integrating traditional Javanese wooden boat design into an adolescent training program represents a compelling, holistically beneficial endeavor. It's an innovative crossroads where tradition meets modernity, enriched cultural heritage greets empowering skill learning, and youthful vigor finds a constructive, purposeful outlet. With strategic adaptation that appropriately aligns with adolescents' cognitive capacities and interests, this fusion of boatbuilding craft with modern

pedagogical techniques emerges as a promising avenue for engaging, empowering, and educating the next generation. By creating a learning space that respects and highlights the intricacies of Javanese boatbuilding craftsmanship while ensuring the experience remains appealing and relatable to modern youth, the training brings about a vibrant educational panorama. It encompasses skill-building, character shaping, and cultural education in an integrated, immersive, and hand-on manner. The process is just as striking as the product, a unique educational journey where adolescents explore, indulge their curiosity, challenge their creativity, and apply their problem-solving acuity.

This harmonious amalgamation of traditional knowledge and contemporary teaching approaches equips youth with an array of tangible and intangible skills. It fosters in them a sense of pride in their cultural identity, a conviction in their capacity to work constructively and collaboratively, and a confidence in their hands-on abilities. The training embodies a symbiotic blend of imparting proven craftsmanship, transmitting cultural essence, and cultivating personal capabilities.

At its core, the adapted training program aims to retain the essence of traditional Javanese boat design while making it a lively, appealing, and empowering learning environment for youth. With both physical and digital tools, fostered team dynamics, and an engaging curriculum that seamlessly interweaves learning with application, the program sets sail to craft an experience as unique as the boats themselves.

It unfolds as a pathway that not only introduces the intricacies of Javanese tradition to a younger demographic but also tangibly empowers them with a tactile, innovative craft. But importantly, the empowerment transcends the confines of the workshop, it is the empowerment of self-confidence, creative expression, cognitive flexibility, and cultural appreciation. So, with every wooden plank carved and every boat finished, students don't just learn to build boats, they learn to navigate new avenues of personal growth, societal contribution, and cultural preservation.

In conclusion, the promising prospect of adapting Javanese wooden boat design for an adolescent training program speaks of an engaged, meaningful, and empowering educational experience. It represents a steppingstone towards connecting young minds with their cultural roots on a personal, relatable, and impactful level. By bridging the gap between the old and the new, the practical and the conceptual, the individual and the collective, the training project creates an educational space that resonates with the dynamism, curiosity, and potential of adolescence. This adaptation, therefore, guiding the younger generation to create a future that respects the past and readily shapes the present in the pursuit of “mastery for the seas.”

# PROCEEDINGS OF THE 15<sup>TH</sup> INTERNATIONAL MARINE DESIGN CONFERENCE

The aim of the **15<sup>th</sup> International Marine Design Conference (IMDC 2024)** is to promote all aspects of marine design as an engineering discipline. The focus of IMDC-2024 is on the key design challenges and opportunities in the maritime field with special emphasis on the following themes:

- **Ship design methodology**
- **Novel marine design concepts**
- **Offshore design methodology**
- Influence of the **energy transition** on maritime design
- Influence of the **unmanned and autonomous transition** on maritime design
- Influence of the **digital transition** on maritime design
- **Influence of regulations on maritime design**
- **Maritime design education.**
